The first experimentation work aims at optimizing the energy performance of the building skin in tower buildings in order to identify , their "energetically active parts", through the definition of a range of values and to determine their annual gain in terms of energy production. Specifically, after defining the reference weather conditions and the object geometry, the environmental analysis was conducted using a software able to optimize the skin behavior. Thanks to parametric design tools in Rhinoceros software - in particular the link between Grasshopper and its plug-ins Geco and Ecotect - it was possible to evaluate in real time the effects of any changes made in the designed building skin.

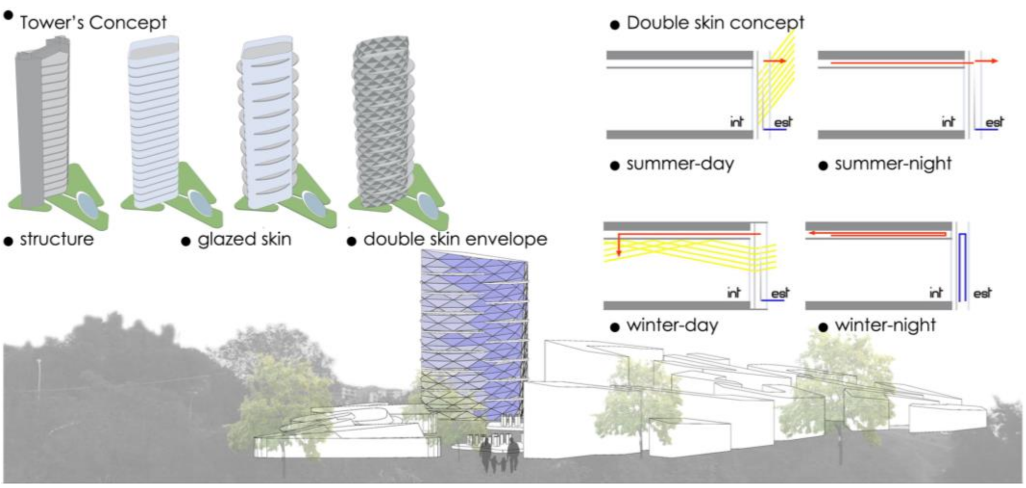

Figure 4 Tower's design concept: double skin development and conceptual design of the tower building in an urban context.

It was decided to use a dynamic double skin façade. As a first step, the geometric pattern of the outer skin was defined through its panelling with the plug-in Launchbox[2] in Grasshopper environment. In the second step the skin was analyzed from an environmental point of view with the software Ecotect. Among the analyzed parameters, special importance was given to the solar irradiation on the outer surface, expressed in kWh/year. In this way it was possible to define the “energetically active” part of the outer surface and to obtain an early pre- dimensioning of the façade system and an estimate of its energy production.
In addition, the methodology of this experimentation and work can be repeated for different climatic zones and for different architectural configurations by replacing the weather file in input stage.

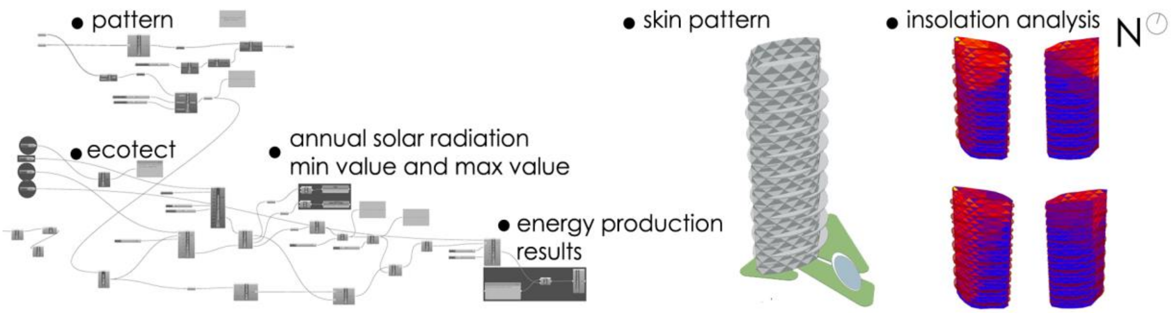

Figure 5 Bottom-up process for skin optimization: process for the evaluation of incident annual solar radiation through the link between Grasshopper and Ecotect.

The second experimentation work aims at defining an intelligent and adaptive technological system to be applied to tower buildings, able to ensure an optimized response to inputs coming from the external environment. Specifically, after identifying the adaptive system, the analyzed surface “was panelled” using the software package Grasshopper inside Rhinoceros, and then the result were evaluated using the software Ecotect and Geco. Once input process, climate files and geometry were defined, the surface behavior was analyzed in response to the inclination of the solar irradiation, in order to study its dynamic and adaptive potentiality.

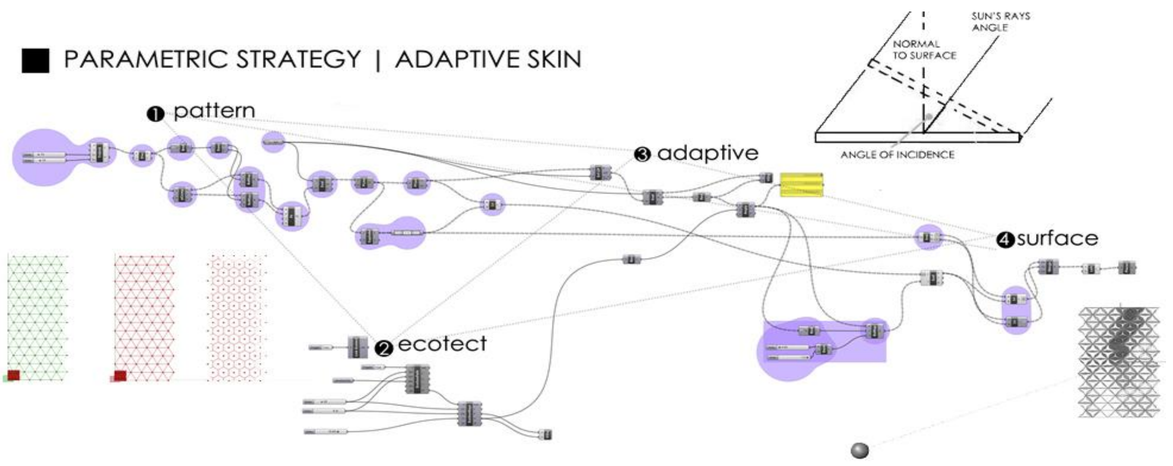

Figure 6 “Panellization to adaptation” process: adaptation of daylight system in Mediterranean area.

In particular the image shows the adaptation of the skin surface in relation to the inclination of the suns’ s rays and the process:
The dynamic analysis of an adaptive device is preparatory to the creation of the technology scheme of the

[2] Launchbox is a free plug-in for Rhino-Grasshopper, for the surfaces panelization. With this plug-in it is possible to define a geometrical pattern and to analyze it in all its parts (nodes, rods, panels).

façade. In the first phase of this second experimentation work the components of the façade are identified and classified into two types:

- Fixed parts: primary structure composed of panels of varying sizes (maximum extension 1.95 x 1.75 m) realized with innovative production systems, robotics and CNC fabrication,
- Moving parts: extensible cables to ensure the correct dynamic operation of the panels made from innovative materials including bioplastic and fibro elastic textiles.

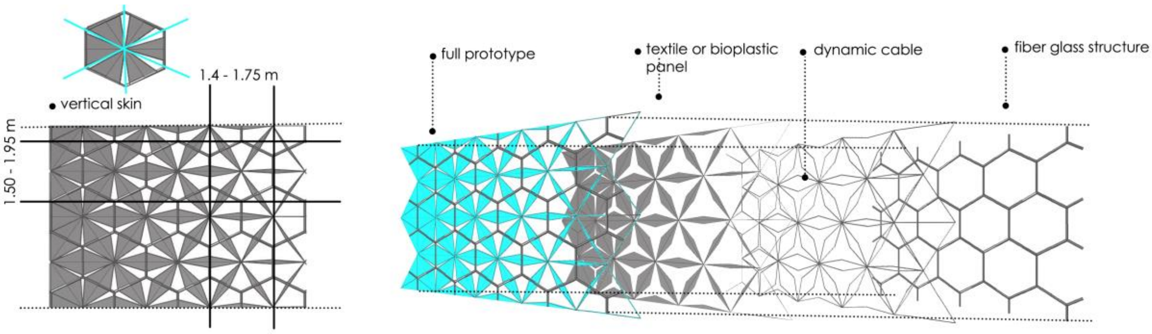

Figure 7 Skin design: a possible development of the skin system for the environmental rehabilitation of buildings in the Mediterranean area.

EXPERIMENTATIONS AND RESULTS

Both experimentation works aim at studying the behavior of surfaces in response to specific environmental and climate input changes; in the first case the incident solar radiation on the entire surface, measured in kWh/year, is used to define the energetically active parts of the surface and assess the need of technological devices able to shield and avoid its overheating. In the preliminary project phase, better don't underestimate the possibility to assess the energy gain derived from the surfaces energetically active parts.

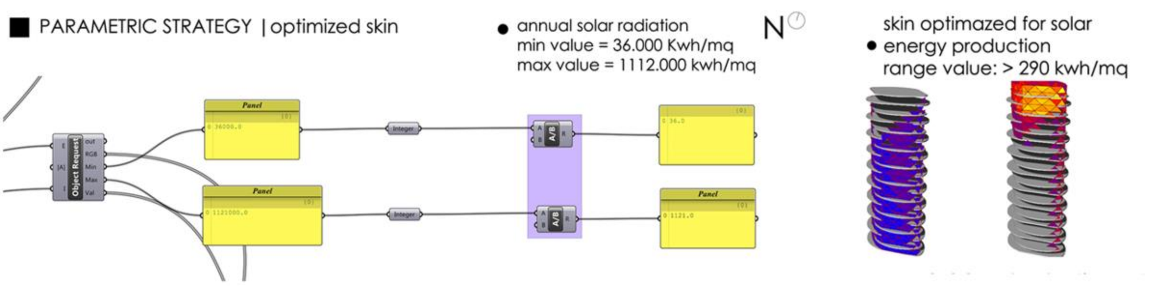

Figure 8 energetically active parts of the buildings surface and assessment of the need of technological devices able to shield and avoid its overheating through the definition of a range of values.

In order to define the energetically active part of the skin and in accordance with the climatic characteristics of the project site and with the chosen HVAC system a range of annual energy demand between, < 290 and >290 kWh / year was established. Thanks to the use of the LUA script COMMAND - present in Geco - it was possible to estimate the production of electricity, expressed in kWh/ year. The script "0: Calc.resource, solar" allows to calculate these gains through the link with Ecotect, panel analysis and resource consumption, and to estimate the area of application and the number of used elements. The direct connection between skin geometry, geometric pattern and analysis software environment, allows also to have a real-time update of the analysis with respect to geometric variations typical of the early stage of architectural and components design.

Figure 9 Thanks to Geco and Lua Command Script we can underestimate the possibility to assess the gain derived from the surfaces energetically active parts.

In the second experimentation work the adaptive capacity of the buildings external surface was tested in relation to the solar path, angle and incidence on the surface. The process aims particularly at defining a dynamic surface able to open and close in an adaptive way according to the variation during the time of the external conditions inputs, in particular of natural lighting. The optimization as a guide in complex processes. Main difficulties, until a few years ago, resided in the technological know-how that would allow to consider architecture as a living and adaptive organism. Each architecture would have its genetic composition and a specific combination of genes. The genotype will represent the intrinsic characters while the phenotype would be the character set that the architecture shows clearly. In biology it's well known: the phenotype depends on the genotype but also by iterations between genes and environment.

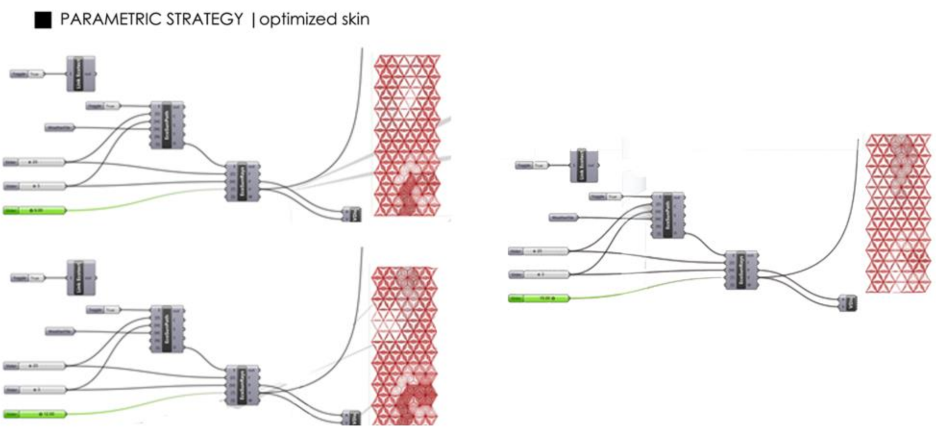

Figure 10 Adaptive capacity of the building external surface is tested in relation to the solar path, angle and incidence on the surface three times of the day.

The ability to analyze the dynamic behavior of building skin technological components is fundamental in the preliminary phase of the design as it allows to significantly reduce the gap between digital design and physical experimentation.
Considering the large amount of available data, commonly called “open data”, it is not difficult to imagine how such a process can bring substantial advantage, especially in building retrofitting, where is necessary to add new parts or components in order to reduce the energy demand and ensure a adequate indoor comfort level compatible wit the actual standards and regulation.

APPLICATION IN EXISTING BUILDINGS

In Italy, the country chosen as a case study for this research, in fact, there is no need to build many new buildings, while a big problem consists of existing buildings, mostly made in the years 60'-80 'and characterized by a high energy consumption and a low level of environmental comfort inside. Therefore, it is necessary to find a solution to this problem, mainly caused by building envelopes of poor quality and obsolete buildings in general. A dynamic and adaptive technology device (e.g. a building skin designed to respond to specific input from the external environment), can formally design in an innovative way the existing façades and also reduce the problems arising from excessive solar radiation, e.g. overheating of the exterior walls and of the interior spaces.

The developed adaptive envelope system has been applied in existing tower buildings, located in Ascoli Pieno and realized in the 80's. This application is actually in a test-phase, but the experiments made so far are giving very good results.

Figure 11 The image show the possible application of dynamic façade in Ascoli Piceno area, Italy lat. 42° 51' - long. 13 ° 35 ' .

CONCLUSION AND OUTLOOK

The presented research proposed a new bottom-up process for developing a new type of building's dynamic façade. Skin becomes a technological intelligent system that interfaces with the external environment and its inputs. In this way the technological system is equipped with artificial intelligence able to collect and process data from the environment in order to return an optimized and adaptive response. If at the dawn of the modern movement response the slogan was "form follows function" today, thanks to the developed digital technology, it is possible to safely talk about "form follows energy flows". The use of parametric modeling software combined with assessment tools and simulation of environmental performance, allows the development of technology components which record and respond to climate change creating a further project phase. In addition the skill of ensuring the kinetic movement, through the use of nanotechnology and smart materials and the possibility of strongly reducing the manufacturing imperfections through the digital manufacturing, can further reduce the gap present between digital and physical experimentation and production and ensure a better relationship between construction costs and performance of device.

In the next step of research the main objective is a territory research of companies able to invest and ensure technical and financial support for the realization of the prototype. The final goal is to create a database, clear and easy to read, able to make the know-how available immediately and to reduce the gap between the research subject and the industrial production world.

ABSTR ACT HEADING

The performance of building envelopes significantly affects the indoor energy consumption, thermal comfort, and durability of a building. Numerous studies have focused on the thickness of insulation materials and considerations for insulation placement (installing insulation inside or outside the wall), however most of the studies have discussed insulation placement in each building's components and form (wall, roof, floor), and very few of them have considered the insulation as an insulation system of the building. In 1999, the Japanese Institute for Building Environment and Energy Conservation issued the standards for residential energy efficiency that specified the standards of building envelope thermal transmittance and overall heat loss coefficients however; the insulation placement was not well explained. Additionally, it is common in Japan to use intermittent air-condition systems rather than having the air conditioning units continuously operating. It is necessary to investigate the performance of insulation taking into consideration the specific life styles of people living and working in Japan. In this research, we will (1) develop new interior insulation to conduct insulation on all of the interior surfaces of building units (walls, ceilings and floors) for environmental building design based on the calculation of heat loss; (2) discuss and demonstrate the effect of high heat capacity on each of the building components and thermal bridge by building environmental simulations; (3) carry out the simulation in different cities in Japan (Sapporo, Hachinohe, Sendai, Toyama, Tokyo, Miyazaki and Naha) and discuss the applicability in these different areas of Japan. Comparing the environmental qualities among three insulation styles (outside insulation on outside walls, inside insulation on outside walls, and interior insulation which is an innovative insulation style in Japan), the energy saving and thermal comfort advantages will be demonstrated. This research will provide an innovative insulation style that could contribute to new generations of energy-saving standards and formulations in Japan.

INTRODUCTION

In order to tackle global environmental issues in Japan, the "Act of The Rational Use of Energy" and the "Energy-Saving Standards for Houses and Buildings" were reformed in May 2008 and January 2009 respectively (IBEEC, 2009). These were aimed not to improve energy conservation performance at individual houses, but rather to focus on promoting and spreading energy savings throughout the whole housing industry, indicating that further discussion of housing energy savings will be anticipated. Therefore, we once again need to clarify the features of different insulations in common housing complexes, as well as how insulation affects indoor thermal environment and energetic load (Wang et al., 2010). Meanwhile, the building envelope thermal performance consideration shows building materials with high thermal insulation properties should be used in the outer walls, floors and other parts

Yupeng Wang is a Postdoc Fellow in the Department of BCEE, Concordia University, Montreal, Canada. Hiroatsu Fukuda is a Professor at the University of Kitakyushu, Kitakyushu, Japan.

of the building envelop (Evans et al., 2009). This guideline is not including a detailed indication about the difference of outside and inside insulation with a dynamic indoor and outdoor enviormant and the comparsion of the impacts of Heat Bridges. We need to coordinate indoor thermal environment that are looked around about thermal comfort as shown by (Kuma et al., 2008). This study aimed indoor thermal environment and comfort. Three insulation methods were compared from an indoor thermal environment perspective in which the room temperature, surface temperature, operative temperature at a model dwelling unit was adjusted by Thermal Load Calculation Software (THERB) to modify conditions such as location, climate and air conditioning. This research could contribute to the expansion of Japanese sustainable building standard development.

METHODOLOGY

Environmental Simulation Program

For the environmental performance evaluation, simulation program "THERB" was used in this research. THERB for this analysis is dynamic simulation software which can estimate temperature, humidity, sensible temperature, and heating/cooling loads for multiple-zone buildings (Ozaki, 2004; Ozaki and Tsujimaru, 2006). THERB has the following features:

1) Successive transition method and a trapezoid hold function that can adjust itself to a time-discrete domain are used.

2) Dimensionless equations are used to calculate convective heat transfer coefficients for every part of the unit under study.

3) Longwave and shortwave absorption coefficients are taken into account in order to simulate the net absorption of radiant heat and transmitted solar radiation.

4) A multilayer window model, which defines the overall transmittance, absorptance, and reflectance of solar radiation, is used. (At present, the model cannot account for window curtains.)

5) A network airflow model is used to calculate ventilation quantities.

Model

The unit model that used in this simulation is a common dwelling in a residential complex in Tokyo; that mentioned in Journal of Architectural Knowledge (2004). We are going to analysis the unit which is on the middle floor, at the centre of the floor. Figure 1 shows floor plan, and figure 2 shows the details of three insulation types.

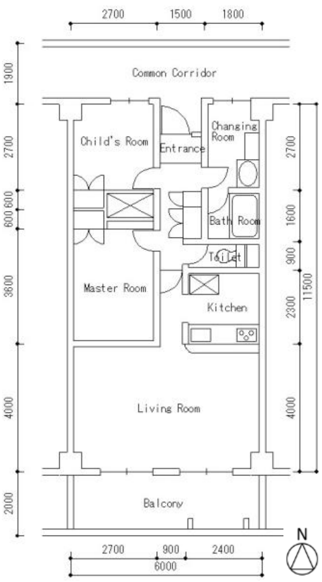

Figure 1. Unit Plan

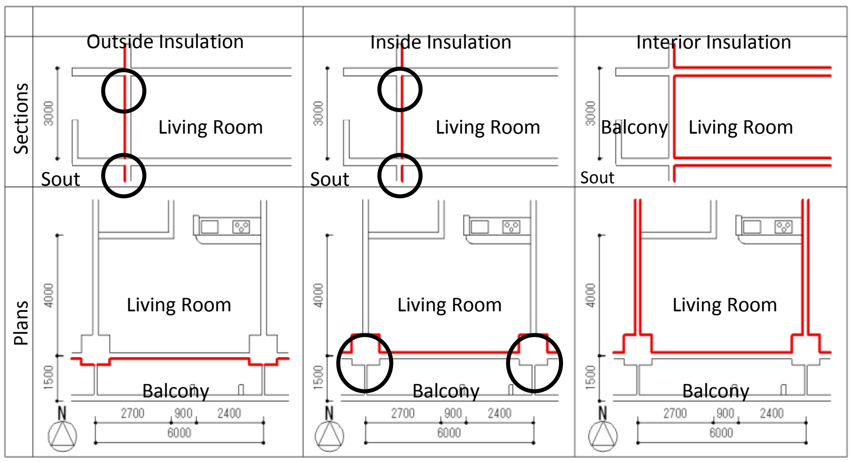

Figure 2. Details of the Three Heat-Insulation Styles, Dark Circles are Showing the Locations of Heat Bridge

Heat Insulation Styles

In the 1980s, interior insulation used to be the common insulation style in Japan. However, dewing inside of the wall was observed in most of inside insulation buildings, because of the underdeveloped construction technique at that age. After that, outside insulation is becoming the common insulation style in Japan, but the performance on thermal comfort and energy consumption between these two insulation styles are still being argued in the academic world. A new insulation style as the promoted inside insulation is proposed and compared with the traditional outside insulation and inside insulation.

In the interior insulation method, not only areas exposed to the air such as external wall and roof but also confining wall, flooring and ceiling were insulated aiming to insulate the whole building from the inner side. We complied with the Next Generation Energy-Saving Standards regarding what materials were used, how thick they were or where they were installed. Three kinds of Class A Extruded Polystyrene Form Heat Insulation were mainly used as insulation materials. High Grade Glass Wool 16K was used on the flooring only for the interior insulation4). Except for the external wall and roof for the interior insulation, the thicknesses of insulation materials were 30mm Class A Extruded Polystyrene Form Heat Insulation for walls and 50mm High Grade Glass Wool 16K insulation for flooring. Figure 2 and Table 2 show location and thickness of insulation materials.

HEAT LOSS CALCULATION

Currently, in Japan, standards and guidelines such like CASBEE and “Explanation of the energy-saving standards for houses” are indicated the performance about inside insulation and outside insulation of exterior walls and floors. However, these discussions are not including the consideration about interior walls and ceiling, which also has a high heat capacity to affect the indoor thermal comfort and energy use. Meanwhile, heat loss through Heat Bridge is also a big issue of building thermal performance. In this section, thermal resistance and thermal transmittance are calculated following equation 1 and 2, and the results are showing in table 1. The total heat loss by thermal transmittance of the unit model is calculated according to equation 3 and the unit construction and volum, and the result is shown in figure 3.

Thermal Resistance ($m^2 \cdot K/W$) = Thickness (m) / Thermal Conductivity ($W/m \cdot K$) **(1)**

Thermal Transmittance (U) ($W/m^2 \cdot K$) = 1 / Thermal Resistance ($m^2 \cdot K/W$) **(2)**

Heat Loss through Thermal Transmittance (W/K) = $U \cdot A \cdot K$ **(3)**

Where: U is Thermal Transmittance ($W/m^2 \cdot K$)
A is Area (m^2)
K is Temperature Difference Coefficient (K=1.0, for exterior walls)

Table 1. Thermal Transmittance Calculation

Exterior Walls

	Thickness (m)	Thermal conductivity (W/m·K)	Thermal resistance ($m^2 \cdot K/W$)
Extruded poly styrene foam blooks A-3	0.03	0.028	1.07
Concrete	0.20	1.600	0.13
Plaster board	0.01	0.220	0.05

Total thermal resistance ($m^2 \cdot K/W$)	1.24
Thermal transmittance ($W/m^2 \cdot K$)	**0.81**

Heat Bridge

	Thickness (m)	Thermal conductivity (W/m·K)	Thermal resistance ($m^2 \cdot K/W$)
Concrete	0.20	1.600	0.13
Plaster board	0.01	0.220	0.05

Total thermal resistance ($m^2 \cdot K/W$)	0.17
Thermal transmittance ($W/m^2 \cdot K$)	**5.87**

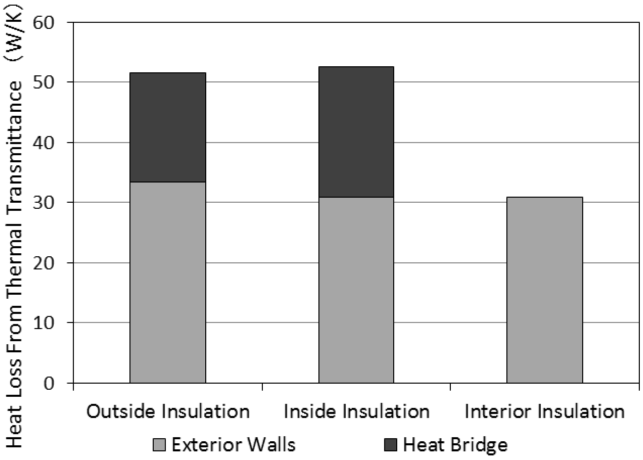

Figure 3. Heat Loss by Thermal Transmittance with Three Insulation Styles

As the result in the table 1, the thermal transmittance of Heat Bridge is over 7 times of that of exterior walls. Heat loss through Heat Bridge is obveriously higher than that through exterior walls. According to that pointed in figure 2, Heat Bridge in the units with exsting outside insulation and inside insulation style could be founded between the floor and the exterior walls, and between the pillers and interior walls. In the porposed interior insulation unit, Heat Bridge could be avoided by conducting insultion at all of the interior surfaces. Compare the total heat loss through unit envelop among three insulation types, the unit with inside insulation is slightly higher than outside insulation unit. This is because of the Heat Brigh between the pillers and the interior walls which is not exst in outside insulation units. The heat loss in units with interior insulation is about 40% lower than the other two units. This is because of the promotion in the respect of Heat Bridge. Heat loss through the exterior walls is also slightly changed by the different insulation thickness requirement by “Explanation of the energy-saving standards for houses” in Japan, which is indicated in table 2. But the consideration of the whole unit and the comprehensive building envelop thermal performance, the consideration of the complete combination of the insulation performance in each building components is also an important issue for building thermal insulation.

AC ENERGY CONSUMPTION IN VARIED JAPANESE CITIES

Simulation Details

In this simulation, we used reference data from Expanded AMeDAS Weather Data that in the period between 1981 and 2000. We compared the effects with different weather conditions. We chose seven target cities in six areas that assigned in Japanese Next Generation Energy-Saving Standards (Explanation of the energy-saving standards for houses) by different weather characters. Figure 4 shows the location of seven cities. The average temperature in north cities is lower than that in south cities.

According to different areas, the recommended thicknesses of insulation materials are provided in the Explanation of the energy-saving standards for houses in Japan. The detail of varied insulation materials thickness is showing in table 2. Considering the different characters of seven cities, heating and cooling periods are varied. Heating period is that monthly average temperature is equal to or lower than 15 ℃ (setting temperature: 20 ℃, percentage humidity: 40%). Period of cooling is that which monthly average temperature is higher than 15 ℃ (setting temperature: 26 ℃, percentage humidity: 60%). Table 3 shows varied heating and cooling period in different cities.

To observe how difference in life style affects heat load, we prepared four different air-conditioned rooms where residents with a different lifestyle were allocated to live with different AC usage patterns. Table 4 shows the AC details. These conditions were as follows:

①. No one is at home during the day, and the air-conditioner is not in use during sleeping hours. (A couple with dual income no kids – DINK);

②. No one is at home during the day, and the air-conditioner is not in use during sleeping hours. (A family consisting of a husband, a full-time housewife and a primary school child.);

③. No one is at home during the day, and the air-conditioner is in use during sleeping hours. (An elderly couple);

④. 24-hour air-conditioning.

Additionally, all rooms were continuously ventilated once every two hours, as well as automatically ventilated on an as-needed basis in the living room, dining room, kitchen and bathroom.

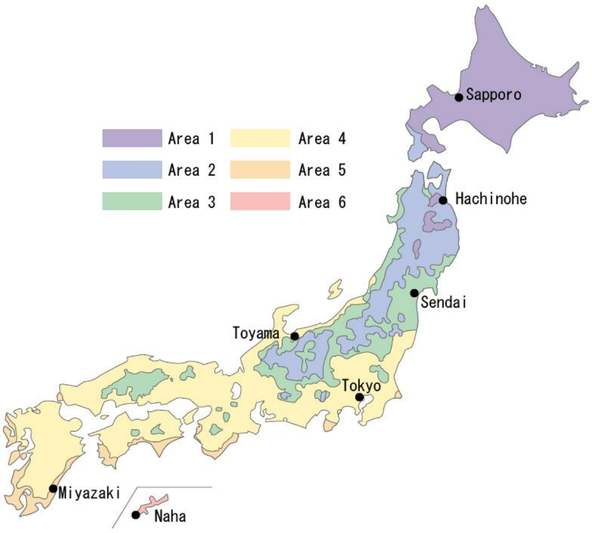

Figure 4. Weather Areas and Target Cities

Effect Variation in Japanese Cities (Simulation Result 1)

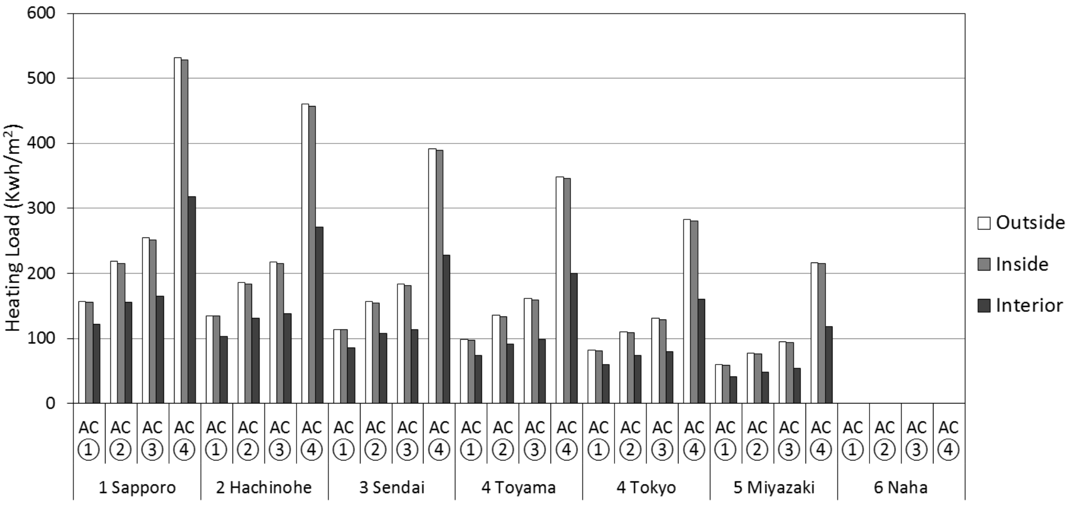

Figure 5. Heating Load in Seven Japanese Cites with all AC Usage Patterns

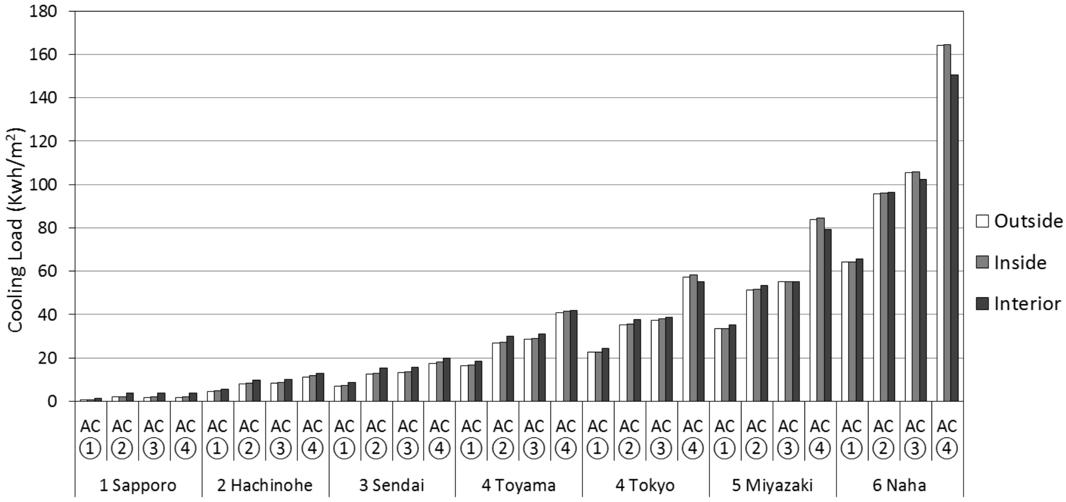

Figure 6. Cooling Load in Seven Japanese Cites with all AC-usage Patterns

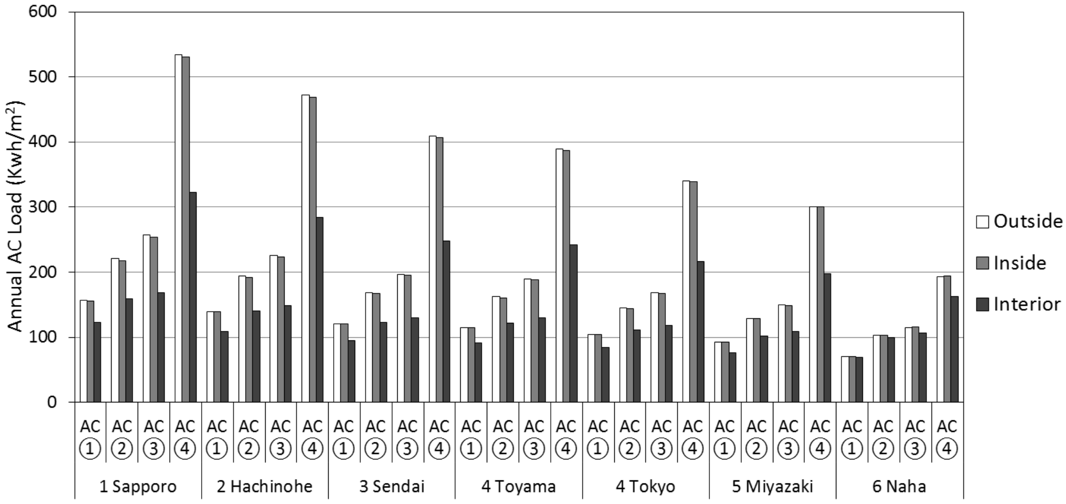

Figure 7. Annual AC Load in Seven Japanese Cites with all AC Usage Patterns

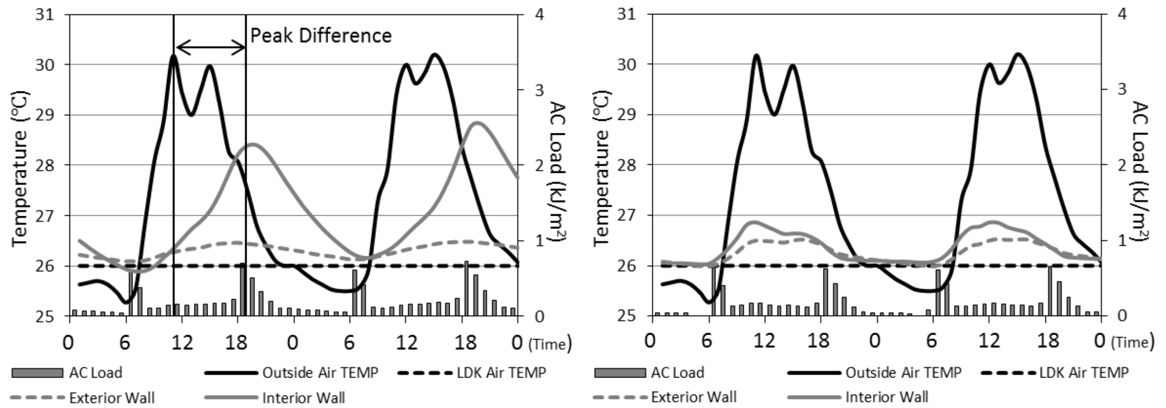
Figure 5 shows the comparison of heating load in seven Japanese cites with all AC usage patterns. Overall, heating load in warm city is lower than that in cold city. In the seven cities with four AC usage patterns, heating load of interior insulation unit is lower than that of outside insulation unit. The average decreased ratio is 29.7%. The highest decreased ratio is 45.5% in Miyazaki with using AC ④. Heating load of inside insulation unit is slightly lower than that of outside insulation. The averagely decreased ratio is 0.9%.

Figure 6 shows cooling load in summer in the units with varied conditions. Cooling load in north cities is lower than that in south cities. Cooling load in Sapporo is the lowest, and that in Naha is the highest. Cooling load of inside insulation unit is mostly higher than that of outside insulation unit, except using AC ① in Naha. Cooling load in inside insulation unit is averagely 3.7% higher than that in outside insulation unit. In interior insulation unit, cooling load is mostly higher than that in outside insulation unit. The highest ratio of the difference is using AC ① in Sapporo, cooling load of interior insulation unit is 56.3% higher than that of outside insulation unit. However, with using AC ④ in Tokyo, Miyazaki and using AC ③,④ in Naha, cooling load is lower in interior insulation unit than that in outside insulation unit. Generally, the differences between three insulation types are not as big as heating load in winter.

Figure 7 shows AC load in seven Japanese cities. In warmer cities, annual AC load is lower than that in colder cities. This is because heating load consists mostly of annual AC load. Annually, with the same AC usage pattern in a same city, AC load of apartment unit with outside insulation is higher than that of inside insulation unit. AC load of interior insulation unit is the lowest in the units with three varied insulation styles. AC load of inside and outside insulation units is very small. In all of the cases, inside insulation unit is averagely 0.5% lower than that of outside insulation unit. For comparison, AC load of interior insulation unit is averagely 25.8% lower than that of outside insulation unit. The highest ratio of AC load decrease between these two insulation styles is 39.7%, in Hachinohe, using AC ④. In Sapporo, almost 100% of AC consumption is heating. And the heating load in Hachinohe and Sendai is over 90% of annual AC load. On another hand, in Naha, annual ratio of heating load is under 15%. How to reduce heating load in northern cities is an important mission.

Effects of Heat Capacity on Indoor Thermal Environment (Simulation Result 2)



Outside Insulation **Interior Insulation**

Figure 8. Cooling Load and temperature change in two summer days with outside insulation and interior insulation from 15th to 16th, August, use AC ④, in Tokyo

For demonstrating the effect from the high heat capacity walls, the comparsion of indoor air temperature and wall surface temperatures are carried out in the figure 8. The peak of outdoor air temperature is observed between 12am to 15pm. In outside insulation, the peak temperature of exterior and interior walls surface is observed around 18pm, about 3 to 6 hours later than the outside air temperature. This is because of the high heat capacity of interior building materials. In the interior insulation unit, the peaks of interior surfaces are the same of outside air temperature, and the temperature of interior wall surface temperature is about 1.5 ℃ lower than that in outside insulation unit. Therefore, low heat capacity of walls creats a controllable indoor thermal condition, and reduces cooling load in summer days.

CONCLUSION

In this paper, an innovative insulation style of interior insulation is proposed and investigated. A calculation of heat loss in three types of insulated units demonstrated the mechanism of heat loss through Heat Bridge, and the advantage of interior insulation. Heat Bridge in outside and inside insulation units is distinctly effect to the building thermal performance, and the heat loss through Heat Bridge is avoided by interior insulation implement. Subsequently, AC load and thermal comfort of apartment unit with three insulation types are compared and discussed with numerical simulation. In both of heating and cooling seasons, indoor air temperature of outside insulation unit is the most stable. In cooling season, indoor temperature of the interior insulation unit is the lowest in three insulation type units when the cooling is not in use. Look at the AC load, it is various in different cities and seasons. Compare to outside and inside insulation units, annual AC load of interior insulation unit is the lowest in all of the conditions.

In terms of indoor thermal environment, outside insulation is the best to stabilize room temperature. However, in winter, the temperature of indoor wall surfaces in outside insulation unit is much lower than that in interior insulated unit. This leads to an uncomfortable indoor environment and high heating energy comsumption.

Finally, as we discussed about the features of the three insulation styles, the advantage of new proposed interior insulation is demonstrated, and the advantages and disadvantages of these three insulation styles are verified and expounded. Various factors should be considered such as regional characteristics, insulation efficiency levels and design conditions, before the building will be built.

ABSTRACT

Buildings consume energy in different ways. In the last decades, particular consideration has been given to buildings' operational energy such as heating, cooling and lighting energy demand. However, with the increased environmental awareness and further advances in the regulatory frameworks globally, the energy consumption embedded in the material extraction and in the construction process is becoming increasingly relevant. The hypothesis of this paper is that naturally sourced, low cost and low embodied energy materials can be used as an alternative to conventional ones in Colombia. An analysis of earthen techniques such as Stabilized Rammed Earth (SRE) and Compressed Stabilized Earth Blocks (CSEB) is made in comparison to conventional massive and aerated fired bricks in terms of their thermal performance. Fieldwork undertaken at an earthen building is presented, informing on the thermal behaviour of Rammed Earth for wall construction. Furthermore, the thermal inertia of earthen materials is analysed for both domestic and non-domestic building typologies, through dynamic thermal simulation. The applicability of earthen mass in different envelope components is assessed defining design guidelines for its successful use in the specific climate and context of Bogotá.

Keywords: stabilized rammed earth (SRE), compressed stabilized earth blocks (CSEB), natural fibres, thermal mass, heat capacity, diurnal fluctuation.

INTRODUCTION

The practice of sustainable design is highly related with the choice of materials since it deals with both embodied and operational energy. Traditional techniques have proven to be an alternative for reducing the embodied energy of buildings still showing potential for improving the operational one. In Colombia, these techniques are being reconsidered after several decades of urban development based on industrialized materials. The main question that is addressed in this paper is whether earthen materials can perform as an alternative to conventional ones. The focus of the article is on the thermal performance of earthen techniques such as Stabilized Rammed (SRE) and Compressed Stabilized Earth Blocks (CSEB) in comparison to conventional fired bricks. For this purpose, a first approach to earthen materials is presented through the study of earthen composites. Furthermore, fieldwork undertaken in an earthen building establishes an introduction to the thermal performance of these materials. In addition, Bogotá's climate was defined and basic questions regarding thermal performance, passive strategies and envelope specification of domestic and non-domestic building typologies were answered through simulations in EDSL TAS establishing applicability guidelines.

EARTHEN COMPOSITES

Earthen constructions present structural limitations. In fact, while the thickness of conventional wall construction made out of brick or concrete is about 30 cm, a wall made out of rammed earth is normally around 50 cm thick. Earthen composites were assessed in terms of their conductivity, volumetric heat capacity and compressive strength as shown in Figure 1. It can be seen that the potential of fibres is from their insulation properties, which is due to their low conductivity values about 0.05 W/mK. Thus, they could be used as insulations boards for floors, walls and roofs. For thermal purposes, the combination of loam and fibres shows high potential due to low conductivity values about 0.2 W/mK, appropriate for insulating purposes, and relatively high volumetric heat capacity between 1100 and 1790 kJ/m^3.K convenient for thermal mass strategies can be achieved. In the case of stabilized earthen composites, it was shown that the structural limitations of the material could be addressed. In fact, the SRE can achieve half of the structural performance of a conventional brick and the CSEB can achieve about the same compressive strength. In addition, both proved to have the highest Volumetric Heat capacity reaching values of 1900 kJ/m^3.K. From the above, further analysis considered CSEB and SRE materials for thermal mass strategies, and fibres for insulating purposes.

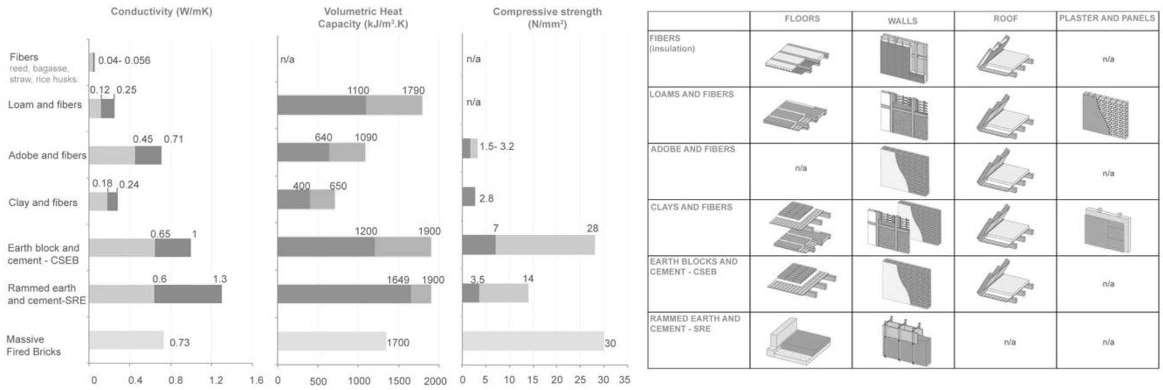

Figure 1. Earthen composites' properties and possible applications. Adapted from: Ashour et al. (2010); Lertwattanaruk and Choksiriwanna (2011); Goodhew and Griffiths (2004); Morton, (2008); Walker et al. (2005) Hall and Allinson (2008) and Schreckenback, (2004).

BREATHABILITY

Another aspect of these materials that adds quality to them is their breathability. May (2005) defined the latter as the ability of materials to absorb and release water as vapor (hygroscopicity) andthe ability to absorb and release water as liquid (capillarity). The relevance of the breathability of a building is the fact that the moisture affects building's thermal performance as well as the health of the occupants. It has been demonstrated through monitoring that earthen masonry has potential to regulate the internal relative humidity of a building between 40 and 60 %6 (Morton, 2008).

CASE STUDY

A buildingwas studied to understand the performance of earthen construction by installing dataloggers in the internal space, buffer space and in the exterior of a rammed earth building.

The case study presented corresponds to a circular auditorium with a double double-layered façade where the inner façade is made out of rammed earth. The theatre is an auditorium with capacity for 200 people (Figure 2). Depending on the event, the occupancy could vary between 10 to 200 people. During the visit, lectures took place between 9:00 h and 18:00 h and it was intermittently occupied by 20 people.

Set up and procedure: Three data loggers were placed during the visit in order to understand the relation between the external climatic conditions, the southern buffer space and the interior of the auditorium. The monitoring was made for a period of 24 hours between May 26th and May 27th 2012. Moreover, data were provided by local engineers regarding monitoring made in the walls for the day of the visit.

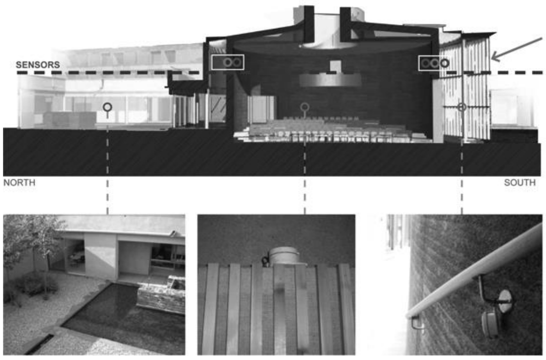

Figure 2. Case study images.

Results from data loggers: Figure 3 shows the temperature and relative humidity results obtained from the three different data loggers installed. There is a grading in the temperature from the outside, the buffer space and the inside of the auditorium. While the night temperature fluctuated by 12 K, it remained stable in the buffer space around 21 ºC and inside around 22 ºC. Moreover, at the coldest time of the night when the temperature was 16 ºC, the internal temperature was higher by 7K. During the morning time, around 9:30 h, the outside temperature increased significantly, while the internal temperature in the buffer space and auditorium remained constant between 21 and 22 ºC for a period of three hours, before the door was opened and the internal temperature reached the external conditions.
In regards to the relative humidity, there is an increasing relation from the interior of the auditorium to the buffer space and the exterior. While the external relative humidity reached levels of 90 %, it remained constant in the buffer space and the auditorium around 50 and 55 % respectively. Although there was a drop in the humidity levels in the buffer space around midday, the internal relative humidity remained stable inside the auditorium around 55 %.

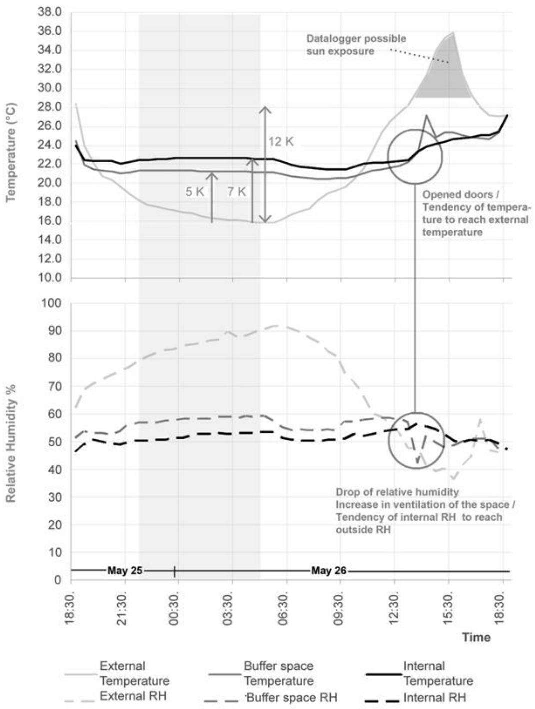

Figure 3: Air temperature and relative humidity from dataloggers.

CLIMATE

A weather file for Bogotá from Meteonorm 6.1 was analysed.

- Temperature: the mean temperature in Bogotá is constant throughout the year with a value around 13 ºC achieving a mean minimum and maximum values 7 ºC and 19 ºC respectively. In a typical day in June, diurnal fluctuations can be as high as 15 K with temperatures between 6 ºC and 21 ºC.

- Humidity: although relative humidity can achieve values up to 80 %, the humidity is not an issue since the moisture content remains within a range of 4g/kg and 12 g/kg which is within the comfortable range (Szokolay, 2004).
- Solar radiation: in regards to the mean hourly solar radiation values for different orientations, it can be seen that east and west vertical planes are likely to receive constant solar radiation throughout the year around 2.5 kWh/m^2. In contrast, north façade's radiation varies, being constant between April and September about 1.2 kWh/m^2 achieving up to 2.4 kWh/m^2 for the rest of the year.

THERMAL COMFORT

Thermal perception was understood through the notion of thermal neutrality (Tn), which considers physiological factors of acclimatization. The adaptive model by Aluciems (1981) can be defined as follows: Tn = 17.6 + 0.31 Toavg; where Tn= neutral temperature and Toavg= mean outdoor temperature. In addition, adding or subtracting 2.5 K defines a comfort range with 90 % of acceptability. Conversely, adding or subtracting 3.5 K, a comfort range with 80 % of acceptability is defined (Figure 4).

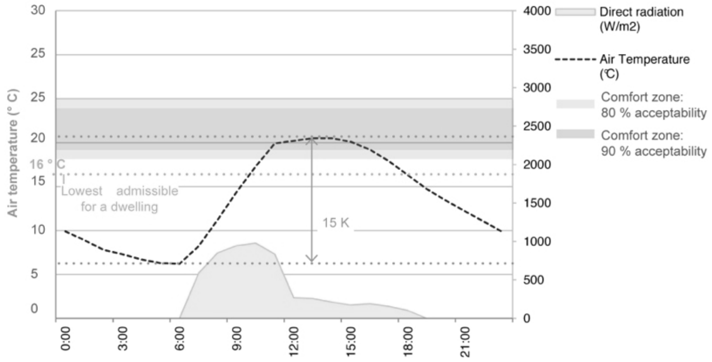

Figure 4. Diurnal fluctuations and thermal comfort parameters, June the 14th.

HYPOTHESIS

In regards to the domestic building typology, the following hypothesis can be established:

- Passive heating requires no more than a well-oriented and sized window (Szokolay, 2004). West seems to be the most desirable orientation.
- Due to diurnal fluctuations, thermal storage mass maybe required. This depends on a careful distribution of the thermal mass.

As far as non-domestic and high internal gains building typologies are concerned, the following could be extracted:

- For cooling purposes in high occupancy buildings, thermal mass can be appropriate since it would perform as a heat sink.
- The climate analysis suggests north orientation as the most suitable.

As diurnal temperature fluctuations are as high as 15K, the thermal mass could work together with natural and/or night ventilation strategies (Baker, 2009).

THERMAL ANALYSIS

An analysis regarding the thermal performance of domestic and non-domestic building typologies was carried out aiming to answer the following questions:

- How do earthen materials perform compared to conventional ones?
- How much earthen mass is required to achieve a significant heat storage effect?
- In what position is earthen mass most beneficial?
- For building programmes with potential overheating issues, can ventilation strategies improve the thermal mass effect of earthen materials?

DOMESTIC BUILDING TYPOLOGY

A stand alone and west oriented dwelling with an area of 30 m^2 was defined and the input parameters for simulation can be seen in Table 1. The dwelling was assumed to be occupied by two adults between 18:00 and 6:00 in weekdays and from 16:00 to 9:00 h in weekends. In addition, Table 2 shows the parameters considered for the different materials defined in the model

Table 1: Initial input parameters for the simplified model.

Geometry		Internal gains		
Area	30 m2	Equipment	7.4 W/m2	
Volume	90 m3	Set back value:	1.0 W/m2	
Window area	4.5 m2	Lighting:	1.4 W/m2	
External wall area	64 m2	Occupancy(x2)	6.4 W/m2	
Window to floor ratio	15%	**Infiltration rate**	0.5 ACH	
U Values	W/m2.K	**Schedules**	Weekday	Weekend
Aerated fired Brick Walls:	1.8	Equipment	5:00 - 7:00	8:00 to 9:00
Fibre cement roof:	5.7		18:00 to 22:00	16:00 to 23:00
Ground floor:	0.25	Lighting:	same as above	18:00 to 22:00 h
Windows (SG)	5.6	Occupancy(x2)	18:00 to 6:00	16:00 to 9:00 h

Table 2: Material properties.Adapted from Goodhew and Griffiths (2004); Hall and Allinson (2009); Ashour et Al. (2010).

	Density kg/m3	Specific Heat KJ/kg.K	Conductivity W/m.K	Volumetric Heat Capacity kJ/m3.K
Lightweight	500	0.176	0.14	88
Aerated Fired Bricks (AFB)	1000	0.84	0.3	840
Fired Brick	1700	0.8	0.73	1360
SRE (7% cement)	1900	0.868	0.643	1649
CSEB (5% Cement)	1900	1	1	1900
Loam/ Earth plaster	1790	1	0.25	1790
Reed mat (20 or 50 mm thick)	190	-	0.056	-

Roof: Since earthen roofs are commonly supported by slatted timber and reeds, the effect of these was first assessed. Then, the progressive addition of external earthen mass was tested. Figure 5 shows that reed insulation (run 2) improved thermal conditions and the percentage of hours that the yearly resultant temperature was between 90 % and 80 % of acceptability increased from 21% and 30 % to 27% and 40% respectively. Moreover, the external addition of earthen mass did not show any significant improvement and above 10 cm thickness, the benefit is negligible. Up to such thickness, the improvements are mainly due to an U-Value reduction to 0.7 W/m^{2}K.

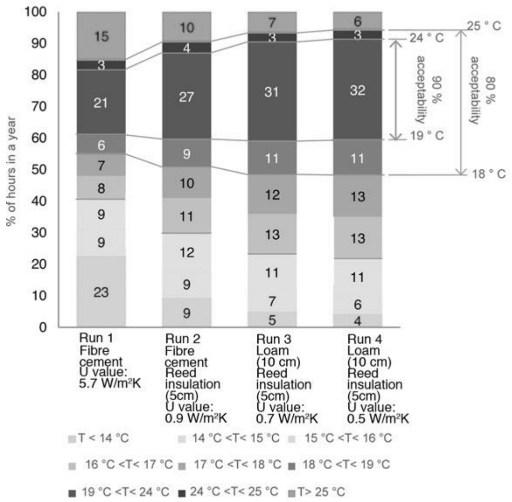

Figure 5: Resultant temperature frequency distribution in a year for different roofs.

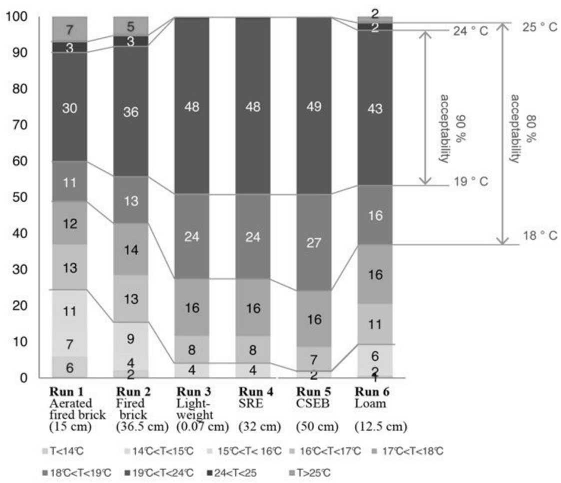

Figure 6: Resultant temperature frequency distribution in a year for different materials tested with same U value.

Material comparison fixed U-Value: In order to assess only the Volumetric Heat Capacity (VHC) and the effect of mass and given the fact that the U-Value depends on the wall thickness and on the material conductivity, U-values were set to be the same (1.5 W/m^{2}K). Figure 6 shows that all-massive construction materials have a similar performance achieving 90% of acceptability for 49 % of the year. In addition, the AFB walls would generate the highest diurnal resultant temperature fluctuation in June 14 th about 10 K while the lightweight construction and CSEB would fluctuate by 8K and 2.5 K respectively. This can be partially explained by the fact that the effect of mass of thick wall constructions is required to achieve the set U-value.

Earthen mass: the effect of mass has potential for improving internal comfort and is likely to be most effective when coupled with internal spaces (Baker, 2009). In order to assess the required quantity, earthen mass was progressively added on internal surfaces. Loam was used for ceiling, CSEB for walls and SRE for floors. It was shown that the dwelling's thermal performance is sensible to the amount of applied mass on internal surfaces. By increasing envelope's elements by 20 cm, the percentage of hours within 80 % and 90 % of acceptability increased from 33% to 42 % and from 49% to 74% respectively. Nevertheless, due to construction feasibility, a maximum wall thickness of 35 cm was considered admissible. This corresponds to the addition of 15 cm of SRE and loam on floors and ceiling respectively. The addition of mass reduced the internal fluctuation from 6K to 2K in a typical day.
The window sizing and the amount and position of insulation were optimized by adjusting the window to floor ratio to 30% and 5 cm of reed insulation placed outside the wall would optimise the performance (Walls U-value = 1.1 W/m2. K). With these variations on the simplified model, further analysis was undertaken.
Earthen mass position: a concern for architectural design is the position where the thermal mass is most effective in a building. This was assessed by changing one envelope element at the time (improved roof, floors and walls) and then looking at the overall effect of the heavyweight construction from the previous analysis. For the geometry considered, the best improvements were the earthen roof and the earthen walls showing a decrease in the percentage of overheating hours, from 19 % to 10% and 9% respectively. Moreover, the use of mass for internal partitions showed a significant improvement increasing the percentage of hours within 80% of acceptability by 14 %. Overall, the extensive use of mass increased the percentage within 90% and 80% of acceptability to 67% and 86% respectively. Figure 5 shows the resultant temperatures for the base case (run 1) and the optimized scenario with extensive thermal mass (run 6). For this case the resultant temperature fluctuates by only 4K in a typical week while lightweight construction would generate fluctuations of 20 K (Figure 7). This is explained by the fact that the largest the surface on which it is applied, the most effective is the thermal mass (Balcomb, 1983).

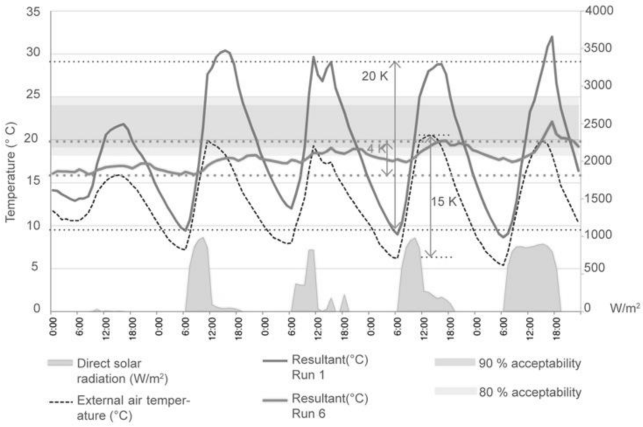

Figure 7: Resultant temperatures between June 11 th and 15 th for base case and heavyweight constructions, domestic building type.

NON-DOMESTIC BUILDING TYPOLOGY

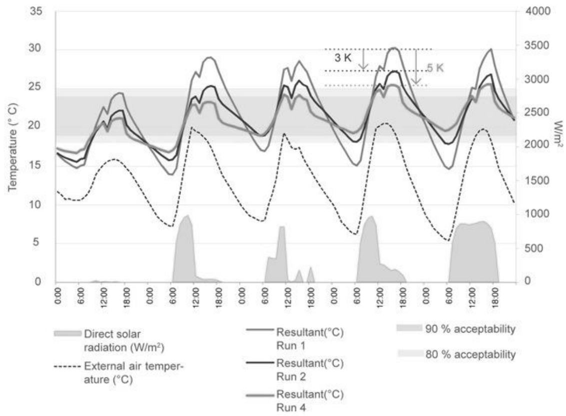
Other building programmes such as schools may suffer from overheating issues and could benefit from the mass effect provided by earthen materials. A simplified model was simulated considering the parameters listed in Table 3. The classroom is assumed to be occupied by 32 people from 8:00 to 18:00. During lunch time (13:00 h to 14:00 h), half of the occupancy is assumed. The classroom is oriented north and south walls are shaded. The main focus of the simulations was to look at the amount of mass required in a high occupancy programme and the potential ventilation may have to improve the mass effect for cooling in Bogotá.

Table 3.Initial input parameters for classroom-simplified model.

Geometry		Internal gains	
Area	72 m2	Equipment	6 W/m2
Volume	216 m3	Set back value:	1.0 W/m2
Window area	10.8 m2	Lighting:	3 W/m2
External wall area	45.6 m2	Occupancy(x32)	45 W/m2
Internal wall area	43.2 m2	**Infiltration rate**	0.5 ACH
WFR	20%	**Fresh air req**	4.5 ACH
U Values	W/m2.K	**Schedules**	Weekday
External walls	1.9	Equipment	8:00 - 18:00
Roof:	0.7		
Ground floor:	0.25	Lighting:	6:00-18:00
Windows (SG)	5.1	Occupancy(x32)	8:00 to 18:00

Earthen mass: By changing the wall construction from lightweight to heavyweight, the percentage of overheating hours during occupancy decreased from 37 % to 12 %. The addition of internal mass proved to be effective up to 10 cm thickness for floors and ceilings and 30 cm thick walls. Figure 8 shows the resultant temperatures during a week from lightweight walls, to heavyweight walls and the optimal internal addition of mass. It can be seen that the second (run 2) reduced the temperature peak by 3K compared to the first for the warmest day of the week. Moreover, the addition of internal mass (run 4) reduced this peak by 2K compared to the second.

Ventilation: Natural ventilation and night ventilation could work jointly with thermal mass (Baker, 2009). Simulations aimed at assessing the impact of multiple ventilation rates as well as night ventilation potential. It was shown that the increase of ventilation rate during the day would reduce the percentage of hours within 90 % of acceptability. In contrast, ventilating at 4.5 ACH during occupancy and doubling the rate during the night allowed to increase the percentage of hours within 90 % of acceptability from 84 % to 86 %. In addition, it was shown that night ventilation has potential for reducing the resultant temperature's peak by about 2K compared to the initial case (Figure 8 b).



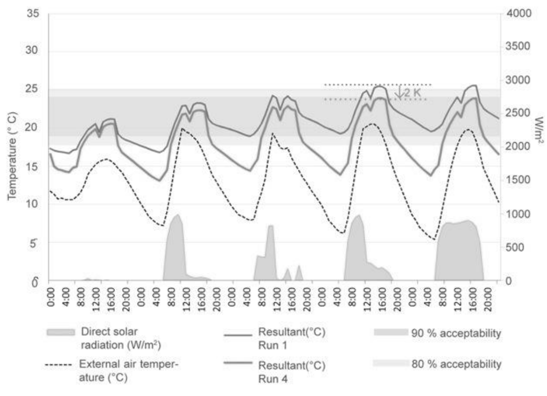


Figure 8 a: Resultant temperatures between June 11th and June 15 th for base case, heavyweight walls and optimal case**.**

Figure 8 b: Resultant temperatures between June 11th and June 15 th for base case and optimal ventilation strategy.

CONCLUSION

The questions answered in this paper aim to conceive guidelines for the applicability of traditional building techniques in a contemporary context. Earthen composites made with low cement proportions were mainly considered. Material comparisons, envelope specifications, thermal mass and ventilation strategies framed the contemporary application of traditional earthen materials for domestic and non-domestic buildings. It was proven that locally sourced techniques such as compressed stabilized earth blocks could perform thermally as well as conventional bricks. Moreover, the thermal mass strategy proved to be more effective for cooling than for heating purposes in Bogotá. Further research should consider the effect of earthen techniques in terms of embodied energy and cost in order to reach a holistic assessment of the material. In addition, considering the hygrothermal properties of earthen constructions, the different techniques studied in this work should be analysed and compared in terms of their humidity balancing potential and condensation risk.

ABSTR ACT

This study focuses on the comparative thermal performance of a selection of cases from three distinct generic types of vernacular houses at Lucknow, a culturally & architecturally renowned city in the Gangetic plains of Northern India. The objective of the study has been to evaluate the core urban courtyard houses, colonial adapted bungalows and semi-rural mud houses at Lucknow to ascertain which type(s) have responded to the prevailing climate better than others and what factor(s) or strategies may be contributing for its (their) improved performances. Most significantly it has aimed to search for emergent energy efficient principles applicable to the region's composite climate characterised by hot-dry summers, cold winters and intermediate warm-humid monsoon season. This has been pursued firstly by an in-depth study of deviant cases within each generic house type with respect to Lucknow's composite climate assessing their anticipated performances. Later simultaneous monitoring of indoor temperatures and humidity in identified periods of each season has been analysed among these cases followed by their testing against the adaptive model of thermal comfort prescribed by Nicol and Humphreys. Moreover their simulations on Ecotect software have been examined and calibrated making them suitable for extended research. Conclusively, this study has acknowledged the significance of a combined chemistry of varied strategies & sub-strategies functioning together in each house for effective thermal response in this region. Furthermore, it has given a range of multiple tactics to fall back upon instead of a myopic view of just orientation or thermal mass or others & more importantly it has substantiated the role of ventilation & air movement for the favourable thermal performance of a built envelope. As a whole this research has been useful in deriving inexpensive passive strategies useful for Lucknow also resulting in principles and recommendations suitable for the composite climate of the region.

BACKGROUND

The significance of learning from the vernacular has been corroborated by a number of scholarships that have also ascertained that, their responses to prevailing climatic conditions have been favourable. These lessons are even more meaningful in the contemporary Indian context with low energy resources and the unremitting escalating needs of an exploding population. Moreover learnings from the Indian vernacular have also established their effective thermal performances with respect to existing environments especially the hot-dry and warm-humid climates. Lucknow, is a culturally and architecturally rich North Indian city located in the Gangetic plains, experiencing a composite type climate that necessitates varied responses from a built form all through the year. Furthermore the city fabric consists of broadly three vernacular house types comprising of the core urban courtyard type, bungalow type and the semi-rural mud house type, within its precincts, that have not yet been examined for their thermal responses. It is interesting to note that all these generic house forms are distinct and varied from each other and yet seem to be thermally comfortable in the varying composite climatic conditions of the region.

THERMAL COMFORT: SELECTED MODELS & METHOD:

A review of previous scholarships has acknowledged the role of thermal comfort as most significant within a built form that could be defined as a condition expressing satisfaction with the thermal environment. Moreover the scientific interventions for assessment of thermal comfort have included various models like the steady state (ASHRAE 55), PMV (Fanger) beside other empirical & analytical indices. These have led to the significance of adaptive model of thermal comfort which relates the outside prevailing conditions to the indoors, thus establishing that people have remained comfortable approximately to the average indoor temperature they encountered. Equations for the same have been derived by Humphreys & Nicol as $Tn = 12.1 + 0.534^* Tm$ and $Tn = 17 + 0.38^*Tm$ respectively, where Tn was the predicted indoor comfort temperature directly determined by the outdoor temperature of a place, and Tm that was the monthly mean outdoor temperature (Auliciems). These models gave a flexible thermal comfort band of 5°C to 7°C in which a person could become comfortable by short term actions or long term acclimatization validating their utility in the diverse tropical climate of the Indian Subcontinent simultaneously reducing the energy demands created by uniform steady temperature standards. Furthermore, the recognised most controllable factors affecting the thermal performance of a building envelope within the architectural premise include its Siting, Location, Orientation, Form and Massing, Spatial Organisation, Open Built Distribution, Material and Construction Techniques besides special elements responsive to existing climatic conditions. Accordingly they shall assume a significant role in selection of cases for study and the subsequent extrapolation of passive strategies.

LUCKNOW: CONTEXT CLIMATE & SELECTED STUDIES:

Lucknow city is regarded as one of the “finest cities of North India both in the architectural and cultural context” (Siddiqui 27). As a spontaneously accretive grown city, it is more a consequence of the various layers of development added to it by the diverse rules and colonisations due to which the city’s morphology is an amalgamation of organic & geometric parts. Broadly three types of house forms have developed, the most significant of them being the city courtyard houses, inhabited both by Hindus and Muslims; the bungalows that have been colonial adaptations by British; and the semi- rural mud houses present on the fringes of the city. While most of the courtyard houses are introverted and situated in the old city areas accessed by winding streets among *mohallas*, some later ones have formed part of newly well-defined settlements. The bungalows on the other hand have constituted of more formal well-defined spaces with extroverted arrangements set amidst large secure compounds within well-maintained cantonment or similar precincts. In contrast the semi-rural mud houses have existed as semi-introverted courtyard houses in informal clusters with an agrarian population of informal usage patterns.

All these house types have evolved in diverse contexts and conditions but have co-existed in the city for more than hundred years. Furthermore they have been built after numerous checks and balances making them vernacular in the true sense of the word. The core urban courtyard houses with shared walls have one or two courts with a single bay of rooms around it opening to narrow shaded streets within dense built contexts. Distinctly the Muslim houses have had two courtyards segregated for both men and women while the Hindu houses possessed a single courtyard both utilized for similar informal activities. Of introverted centripetal organisation, with thick lakhori brick, surkhi lime construction their roofs have been made of timber joists or jack arches. Within these, four variations were selected for the study namely Farangi Mahal house, Jannat Ki Khirki, Kaiserjahan house and Narhai house.The colonial adapted bungalows being detached monolithic units have centripetal extroverted configurations well lighted and exposed to the large open environment around them. These are made of thick walls of brick, surkhi, lime mortar and are usually single storied with flat jack arch with varied heighted roofs and verandahs in strategic directions. Within these, three variables in form of Majithia house David house and Rachna house have been selected as cases for examination. The semi-rural mud houses were semi-detached houses in clustered formations on large vegetated sites. Consisting of singly banked rooms around courtyards with transitional verandahs the selected cases consisted of the Pradhan house, Rumesh house, small mud house & Rajmahendar house. It is to be reiterated here that while the three types of

house forms at Lucknow were already generically different in terms of organisation & siting the variables amongst each case varied in terms of shared walls; orientation; fenestration percentage; Courtyard proportions and massing. The objective of the selection of the cases was to ascertain the role of specific factors in the varying thermal performances of houses within one generic type and among diverse types.

TOOLS & TECHNIQUES:

An in-depth critical review of utilised procedures and techniques for assessment of thermal performance of buildings all over the world was done to arrive at a comprehensive methodology for the study. These included theoretical studies without on-site documentation by Nevins & Dabaieh ; extensive site analysis with some numerical simulations by Ford & Associates, Vinod Gupta, Ashok Lall and Campos among others; on –site monitoring with extensive site- study by Brian Ford, Kotharkar, Ahmad and Fanchiotti; simulations & site studies by Kanika Agrawal, Antarikananda, Avlokita Agrawal, Haschem and Alanzi; on-site monitoring with simulations by Arvind Krishan, Young and Summers Francoise amid others. The simulating software was selected after assessing the reviews of Crawley, Ling and Summers amid others. Subsequent to the systematic analysis the methodology devised for this study was all inclusive, incorporating a detailed recording of the selected houses being variables of each generic type of house form at Lucknow. The expected thermal performance of each study was evaluated for each case against theoretical parameters after which an onsite simultaneous monitoring by Hobo Data loggers was conducted in the living rooms of all the houses for similar periods all over the year. These results were plotted on the predicted comfort equations by both Humphreys and Nicol for the assessment of recorded data of all selected cases. Concurrently Ecotect models were developed for all cases with simulation for critical discomfort periods and tested for varying parameters. Later the results from monitoring & Ecotect were put together and analysed to assess the performance of each case to establish principles useful for this region.

ANALYSIS OF DATA & DISCUSSION OF RESULTS:

The comparative analysis of the on-site monitoring data of all studies was conducted with respect to the predicted comfort bands by both Humphreys & Nicol formulated on the basis of Lucknow metereological data. On basis of Aulliciems a comfort band of 7 ºC width was considered as these houses utilised an adaptive informal lifestyle. The scrutiny showed that in summers the variable cases within all generic types of houses lay within the band with a difference of just 3.5°C within the closest and farthest cases. However in this season as per the afore-mentioned analysis, the city courtyard houses (Narhai house closest) generically performed better than the bungalows & mud houses. Furthermore in winters the bungalows as a type showed improved performances (Rachna house closest to desirable comfort temperature) while the city houses with larger courtyards achieved lower thermal performances & the mud houses were even worse. In monsoons generically the city courtyard houses (Narhai house followed by Jannat house) performed better than mud houses & even more so than bungalows.

On a finer analysis of the temperature data of variables within one type it was gathered that there was significant deviation within the thermal performance of one generic type meaning that in the same season one case within the same generic type performed best while another was one of the poorest amongst all cases. Notwithstanding the above, the most important inference was that within all cases the temperature variation was not great while the difference in the indoor relative humidity readings was even more minimal. In summers and winters the difference in maximas & minimas was less than 5°C while in monsoons the variation was limited to only 3°C. It was also observed that the bungalows recorded the lowest diurnal variations among all cases. Relative spot readings within the same house indicated a difference of up to 2°C in the temperatures. On close observations it was found that Narhai house- a core urban courtyard house recorded lowest indoor temperature in summers while the Rachna bungalow experienced higher internal temperatures in winters whereas in monsoons Narhai and Jannat courtyard houses noted best inside conditions. These outcomes also led to the understanding that all the

selected cases of vernacular houses were thermally comfortable although the superiority of one type over the other could not be distinctly established in any season. In fact it was realised that each house utilized a combined chemistry of varied strategies and sub-strategies for effective responses to varied seasons.

The Ecotect simulations for each case was calibrated on basis on existing data and the comparative assessment of their cooling, heating loads, monthly discomfort hours & temperature distribution was made. After which these models were also simulated with varying factors of orientation, material properties, and fenestration, shared walls, changed massing & varying shading systems. The implications of analysis by Ecotect revealed that the maximum heating loads were required by the Small Mud House while Rachna Bungalow and Narhai House needed minimum heating loads. Alternately maximum cooling loads were used by Pradhan House and minimum by Majithia, Narhai and Rajmahendar Houses. The living areas of all houses exhibited more constant hourly temperature profile than the other rooms. Variations in the simulation models also revealed the change in loads with modifications in upper floors, shared walls, orientation, fenestration, shading and materials that have been summarised in the coming paragraphs.

CONCLUSION

The most significant inference of the study was that all the generic vernacular house types of Lucknow were found to be thermally comfortable in the varying seasons of the region due to diverse multiple passive strategies adopted by them to counter the extremities of outdoor conditions. While the superiority of thermal performance of one generic type over the other could not be distinctly established in any season it was evident that the combined chemistry of varied strategies & sub-strategies were utilized by each case for effective thermal response to the existing climatic conditions of Lucknow. The architectural study of the selected cases within each generic type and across types revealed the passive strategies and sub-strategies utilised by the variants for effective response to prevailing climatic conditions. The core urban city courtyard houses employed siting amid narrow mutually shaded dense winding streets with minimal fragmented spaces whereas the bungalows comprised of siting in large open airy heaviliy foliaged sites. The mud houses on the other hand used a combination of the above with dense clusters amid large open sites. Furthermore the city houses had multiple shared walls with staggered massing of over floor to counteract heat gain & provide shade while the bungalows employed a minimised envelope with shaded verandahs and trees on periphery for the same. The mud houses on the other hand used partial shared walls and shading from adjoining large trees. Moreover the city and mud houses have used introverted courtyard plans with minimal outside fenestrations for preventing heat gain while bungalows have utilised large fenestrations opening into shaded verandahs and high ceilings with ventilators for enhancing convective cooling & ventilation. The use of high thermal capacity materials with high thermal lag in all the houses has contributed to constant temperatures all day and over the year.

It was also quantified by simulations of the selected cases that, the use of high thermal mass in building elements could improve the performance of the envelope to 70% but would prove detrimental without night purge ventilation validating the role of ventilation versus insulation. Furthermore it was observed that the strategy of orientation of vertical facades with respect to sun has been largely overrated in this region for structures below 3 stories. It contributed to a deviation of only 5 to 10% whereas the influence of effective mutual shading could improve the performance up to 30%. This study also substantiated that although solar radiation assumed maximum significance within the tropical Indian climate **the role of wind and air movement had to be taken into account for favourable thermal performance of built envelope**. Moreover Roof shading has shown to be extremely effective in this climate while effective massing improved the performance of lower floor up to 45%. Effective Shading of walls & fenestration have shown to reduce heating & cooling loads by 30% while presence of small courtyards has also indicated usefulness in all seasons. Verandahs as shading devices have exhibited significance & have a larger role to play built forms at Lucknow to articulate facades provide shading & prevent thermal shock in extreme outdoor conditions. The recommended Fenestration proportions have

seen to work more effectively in combination of ventilators & doors reducing loads by up to 32%. The study also showed that a non-parochial view of materials was to be required and their role in a combined assembly system should be assessed.

Furthermore Simulative modelling techniques have made visualisation and subsequent design much easier but **the study resolves that the unrestrained use of simulation software's without an assessment of real conditions are a cause of concern** because despite multiple configurations **they underestimate the role of wind and air movement.** Furthermore in simulative models **insufficient credence is given to adaptations** due to physical actions in actual environments leading in inaccurate results. Especially in the case of naturally ventilated buildings in the Indian climate their role has to be examined more closely and thus selected with extreme care that would need to be calibrated with actual on-site data. India is fast becoming a global phenomenon as a result of which **modern living comparatively has become more inflexible** with minimal space reallocation even in the extreme conditions. In an age of fast depleting resources and power crisis learning from the adaptive and flexibility principles of the vernacular makes sense to restrict reliance on active systems of cooling and heating loads

Assessing Sustainable Retrofit of the old Dwellings Stock in Brussels Capital Region

Trachte Sophie – Arnaud Evrard
[Architecture et Climat – UCL]
sophie.trachte@uclouvain.be

Arancha Galan - Aristide Athanassiadis
[Bâtir – Université Libre de Bruxelles]

ABSTRACT

In the framework of the research project "B³RetroTool", a typology of existing dwellings, built before 1945, has been made, based on a literature review of main steps of the urban and building development of Brussels area. This old part of the Brussels dwellings stock has been chosen because it represents 60% of the dwelling stock but moreover, it gives to Brussels its identity, its architectural and its historical legacy.

This contribution presents the methodology to identify typology, to structure a representative database of existing dwellings stock (with spatial distribution in Brussels area) and to define criteria to assess retrofitting strategies for each dwelling type in order to enhance heritage value and to combine it with relevant energy and environmental performances. The originality of this research is to consider energy, environmental and heritage aspects in a non-compartmentalized and complementary way, in order to help designers to reach their objective of a greater sustainability.

INTRODUCTION

The dwellings stock built before 1940 in Brussels has a great heritage value for Brussels Capitale. It also represents 60% of built areas and is responsible for 62% of the region's energy consumption. This fact has prompted Brussels to invest in strong support for reducing energy consumption in buildings through systems of subsidies. These include subsidies for insulation, replacement of windows, boilers ... So as to target the strategic policy actions in terms of reduction; the Brussels Capital Region has also invested in targeted studies on the state of the existing building stock and opportunities for improvement. All of these studies, mainly based on statistical studies have rarely considered both the heritage and historic value of the buildings and the improvement potential related to buildings components and design principles.

The research's objective is to achieve important improvements in the energy performance of existing Brussels dwellings stock while preserving heritage value and reducing environmental impact.

The research focuses only on the dwelling stock built before 1940 for three main reasons. First, this is the largest share of the Brussels dwellings stock. Secondly the differents types of dwelling could easely be identified.Thirdly, this dwellings stock requires urgent improvements in terms of energy performance and inhabitancy. It should also be noted that dwelling demand is very strong in Brussels. So the retrofit of this dwelling stock could meet this demand by densifying some dwelling types.

This contribution presents identification of dwelling typology built before 1940, proposition of retrofitting scenarios and definition of energy, environmental and heritage value criteria in order to enhance heritage value of the Brussels dwellings stock and to combine it with relevant energy and environmental performances but also suitable materials and systems. It describes in details the methodology used for identification, repartition and spatial distribution of dwelling typology. Retrofitting scenarios and assessment criteria are subsequently presented.

This research is still ongoing and the results of scenarios assessment are not yet known. The overall results: dwelling typology, its repartion and spatial distribution as well as improvement scenarios and their assessment through case studies will be incorporated into a pre-assessment tool to retrofit the dwellings in an integrated multi-criteria and multi-scale approach.

HISTORICAL RESEARCH: URBAN DEVELOPMENT OF BRUSSELS, FROM THE 10TH TO 20TH CENTURY

The first step of the research was to study the historical processes [1, 2, 3, 12] that have influenced the development of the city of Brussels and the Brussels-Capital Region in order to understand the urban characteristics and specificities but also to know the origin of the development of certain types of city blocks and dwellings. Brussels-Capital Region, as it is today, was formed mainly during the last two centuries. But some key elements are older. They are, as example, the topographic or hydrographic elements that were at the origin of the spatial and social differentiation between high side (east and more aristocratic) and low side (western, most popular and industrial) of the city. This spatial and social differentiation is still present today, although less pronounced than originally. It is also the work of fortifications that gave the city center of Brussels, a specific and still visible form. It is also major infrastructure projects such as the creation of the boulevards on the second enclosure, the creation of Willebroeck and Brussels-Charleroi canals, the creation of large avenues, the creation of the North-South Train Junction... All those elements must still be reconsidered in strategies for urban renewal of the region through different scales: neighbourhoods, city blocks and buildings.

This historical research focuses mainly on morphology, demography, urban planning, architecture and types of dwelling.

DEFINITION OF DWELLING TYPOLOGY

The study of the dwelling typology before 1945 has been established from the late 17th century for two main reasons. First, dwellings built before 1700 are mainly wooden buildings. In 1695, those wooden buildings were almost destroyed (as the entire city) by the French bombing. The Brussels rebuilding was made with bricks and stones, on the track of the old wooden dwellings. Secondly building permits and the various regulations standardizing construction spread in the 18th century.

Dwelling types were defined according to the historical research of Brussels urban development but also to the changes in lifestyle of Brussels citizen as well as changes in construction methods and materials used. Three main periods of urban development have been identified.

From 1700 to 1890: urban development of Brussels. Period characterized by the first great works of urbanization and development of the future Belgian capital city (1830).

From 1890 to 1914: transition period. Period characterized by hesitation between the nostalgia for the past and the desire for modernity and a new architectural trend, the “Art Nouveau” launched by Victor Horta, with the construction of Hotel Tassel in 1893.

From 1920 to 1945: modern period. Period characterized by a strong demand of housing but also new ways of thinking architecture and urban development.

Regarding the types of dwelling, the research distinguished two key periods:

From 1700 to 1914. Period characterized by a predominance of individual housing (modest, bourgeois and aristocratic), whose spatial organization will be based on the spatial organization of the “maison bourgeoise”;

From 1920 to 1940. Period characterized by the emergence of new types of dwellings, mainly worker house in the garden cities and apartment building but also new constructive processes and new materials, especially concrete.

Based on archival and/or historical documents, each type of dwelling has been studied according to the methodology including a general description of the type (description of dwelling situation, spatial organization, internal circulation and stair case, building systems and materials, roof, façades and building materials), a description of the main characteristics (relation with public space, size of the plot, size of the building, volume, number of floors, presence of annexe, height and width of the main façade…) and description of type variations if they exist.

Dwelling typology from 1700 to 1914 [4, 5, 11, 14]

The single family row house is the most common form of dwelling in Brussels until 1914. For this period, there are three main types of dwelling: the “maison bourgeoise”, the modest or worker house and the “hôtel de maître”. These types are the evolution of the Brussels wooden row house and are thus characterized by the same spatial organization, construction principles and materials that can be presented through the “maison bourgeoise”:

Spatial organization. It reflects the lifestyle of the bourgeoisie in the 19th century and it is organized in three modes: reception, family spaces and services or domestic spaces. Internal spaces are divided into two parts: a main part including the reception and living spaces and a secondary part, narrower, including services, stairs and corridors. The plan is organized with a succession of two or three rooms with a depth of 4 to 4.5 meters. Reception and living spaces have high ceilings, large width and are largely lit.

Construction system, principles and materials. The construction system is mainly governed by the rules of protection against urban fire. It is based on the constructive system of the Brussels wooden row house. Party walls are made of brick locally sourced and are not structural. The wooden floors are perpendicular to the street facades and partition walls. The wooden beams are spaced between 35 and 40 cm. The thickness of the bearing brick walls is also codified by the regulations of buildings to ensure stability. It varies between 28 cm and 48 cm depending on the type and height of walls. Recovery of floors charges and load-bearing walls is ensured by a combination of discharge vaults and metal lintels scattered throughout the façade and load-bearing walls. Only the structure of the roof is based on party walls, wooden beams ranging from wall to wall. The floors of the ground floor are partly made of hard materials. They are tiled or covered with marble. Floors of the upper levels are in wood. The ground cellars are usually performed in clay.
The two façades are narrow (6 m) and high (12 to 18m) but there is however a big difference in composition between the two façades. Back cover: brick facade, sober and coated. Only a few metal lintels and sills are apparent. Main façade composition depends on different styles: neoclassical, eclectic,... Materials used are brick, natural stone and oak for window frames. The level of the street façade decoration shows the social level of inhabitants.

Dwelling type variations. The type “maison bourgeoise” could be divided into three variations according the construction date: “maison bourgeoise” built before 1800, “neoclassical maison bourgeoise” and “maison bourgeoise bel étage”. Those three variations have the same spatial organization and same internal plan but show variations at the level of groundfloor and stairs installation.

The same construction systems and materials are found in the modest house and in the “hotel de maître”. Only the location, the size of the plot, the width of the main façade, the surface area, number of floors, the appearance of the street façade and interior finishes are different. Modest or worker row houses were mostly located in the popular and industrial districts. Maisons bourgeoises were located in residential districts of the pentagon, mainly in the top of the city. Hôtels de maître built for the upper bourgeoisie and aristocracy, after 1830, were located along large avenues and in some districts extensions. In addition to these three types, there are also houses with shop and apartment houses that show a lot of similarities with the “maison bourgeoise”. Those types of dwelling were located on the corner plots and near train stations and infrastructure.

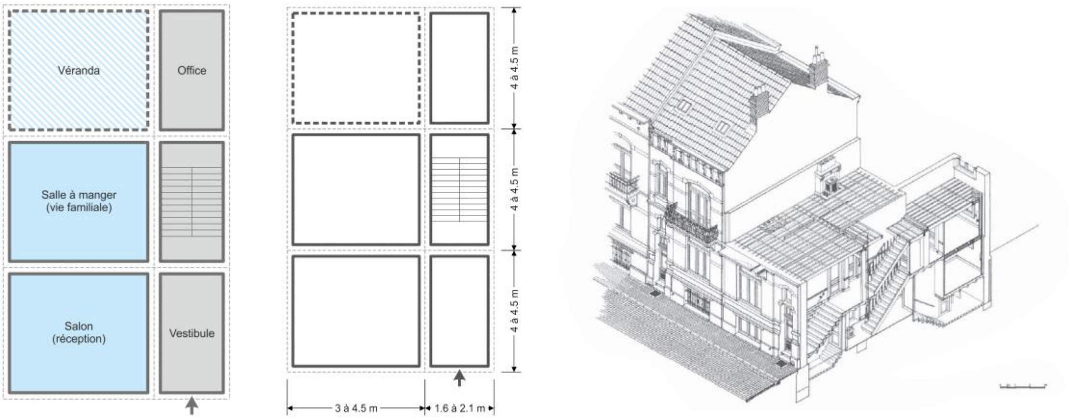

Figure 1 Left: Spatial organization - Center: main dimensions - Right: construction principles of the “maison bourgeoise”

Dwelling typology from 1920 to 1940 [6,7,8, 14] **.**

The beginning of World War I, in 1914, traditionally marks the end of a period both in Western Europe in Brussels. Mentalities as well techniques evolve significantly: the car is spreading, domesticity disappears, the role and place of women change. Changes also appear in the ways of life of the bourgeoisie and the working population. These changes have an impact on the spatial organization of dwellings, on the urban development of Brussels and on the types and styles of dwellings whether individual row house remains predominant. Garden cities are built for the workers at the extremities of the city. By 1930, after the financial crisis of 1929, apartment buildings for middle class - back in town - are growing in Brussels. For this period, we can distinguish three types of dwelling: evolution of the “maison bourgeoise”, worker row house in garden-city and apartment building (social and standard). If the evolution of the “maison bourgeoise” still presents many spatial similarities with the “maison bourgeoise” built before 1914, the two other types show a new spatial organization [figure 2]. All three types also were built with new construction systems, principles and new materials, especially concrete.

Figure 2 Left: Plan of garden-city row house (1922) – Right: plan of standard apartement building (1930)

Case studies of dwelling types

For each type of dwelling, a case study sufficiently representative has been searched. With this objective, various Brussels databases and information sources [15] have been consulted and various architects working with old buildings and dwellings have also been contacted. Each case study will be analysed based on original plans, sections and detailed quantity survey.

Figure 3 Pictures of “neoclassical maison bourgeoise”, “maison bourgeoise bel étage”, “hotel de maître”, apartement house, evolution of maison bourgeoise 1, evolution of maison bourgeoise 2, standart apartement building and social apartement building.

Building stock analysis – Dwelling type repartition

Based on the description of each dwelling type, a simplified characterization has been proposed to fit the data given in the Brussels cadastral matrix (©Administration Generale de la documentation patrimoniale) and to associate each lot to one type. As we can see in the figure 4, the characterization is limited to three factors: date of construction, floor area, number of dwellings per building. There is a total of 159825 buildings and 498819 dwellings registered in the Brussels cadastral matrix.

Type	TYPES BATIMENT B³-RetroTool	avant 1850	1850-1874	1875-1899	1900-1918	1919-1930	1931-1945	Surf utile / Bat	Nb log / Bat	Surf/Log

Figure 4 Characterization of dwellings types

The figure 5 confirms that more than 60% of the buildings were built before 1945. This analysis shows that "maison bourgoise” (type 2 in the figure) outnumbers all other types and that many post-war buildings are apartments.

Then, with ArcGIS software, the resulting database can be used to analyse spatial distribution of each type. The left map [figure 6] shows that type “maison bourgeoise” was mainly built close beyond the first encloser. The right map [figure 6] shows that after 1918 the type “evolution of maison bourgeoise” (type 5) was built further out the centre, beyond the second encloser.

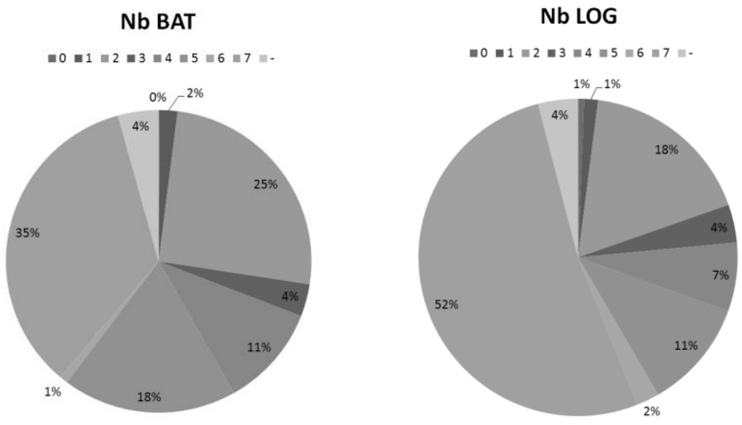

Figure 5 Repartition of dwellings types by building (left) and by dwelling (right)

Figure 6 Spatial distribution of dwellings types: left: “maison bourgeoise” built before 1914 and right: “evolution of maison bourgeoise” built between 1920 and 1930

ASSESSMENT OF POTENTIAL IMPROVEMENTS OF DWELLINGS STOCK

Based on the description of each dwelling type, various scenarios of retrofitting were proposed. They focused mainly on improving the energy performance of each dwelling type but also on creating opportunities for dwelling densification, function diversity and inhabitancy improvement. Scenarios proposed for each dwelling type will then be applied to the specific case study and assessed according to three criterias (heritage value, energy and environmental impact) and compared with the initial situation.

Climatic data of Brussels Capitale Region

The reference Belgian external climate is a relatively cold, humid and rainy temperate climate. The data presented below, were measured by the Belgian Weather Royal Institute in Uccle (Longitude: 4.36°E, Latitude: 50.80°N; Altitude 100 m): average temperature (9.9°C), average relative humidity of the air (80%), average wind speed and orientation (3.6 m/s, south-west), average global solar radiation (108 W/m² with min:0 - max 889) and average precipitation (930 mm per year).

Assessment criteria

Each assessment criteria - energy, heritage value and environmental impact - contains a series of indicators presented in the table on the next page.

Table 1. Assessment criteria

Energy	Heritage value	Environmental Impact
Transmission coefficient [U] of the walls and frame	Building quality	LCA of building materials (GWP, AP, POCP)
Efficiency of the technical systems	Coherence quality	Amout and type of waste produced
Overall performance of the dwelling: - Average U - Level E	Preservation quality	LCA of technical systems (GWP, AP, POCP)
Total grey energy (NRE, RE)	Resilience quality	

Potential improvements of dwellings stock – retrofitting scenarios [9, 14, 15]

Various scenarios were proposed with the objective to improve significantly the energy performance of the dwellings. Those scenarios focused first on the envelope and then on the technical services. The envelope retrofitting scenarios were defined based on a trend analysis performed on the renovation of housing awarded at Exemplary Buildings initiated by Brussels Environment. They are proposed by phases, knowing that today, only few Brussels owners can finance all of the retrofitting works in one phase. The retrofitting steps are proposed in a hierarchical manner, taking into account the state of the dwelling, the influence on the energy performance and the extent of work required. As an example, the envelope retrofitting scenarios for the “maison bourgeoise” are the following:

1. *Roof insulation:* the insulation could be done from inside or outside. Insulation from inside preserves the structure and the covering. Insulation from outside requires a new covering and sometimes a new structure. Insulation from outside also requires a special attention to specific elements and ornaments and could be linked with integration of renewable energy system
2. *Roof insulation + Floor slab insulation*
   In case of “maison bourgeoise bel étage” with a raised ground floor and cellars naturally lit, the floor slab could be insulated from inside. In case of “neoclassical maison bourgeoise” with a ground floor at street level and cellars without natural light, the floor between ground floor and cellars could be insulated (cellars side).
3. *Roof insulation + Floor slab insulation + Frame replacement (back cover façade)*
   In many dwelling, frames are still equipped with single glazing. Those should be replaced by double or triple glazing frames taking into account the possible installation of solar protection (orientation) and increase of the airtightness.
4. *Roof insulation + Floor slab insulation + Frame replacement (back cover façade) + back cover façade insulation*
   Back cover façade could easely be insulated from outside. The most common technique is the coating on EPS insulation but wood-based materials will also be assessed.
5. *Roof insulation + Floor slab insulation + Frame replacement (back cover façade) + back cover façade insulation + Glazing and/or frame replacement (main façade)*
   The main façade being highly ornamented and the frame strong, the replacement of the frame and/or glazing therefore requires a detailed study. Several solutions can be considered: preservation of existing chassis and replacing single glazing by double glazing or replacement of all
6. *Roof insulation + Floor slab insulation + Frame replacement (back cover façade) + Back cover façade insulation + Glazing and/or frame replacement (main façade) + Main façade insulation*
   The main façade being highly ornamented, insulation from outside is really not possible. Insulation by inside means to pay attention to thermal bridges between façades and wooden beams and requires a detailed study [10].

The technical services retrofitting scenarios are proposed taking into account the existing technical services and the possible densification of the dwelling. The scenarios propose improvement strategies for existing techniques but also for integration of ventilation systems, renewable energy systems (solar thermal and PV), rainwater infiltration systems and acoustic insulation (in case of dwelling densification). They presented, for each dwelling type, solutions for ducts implantation.

The densification retrofitting scenarios analyse the possible way to increase the number of dwelling, especially into the “maison bourgeoise” characterized by a very large surface area available (up to 400 m²). Some scenarios propose a diversity of functions by integrating professional spaces into the dwelling.

CONCLUSION

The paper presents the methodology used to analyse and caracterise the brussels existing dwellings stock. The data will be used to develop a tool to help improving global performance of this urban area. A definition of dwelling typology was detailed and each building from cadastrial database was associated with one type. Using ArcGIS tool, a map of each type can be drawn. For each type, refurbishment scenarios were proposed, as well as three set of criteria to assess energetic, environmental and heritage value in parallel. Developping tool should thus allow assessing simultaneously these three aspects and their interactions. This methodology can be applied in other contexts to provide any user with data at different scales, from the building to the entire city, helping to take sustainable decisions.

ASTRACT

Bosnia-Herzegovina, a country going through the process of development, has many challenges to overcome in order to achieve satisfactory energy efficiency of its built structures. In the last couple of years, activities to increase energy efficiency of residential buildings have gained momentum in order to align with the European Union energy efficiency legislature. The majority of those activities consist of building stock refurbishment by simply adding thermal insulation onto existing architecture.

Considering the climatic conditions, of warm summers and cold winters, decreasing heat loss is important aspect in striving to achieve thermal comfort and energy efficiency of the buildings in Bosnia-Herzegovina. Other means to achieving thermal comfort could be found in Bosnian vernacular architecture, especially when considering thermal comfort in the summertime. Vernacular architecture offers original passive architectural design solutions that are waiting to be utilized in contemporary design.

Although comprehensive research on many of the aspects of the traditional Bosnian town house have been done in the past, its passive-design elements have not been recognized as such nor systematically studied. This paper aims to introduce passive architectural elements, passive cooling and ventilation techniques to a broader public.

Excellent house performance could potentially be achieved by the integration of the vernacular design traditions, of the Bosnian town house, into contemporary passive-house designs.

Thermal performance of a traditional Bosnian town house is tested through computer aided simulations and site measurements. The results of the study should provide convincing arguments, for the local architects and policy makers, to steer the often misguided and overly provisional trends in house designs, to the sustainable path.

INTRODUCTION

In efforts to achieve sustainability it is up to each country to select solutions suitable for their specific conditions and environment. In Bosnia-Herzegovina, where privately owned, individual housing represents a popular lodging solution, finding a sustainable solution for this particular architectural category is already overdue. Some of the housing that was already built inadequately is now going through refurbishment process of adding thermal insulation, to increase thermal performance. Domestic

Author A is a Doctorate Candidate at Kobe Design University, Kobe, Japan. Author B is a Dr. Eng. and Professor at Kobe Design University, Kobe, Japan

households take up 52% of final consumption of energy (ESSBIH 2008) and in general buildings mainly have a poor thermal insulation which causes energy loses of up 30% (CPU 2010).

The study of vernacular housing solutions in a particular environment is an excellent venue for revealing design solutions that can be replicated in the same environment but in a contemporary context. This is particularly suited to passive architecture, which makes use of its surrounding natural environment as much as possible. Beside the natural environment, a significant part of passive housing efficiency is based on the occupants' behaviour. One can argue that vernacular architecture is the original passive architecture. Making the contemporary passive architecture possible are several inseparable elements: the natural environment, the lifestyle and the architecture design itself. This paper aims to explore specific passive-architecture elements of a traditional town house in Sarajevo, Bosnia-Herzegovina through the case study of *Svrzo's House* in Sarajevo.

2. THE TRADITIONAL BOSNIAN TOWN HOUSE - BACKGROUND

The house chosen for the study is a two-storey house with elaborate ground and upper floor plans. It is known as "Svrzo's house" and is located on the hills of the old part of the town overlooking the city of Sarajevo. It dates back to the 18th century when it was owned by a wealthy local family. It was later donated to Sarajevo City Museum to be converted into a museum itself during the 20th century. This house is particularly suitable for study since it contains a variety of the typical architectural design elements of Bosnian town house and is kept close to its original state.

Figure 2 The Ground and Upper Floor plans of traditional Bosnian town house: Svrzo's House in Sarajevo, Bosnia-Herzegovina, renovated to original form and turned into a museum.(Grabrijan& Neidhardt 1957, graphic editing by author)

2.1. Lifestyle and occupants' behaviour

Traditionally, parts of the house were classified according to their functions, into four groups: habitation, recreation, domestic activities, circulation (Grabrijan& Neidhardt 1957), but the rooms themselves were used very flexibly. The furniture is also flexible, there is the sofa encircling the room on 3 sides and *Musandra* (a walk in closet consisting of a stove, a shower space and a closet), while the rest of the space of the room is free to be used in different ways.

The number and use of the rooms is set according to the needs of the family, flexibility being the key. The same room can be used as living - dinning room that transforms into bedroom during the night, other rooms can be children, study or guest rooms. The house is typically a two-story where the ground floor is used as winter quarters, and the upper floor is used as summer quarter. Depending on the house configuration the upper floor is sometime used additionally for winter quarters (Grabrijan& Neidhardt 1957). Such use of the house is a result of a the climate, hot summers and cold winters. Winter quarters are connected to the outside through *verandah* (Figure2), and summer quarters open to outside through *divanhana* (open terrace space – Figure 1&2). Common use of the house by its tenants could be categorized in the following way: 1. Summer and winter use and 2. Private and semi-private use. Front part of the house, adjacent to the main gate courtyard, is considered semi-private, since the guests are greeted there, but second part of the house is completely private.

Several unique architectural elements allow for comfortable summer and winter habitation. The occupants' behavior is adjusted based on the season.

2.2. Passive-architecture features of the house

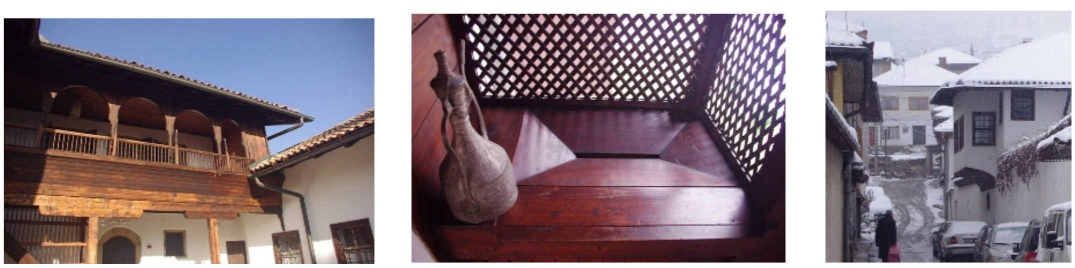

Figure 3 a) Divanhana – open-air terrace space, under deep eaves b)mushebak , c)doksat (photos by author)

Divanhana,(Figure 3.a) an open-air terrace on the first floor settled under deep eaves which provides a comfortable place to reside in hot summer days. All of the rooms adjacent to it have a direct access through massive wooden doors, and with windows looking onto it. Divanhana, together with narrow open hallway, connects pavilions of the house and enhances the airflow throughout the first floor of the house. It is accessible from the ground floor courtyard directly by stairs allowing for quick access to the rest of the house. With its built-in bench and attractive views it is mainly used for recreational activities such as reading, talking, enjoying the scenery, as an outside summer living room. It is even used even as sleeping space in warm summer nights (Grabrijan& Neidhardt 1957).

Mushebak crossing wood lattices in the windows providing enormously valued privacy. It enables cross ventilation of divanhana and hallways (Figure 3.b)

Doksat, a prism with window jutting out in the height of the upper floor of the house, overhanging the street (Figure 3. c). It is a standard architectural element that appears on all typical town houses. Since it provides 180 degree view, it is primarily used to overlook over the surrounding neighbourhood. It additionally plays an important role in house's cross ventilation; windows on all 3 sides which gives room for creating draft and ventilating the room more efficiently (Grabrijan& Neidhardt 1957).

The Garden and courtyards (Figure1&2) are places where one enjoys nature, where decorative and edible plants were planted and taken care of. Summer quarters of the house are oriented onto the garden, which increases the cooling off effect in the hot summer days.

The construction of the house is favourable in terms of thermal mass. The ground floor consists of massive walls, made out of unbaked brick or stone, while the Upper floor consists of wood frame filled in with unbaked brick. The timber frame is resting on the masonry wall. Ceilings are supported by the wood frames and the roof is a heavy wood construction protected by roof tiles.

3. PASSIVE COOLING, VENTILATION, AND HEATING FEATURES

A traditional Bosnian town house (further in the text referred as a TBT house) is, among the locals, recognized as comfortable dwelling in the summer, while at the same time having an adequate thermal mass to sustain the heat in winter months. This study aims to test those qualities on one of the TBT house’s pavilions, which is a representative of typical volumes, materials, and layout.

3.1 Climate conditions

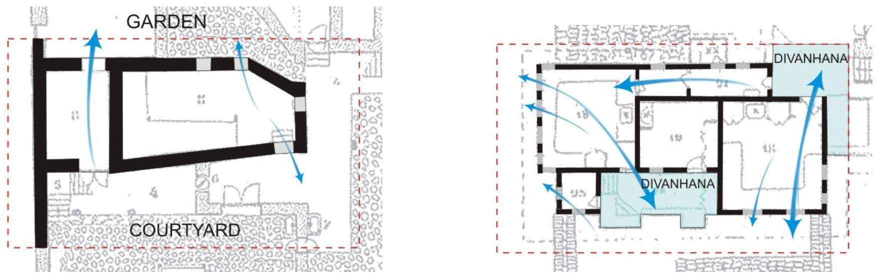
According to The Köppen Climate Classification the subtype for Sarajevo’s climate is "Dfb" (Warm Summer Continental Climate) or a medium continental climate with average winter temperatures of -1,3°C in January, and average summer temperature of 19,1°C in July. The average annual temperature is 9,5°C. The coldest month is January with the lowest recorded temperature of -26.1°C and the highest in July with 37.2°C (Weather Base 2014).

Summertime temperatures fluctuate drastically during the day where the average temperature difference between the early morning, afternoon, and evening can reach up to 10 to 15°C, with even more drastic differences between maximum and minimum temperatures. On average winter temperatures are fairly steady throughout the day, with slight decrease during the night, but with drastic maximum and minimum temperature differences across days (FHMI 2013). Humidity is also changing during the day, going from high in the morning (up to 80% yearly average in the morning), going down to 50% around midday and again getting higher in the evening hours. Prevailing winds are a result of complex geographical features, so there is a huge variety of wind directions and speeds. Prevailing directions are ESE and WNW. Dominant winds are SSW and ESE (FHMI 2013).

Although humidity rises during the night, these kind of climate conditions allow for effective night-time cooling because of the larg drop in temperature during the night. The traditional lifestyle comprises night-time cooling as a part of the daily routine in summer period. The prevailing wind directions suggest that the orientation of the house openings towards South and West is indeed favourable for natural ventilation. The selected TBT house has the optimal South and West facing openings.

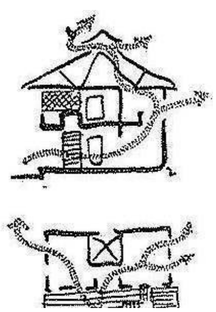
3.2. Cross-ventilation and vertical ventilation

In addition to acting as an outdoor living room in the hot summer days, aforementioned *divanhana* settled under the deep eaves, is a structure that represents a buffer zone, “a layer of air between the hot outer and cool inner spaces which gives rise to air circulation. The rooms behind the *divanhana* are connected to it by windows and doors and open into the side facades so that the ventilation around the corners is also possible”(Grabrijan& Neidhardt 1957)



a) b)

Figure 4. a).: GROUND FLOOR: Cross ventilation through the ground floor openings enabled by the openings' positioning and the difference between the interior temperature and exterior temperature of the courtyard and the garden. B.: UPPER FLOOR: Openings on the both sides of the rooms allow for cross ventilation. *Divanhana* plays an important role in the summer months, creating a buffer zone between outside and inside spaces. (Grabrijan& Neidhardt 1957, graphic editing by author)



The rooms that are placed in the central parts of the house, with no horizontal ventilation possible, are ventilated vertically through other rooms and the opening in the roof, as shown in the sketch (Figure 3.).It is clear why the house has been given an attribute of an "airy house" (Grabrijan& Neidhardt 1957) since it is ventilated in both the horizontal and vertical direction.

Figure 5. The airy house, an archetype layout and section of BTB house (Grabrijan& Neidhardt 1957)

3.3. Indoor thermal comfort – A computer simulation analysis

The thermal comfort of the TBT house was examined Using SolarDesigner simulation software (validation of software demonstrated in the article done by authors; see references: Kodama&Takemasa 1991). The pavilion of the house chosen for the computer simulation, represents a typical two-storey architecture of the area. The Ground floor is constructed through massive stone masonry, while the lighter Upper floor is constructed using the *bondruk system* – a timber framework with unbaked clay brick infill. The performance of the house pavilion Ground floor and Upper floor volumes (Figure 4. a&b) were examined according to different simulation scenarios: summer daytime and nighttime ventilation scenario, and winter *all day closed* mode ventilation scenario. Simulation was conducted for three consecutive days, in winter time, as well as the summertime. *Day 1* is considers as sunny with bright skies, *day 2* as partly cloudy and *day 3* as cloudy. The temperature values represent the maximum and minimum amplitudes recorded in July and January (consecutively the warmest and coldest month of the year).

3.3.1. Summertime ventilation and passive cooling effects

The TBT house, with ample thermal mass, is expected to benefit from the passive nighttime cooling effect in the summer. The computer simulation tested this on the Ground and Upper floor quarters (Figure 4 a&b). Room air fluctuation during July, the warmest month in this climate, is shown in Figure 7. There are noticeable differences between the Ground floor, and the Upper floor air temperature fluctuation. Traditionally utilized the most in the summertime, the Upper floor quarters, if kept closed all day, can provide a fairly steady temperature throughout the day. At this time of the year nighttime ventilation is the optimal ventilation mode. The optimal passive cooling effects are attained in the nighttime ventilation mode from 7 am to 9pm, (Shown in Figure 4) with indoor temperatures dropping up to 15°C, and which allowing the interiors to stay significantly cooler than the outside temperature. Similarly, summer nighttime ventilation on the Ground floor is the optimal ventilation mode, with temperature values going from 12°C up to21°C in the interior spaces. All day closed mode is providing good thermal comfort, with steady temperatures up to just 19-21°C even when the outside temperatures are around 34°C.

ventilation mode	day (8-18)	night(18-8)
daytime ventilation	30 times/h	2 times/h
nighttime ventilation	2 times/h	30 times/h
all day open	30 times/h	30 times/h
all day closed	2 times/h	2 times/h

Table 1 Ventilation modes (room air changes per hour)

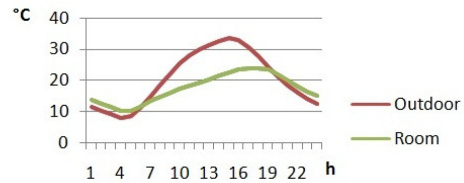


Figure 6. Nighttime ventilation effects on a clear sunny day in July

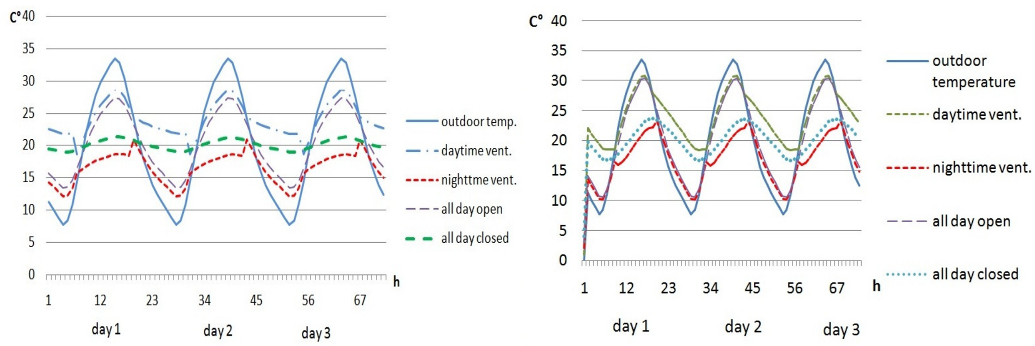


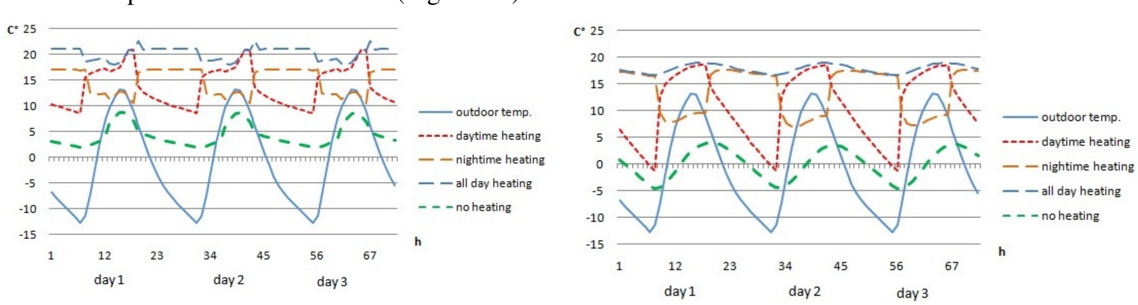
a) b)

Figure 7.a) Ground floor, summertime room air temperature fluctuations according to different ventilation modes b) Upper floor, summertime room air temperature fluctuations according to different ventilation modes

3.3.2. Winter heating mode

The winter outdoor temperature fluctuations between possible maximum and minimum temperatures values can be significant (Figure 8). Ground floor's high thermal mass, as well as the First floor's, provided heating throughout the day (at 21°C), secures the constant comfortable temperature of the interior spaces.

Comparing the thermal performance of the Ground floor and First floor, better performance in winter moths has been observed on the Ground floor. Very thick masonry walls, from 44 to 65cm, with significant thermal mass, unsurprisingly, provide good insulation quality. When kept closed all day, without heating, Ground floor quarters keep the temperature between 2°C and 8°C even when the outside temperatures are at extremes (Figure 8.a).



a) b)

Figure 8. a) Ground floor heating modes **b)** Upper floor heating modes

Since the thermal performance of the house in its original state provides relative thermal comfort only in the case of constant heating regime, there was a need to test possible thermal performance improvements of the house by adding thermal insulation. Two additional performance scenarios have been simulated for both of the floors. These scenarios include adding insulation on the outside or inside of the existing wall structure, consecutively (Figure 9&10).

Thermal performance simulation for either of the floors, as well as comparative analysis of the results, showed that the most favorable scenario, among multiple combinations of heating hours and insulation positioning, is the case where the thermal insulation has been installed on the outside of the existing structure (Figure 9). In afore mentioned case the drop of room temperature, in the non-heating hours, is not as drastic as in the case of non-insulated (Figure 8) or inside insulated existing structure (Figure 10). Better thermal performance, due to high thermal mass, also implies decrease in heating load. This study can be used as a reference in efforts to improve energy efficiency and thermal comfort of the existing housing.

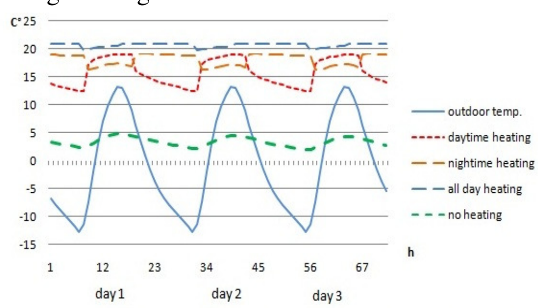


Figure 9. Ground floor:
Winter heating mode with additional thermal insulation *outside* of the existing structure

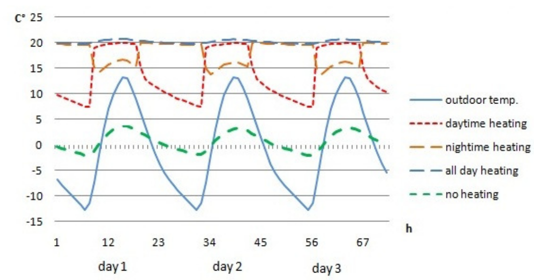

Figure 10. Ground floor:
Winter heating mode with additional thermal insulation *inside* of the existing structure

3.4. Site measurements

A field survey was conducted throughout the TBT house the using Mother Tool-LM-8000 measuring device. Measurements of indoor and outdoor temperature, humidity and wind speed were taken on two winter days, with extremely different conditions: 23rd of January, an unusually warm day with partly cloudy skies and observed outside temperature of 12°C and 25th of January, cloudy skies with snow and the outside temperature slightly below 0°C.

Since the house is used as a museum, some of the rooms are kept open and some are kept closed during most of the day (during working hours) so that the effects of *all day closed* or *all day open* ventilation modes could be observed. On a warm day, inside recorded temperatures in *all day closed - no heating mode* were slightly lower (8,7 to 10,7°C) than the outside 12°C, and on the cold, snowy day the opposite was true, with inside recorded temperatures (4,5 to 8,5°C) were higher than the outside temperatures (-0,7 to 0,2°C) by 4 to 8°C.

Although similarities between site measurements and software simulations are evident, the site measurements conducted are not to be considered as a final and cogent evidence of the house's thermal performance since they were executed in an only limited time frame. They can instead be taken as an encouragement for future filed measurements and studies.

4. CONCLUSION

The analysis of the architectural elements of the traditional Bosnian town house as well at the computer-aided simulation of possible scenarios in terms of achieving optimal thermal performance, showed positive results. The house indeed demonstrates good performance in the wintertime, similar to that of appropriately insulated contemporary housing. It was discovered that in the summertime, the combination of different architectural elements (*divanhana*, deep eaves, pavilion type of layout, gardens and courtyards, massive walls) and techniques (cross ventilation, night-time cooling) contribute to the thermal comfort of the house. These architectural elements and techniques have the potential to change the face of contemporary Bosnian architecture, if utilized properly. Seeking the lost connection with vernacular architecture means re-establishing the most natural way of living, the one in tune with the natural environment. Including vernacular passive elements into contemporary designs is expected to contribute in achieving more energy efficient and comfortable lifestyle while paving a new way to sustainable architecture in Bosnia and Herzegovina.

5. ACKNOWLEDGMENTS

Conducted research and study wouldn't have been possible without the advice, support, and kindness of professors and other professionals that have provided essential advice and made the access to much needed data possible. Many thanks go to friends and family for all the encouragement of efforts made by authors while conducting this and other research. The authors would like to thank to all the staff of Svrzo's House Museum, Federal Meteorological Institute in Sarajevo and Commission to Preserve National Monuments of Bosnia-Herzegovina that facilitated their time and efforts in order to provide much needed information and access to facilities.

Solar Control in Traditional Architecture, Potentials for Passive Design in Hot and Arid Climate

Wael A. Yousef Mousa, MA.[a] **Werner Lang, Prof. Dr.-Ing.[b]**

[a/b]*Institute of Energy Efficient and Sustainable Design and Building, Technical University Munich, Germany*

ABSTRACT

This paper is a part of a research work that targets the evolution of traditional architectural features to develop a passive design strategy for contemporary buildings. It counts on the building as a self-climate modifier in hot and arid climate. The traditional house demonstrates awareness of solar geometry and heat transfer mechanisms as basic physical principles which govern the heat gain/loss process within the building. The work in this paper is confined to examining the effect of traditional solar controls and shading mechanisms. Discussed features are the resulted cross shading in narrow street canyon and window screens. The suggested features were introduced as shading devices to an existing contemporary building within consecutive simulations using TRNSYS 17. The climatic data for Cairo as a case study was considered. The simulation model was tested against indoor temperature and validated by comparing results to measured data. The model then was modified by introducing suggested features which found to be comparatively effective in lowering the indoor temperature.

INTRODUCTION

An abandon of studies showed that the basic principle of traditional building was to accomplish a couple of goals; fulfill privacy; and achieve comfort. These purposes were fulfilled through a passive design strategy applied within urban setting, building form, and building envelop. The analysis identified some key components and other subsidiary elements. The main common aspect is the duality of nature of these key elements through which both thermal comfort and privacy were achieved. This paper focuses on the role of shading systems; street cross shading; and window screens, on reducing indoor air temperature in hot and arid climate regions with reference to the Egyptian capital Cairo.

Cairo is located on 30.0566° N, 31.2262° E in the North East side of the African continent. As most of the countries in its region, Cairo is characterized by a typical hot and arid climate that receives an average annual sum of 3000 hrs. Air temperature exceeds 40º C in the summer, **as shown in figure 1**. The climate in general is characterized by large diurnal temperature differences which allow intense solar radiation during the day and quick cooling down at night. These characteristics impose special considerations upon building design and the urbanization process in general, especially with regards to the solar geometry. The direct solar radiation intensity is up to 814-930 W/m2 on the horizontal surfaces. Solar radiation is direct and strong during the day, but the absence of clouds permits easy release to the heat stored during the daytime, in the form of long-wave radiation towards the sky during night-time (Fathy, 1973). The solar radiation on horizontal surfaces reaches the highest range in June; 7.45 KhW/m²/day in Cairo. Egypt receives an average between 5.4 and 7.1 kWh/m² of annual daily direct solar radiation, **as shown in figure 2**, from north to south (Robaa, 2006).

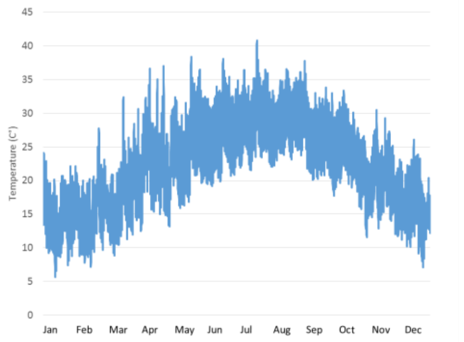

Figure 1 Daily temperature chart for Cairo

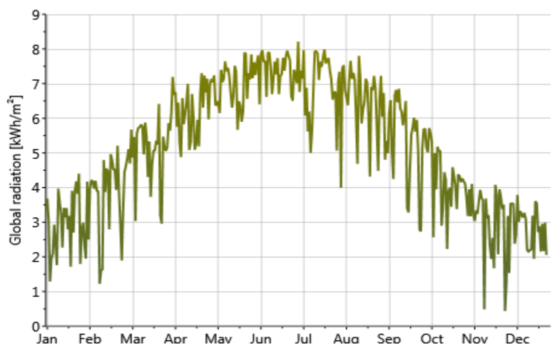

Figure 2 Daily global radiation chart for Cairo (source: Meteonom 7)

Determination of the daily and annual sun path is essential to calculate the solar intensity of radiation hits the building (Hausladen, de Saldanha, & Liedle, 2006). It also helps to predict the resulted shadows and hence the placement of shading devices (Datta, 2001). A stereographic projection of the sun path shows both angles of altitude and azimuth as a diagram for the sun path which can be applied to each latitude. **Figure 3** shows the sun path diagram for Cairo, the sun position at 15:00 hrs. in April 24, the period during which measurements took place for this study. The old town is characterized by almost narrow urban canyons with aspect ratio, height to width H/W = 2, **as shown in figure 4**. As the street width is proportional to the building height, the percentage of overshadowing one building by the other, obstruction angle (ɵ), remains constant for different building heights (Bansal, 1994).

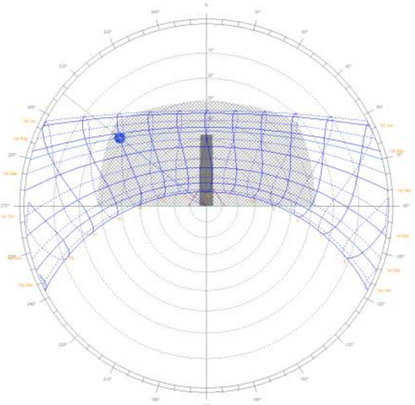

Figure 3 Stereographic projection of sun path, Cairo at 15:00 hrs. in April 24

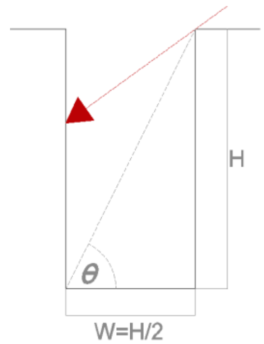

Figure 4 Building shading in relation to aspect ratio

Some recent studies focused on the influence of cross shading, orientation, and proportions of the street canyon on temperature differences. The following results were observed: a study focused on street canyon cross shading concluded that air temperature in the narrow urban canyon (H/W = 2) decreases by 4 °C compared with the wide urban canyon (H/W = 0.5) because of the lower solar gain in summer. A latitude of 33°N, EW street orientation can achieve shading of about 30% for an 8-month period in a year, with aspect ratio, H/W 2:1 or higher. The ratio 0.5:1 is least effective even with NS street orientation, less than 35% street shading (Bourbia, Awbi, 2004)

In 2006 Georgakis and Santamouris showed that ambient temperature above the canyon is found to be higher than the temperature inside the street with maximum of 5°C (Georgakis, Santamouris, 2006) The duration of solar radiation incident on both the east and west facades simultaneously was less than 3 hours in a traditional narrow canyon. The NS street orientation for H/W = 1.5:1 and higher can result in street shading between 40 to 80% of street area, whilst diagonal street orientations NW–SE (S2, S3) and NE–SW (S5, S6), can only manage street shading between 30 to 50% of street area throughout the year.

Studies have proved that incorporating overhangs depending on the different mean azimuth angles for summer and winter direct sunshine decreases the thermal gain through the building. For vertical glazing shaded by horizontal overhangs facing south, the rate of heat transfer into the building was 75 Wm² lower than unshaded windows, for June 21 (Askar, Probert, and Batty, 2001). It has been proven that the use of window screens in hot climates reduces the cooling loads and the perforation ratio of the screens influences the inside temperature. Simulations were applied to screens on west, south, east and north facades and an ultimate ratios were proved as achieving the highest rate of energy saving. Proposed ratio between the width and depth was 1:1 with an 80% perforation in the west and north orientation and 90% in east and south. In comparison with non-shading windows, the energy savings resulted from the use of these screens reached 30%, 30%, 25% and 7% for the west, south, east, and north orientations. (Sherif, El Zafarany, and Arafa, 2012).

METHODOLOGY

The methodology of implementation of this paper was to test the indoor air temperature of an existing contemporary building which adopts the modern construction method prevailing in Cairo. The selected case study was intended to compromise the major opposites to the suggested features which would be introduced to the simulation package in TRNSYS to compare results with those of the base case and hence determine the extent to which those features can influence the indoor temperature. In order to validate the model generated in TRNSYS, in-site measurements took place within a certain timespan, which were then compared to the simulation results that found to be quite identical.

Case Study

The selected case is located on the eastern borders of Cairo within a residential quarter in the district of Heliopolis called the Sheraton Housing Area. **Figure 5** shows a satellite image of the site. The monitored case exists in the first floor of a nine-story residential building on a ground floor area of 310 m². Each floor consists of two identical apartments with an area of 135 m². The main façade is south-west oriented on a main street with 75 m. and a central green area, **shown in figure 6**. The building is a concrete structure and its walls are of hollow red bricks with density of 1790 kg/m³, thermal conductivity 2.1 kJ/hmk, and specific heat 840 J/kg.C according to the Egyptian code for Buildings. Windows are 6mm. single clear glass with aluminum frames and all doors are made of wood. Parquet timber flooring is applied to the monitored case. The monitored room, shaded in the floor plan, **figure 7**, is the main living area of the western apartment in the first floor. The room is overlooking the main street through a relatively wide window 6 m², about 54% of the wall with no shading device. The case shows a lack of any cross shadings from opposite buildings except for the building facing the north east façade.

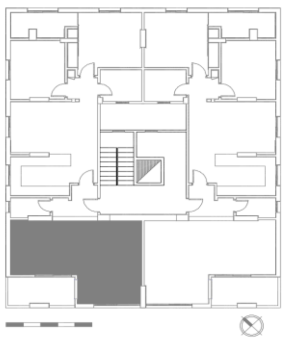

Figure 7 Floor plan

Table 1. Building description

Item	Description
Location	Eastern borders of Cairo
Building type	Residential
Ground floor area	310 m²
Wall material	Hollow red bricks
Skeleton	Concrete
Wall thickness	10-20 cm
Slab thickness	12-18 cm
Windows	6 mm. single clear glass with aluminum frames

Table 2. U-value of material

Material	W/m²K
External wall (solid red brick 20 cm. and 2 cm. plaster	1.82
Internal wall (solid red brick 10 cm. and 2 cm. plaster	2.65
Internal floor (concrete slab 18 cm. and massive wood floor)	0.71
Roof (concrete slab 12 cm with stereo-pore insulation and tiles)	0.45
Glazing (6 mm. single glass)	5.6

Measurements

Filed measurements took place for indoor air temperature of the selected room for one week long from the 18th to 25nd of April using temperature data loggers hanged from the ceiling of the space on a height of 1.7 m. To get more plausible results, two data loggers were installed in the room, one facing the window directly overlooking the street and the other facing the balcony **as shown in figure 8**. A temperature data logger was as well placed outside in the balcony to get real ambient temperature records. The data loggers used are HOBO U12-012. According to the manufacturer, the measurement range of the loggers are -20° to 70° C and 5% to 95% RH. The accuracy of the loggers is ± 0.35° C from 0° to 50° and ± 2.5% from 10% to 90% RH. The loggers were set to continuously take readings each 10 minutes. The space was vacant and totally closed during the measurements periods and no cooling system operated. The results of the field measurements are **shown in figure 9**.

Although the selected period is not the best to represent the hot climate of the region, it was quite adequate for validation of the simulation model that should be tested against real measurements. Moreover, a comparatively high temperatures which reached a maximum of 38° C were recorded, which closely matches the hottest summer days. The weather data for Cairo was obtained on daily basis during the measurements period and a week before from the NOAA (National Oceanic and Atmospheric Administration). The obtained data included hourly records which were subsequently used to create a weather data file that was given to TRNSYS to run the simulation. Some differences were traced between the values of the measured ambient temperature, especially for the minimum values, and those of the obtained weather data which found to be 4° C less in average **as shown in figure 10**. This could be attributed to the differences between both sites of measurements as the weather data is obtained from the weather station that installed in Cairo Air Port in a totally open spacious and un-urbanized area. This is quite different from the site in which the readings were recorded; within relatively dense urban fabric in which the measured temperature should be influenced by the heat island effect and the heat released from the buildings during night-time cooling.

Simulation Package

As the main concern of this stage was to validate the capacity of the simulations by comparing their results to those of the real in-site measurements, a model of the selected case has been created and all related data was given to TRNSYS 17. A 3D model was created by TRNSYS 3D, **as shown in figure 11**, and the previously mentioned construction materials and their thermal properties, **as shown in tables 1 and 2**, were entered in TRNSYS Build. Simulation has run for the selected timespan and five days before upon the created weather data file. Initial values for indoor temperature was set to 21° C and relative humidity to 50%. A comparison then was carried out between the simulation results for indoor temperature of the selected room and the measured values.

Figure 11 Model of the case study created by TRNSYS 3D tool

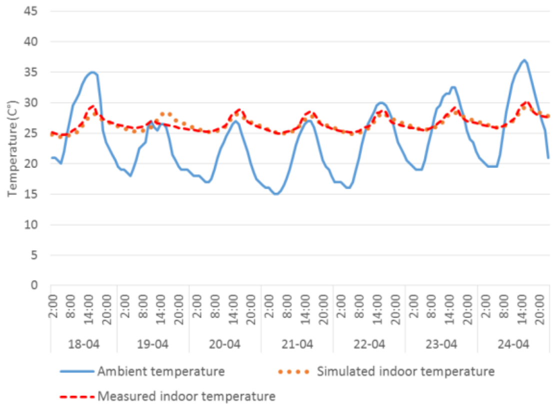

Figure 12 Simulation results for indoor temperature against measured data

The results, **shown in figure 12**, demonstrate remarkable conformity between both profiles of measured and simulated indoor temperature which reaches a maximum of 30° C and a minimum of 25° C in both cases. As described above, the space was closed all along the measurements period and hence no ventilation or infiltration rates were applied. This might explain the relatively narrow gaps between maximum and minimum temperatures as it limits the chances for the occurrence of effective night-time cooling. Ventilation and the role of wind velocity can be discussed within subsequent paper that focuses on the role of the courtyard, as the work of this paper is confined to discussing the shading devices and the response to the solar factor.

Experiments

The main objective of this paper is a preliminary examination of the effect of the traditional shading methods on indoor air temperature in hot climate. As long as simulation results for the basic case were found to be similar to the measured data values, experiments could take place by incorporating the suggested features into the created model and hence results could be compared to those of the basic case to assess potential influences. Two major experiments then took place as follows:

Narrow Street Canyon, Cross Shading. The old traditional city was always characterized by dense urban fabric and narrow streets that generally form deep narrow canyons with average width of 7 cubits. This formation resulted in subsidiary streets which are almost east-west oriented being shaded along the day. The case studied in this paper represents an extreme opposite to this situation with a street width of 75 m., which supposedly played a significant role in the relative high indoor temperature. According to the west-south orientation of the main façade, it would be then exposed to the direct solar radiation especially from the middle of the day on.

This experimental step proposed a building opposite to the main façade and as the same height as the monitored building, leaving a street width of 6m, which creates a relatively deep narrow street canyon with aspect ratio much over 2. Although the case of adding a building in front of another is unlikely to happen within existing urban settlement, this experiment is applied to demonstrate the effect of narrow street canyon cross shading if being considered within urban development that take place in the future. It was added as a shading device in TRNSYS 3D model, **as shown in figure 13**. An updated shading matrix was then generated in TRNSYS Build and the simulation has run as the same as the basic case in terms of period, material properties and other parameters. The results showed a significant decrease in indoor temperature that averages 4° C when compared to the values taken from simulation of the base case, **as shown in figure 14**.

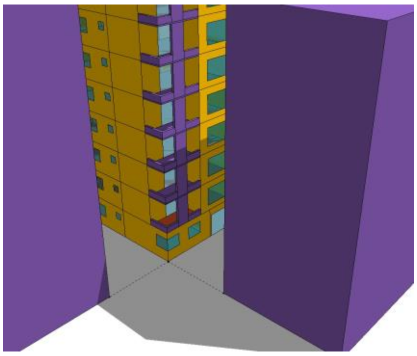

Figure 13 A building opposite to the south-west façade added as a shading device

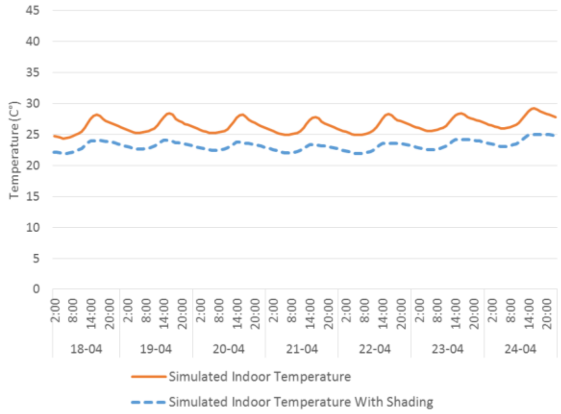

Figure 14 Simulation results for Indoor air temperature with cross-shading compared to base case

Window Screens. Another shading device was added which is a window screen. The screen was incorporated to the window on the south-west façade. The window occupies an area of 6 m², about 54% of its wall. The screen was designed with modular sections of 5x5 cm. with proposed ratio between the width and the depth 1:1 and 50% perforation, **as shown in figure 15**. The resulted exposed glazing surface was then 19%. The simulation has run with new shading matrix generated and without opposite building. The results showed also decrease in maximum indoor air temperature with average value of 2.5° C, **as shown in figure 16**.

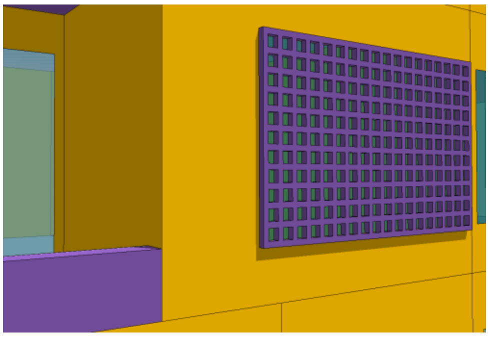

Figure 15 A window screen incorporated on the south-west façade

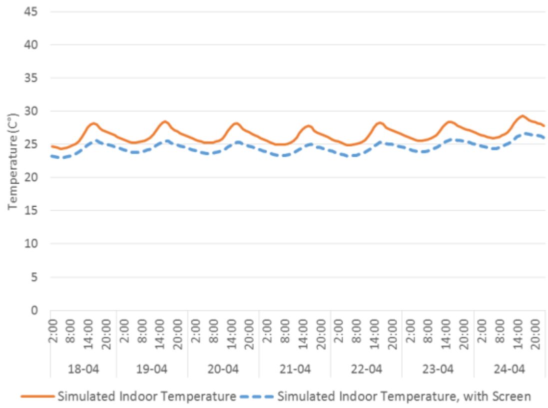

Figure 16 Indoor air temperature after adding a window screen compared to basic case

DISCUSSION

It is quite relevant that the first case in which an opposite building exists is found to reflect better thermal performance, **as shown in figure 17**, this could be attributed to a couple of factors. First is that the entire façade is shaded by the opposite building not only the shaded proportion of the window. Hence the transmitted solar radiation into the space would be significantly reduced, **as shown in figure 18**. The second factor is the role of resulted reduced outdoor temperature of the street and hence the façade temperature. In this case when the sun hits the surface of a building in a street canyon, convective current results as the air density changes the hot air moves to the upper level and be replaced with cooler air which has greater density, **as shown in figure 19**. The exposure of gap to the night sky enhances the night time cooling since the heat radiates up to the sky. The street is cooled down during night and daytime unless the sun is coming on a vertical angle. However, this could be discussed within a following paper.

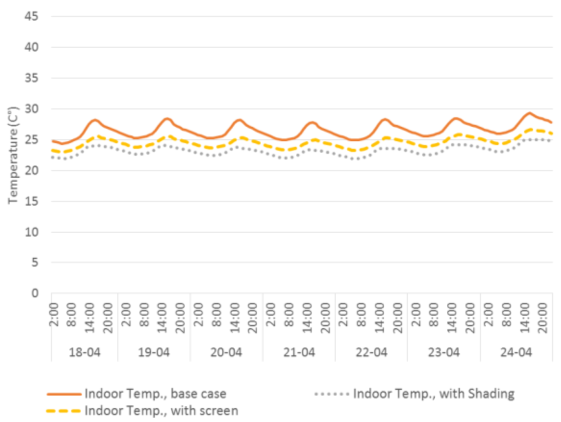

Figure 17 Comparison between the three situations

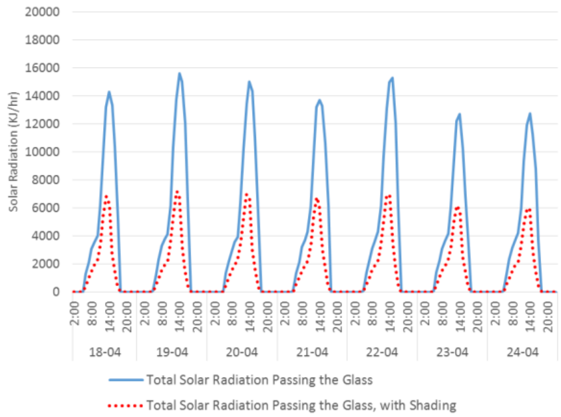

Figure 18 Total solar radiation transmitted through the glass; with and without a shading

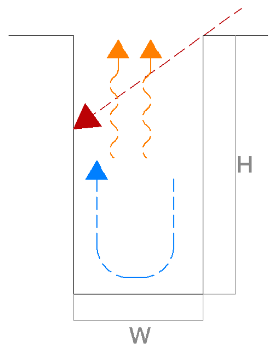

Figure 19 Convective current in street canyon

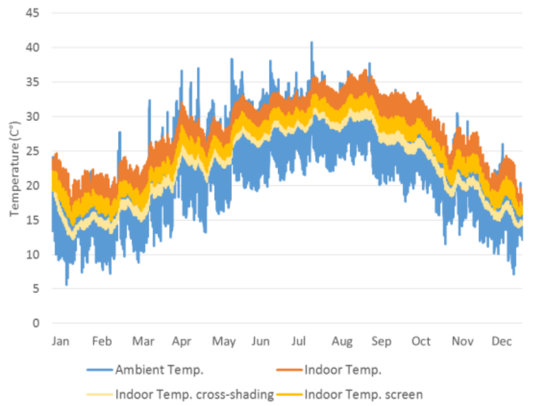

Figure 20 Annual profile for indoor temperature comparing base case with both suggested cases

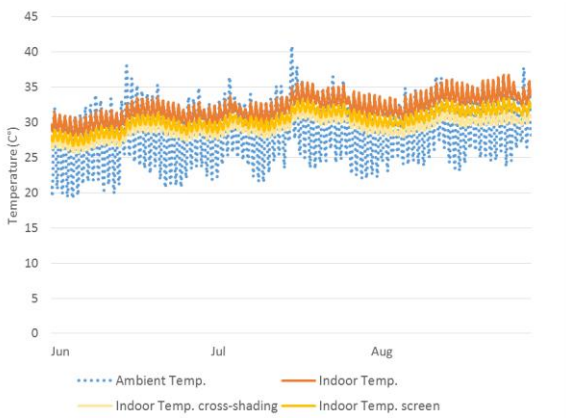

Figure 21 Summer profile for indoor temperature

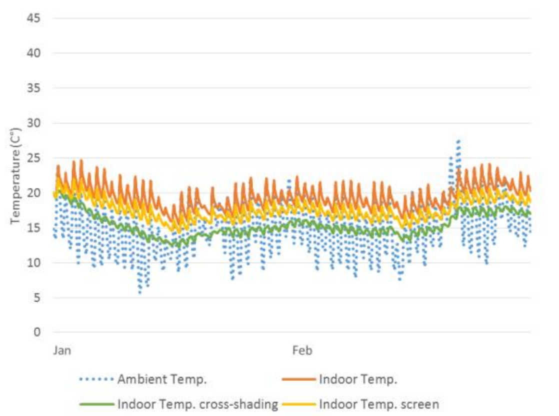

Figure 22 Winter profile for indoor temperature

To predict the performance of the suggested features during the hottest summer days, simulations have run for the base case to a year time span, **figure 20**. The same experiments were applied upon yearly weather data and a relative differences were found for maximum temperature in both cases within summer days in July and August, **as shown in figure 21**. In winter days however, the case of cross shading condition showed comparatively dramatic decrees in indoor temperature during January, **as shown in figure 22**. As the length of shadow on a wall surface can be determined, in relation to solar geometry, by horizontal and vertical shadow angles, **as shown in figure 23**. The decrees of indoor temperature could then be attributed to the position of the sun being too low in the sky and the opposing building that would almost block the radiation that would not reach the lower floors which remain shaded all the time, **as shown in figures 24 a-b**. However the window screens would be less effective in winter due to the limited shading resulted by the angle of the sun beam, **as shown in figures 24 c-d.**

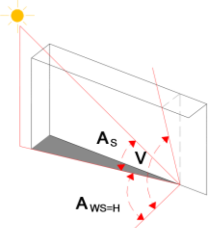

Figure 23 Shadowing angles

CONCLUSION

Solar control was achieved within the old city on both levels of urban density and building envelop. The orientation of main roads in the old town is north-south; however the secondary streets of the residential quarters are east-west oriented. The buildings as a cluster therefore are shading each other. The amount of shading depends mainly on the morphology of the street canyon which results in decrease in the canyon temperature and hence the façade temperature and subsequently the amount of heat transferred by conduction through the walls. The incorporation of window screens also contributes to lower the indoor air temperature in hot and arid climate. The screen acts as a baffle zone between the interior and the exterior, so the glare of sunlight is broken up by the lattice that provides a dark area. By introducing both techniques to a contemporary building by running simulations using TRNSYS it is found to be relatively effective in reducing maximum indoor temperature in hot weather. However, the suggested features can be more efficient when applied within future researches considering convective current resulted in narrow street canyons and the role of cross ventilation in night-time cooling.

ABSTRACT

Land scarcity and rising population in developing countries, particularly in the urban parts of Asia, has led to limited livable floor area for domestic mass housing. Developing countries with similar climate and cultural background face common challenges with their comparatively larger population resulting in high-rise housing. While this may be a solution to accommodating the increasing density in many cities, issues relating to cultural preservation, vernacular architecture conservation, social structures, environmental comfort and sense of community are often in contradiction with this urban solution. In particular, with for a rural community with different characteristics to an urban intent, the transition might prove stressful. In Brunei Darussalam, encouraging living both on water (in Kampong Ayer) and on land is what is being currently proposed. However, as its population is rapidly increasing and living on land is becoming increasingly popular, in this paper, the authors question if the housing developments on the water in Kampong Ayer, promote a sustainable community. The authors explored if waterside housing development, modelled on traditional settlement patterns, can provide a viable solution for rural housing in parts of Brunei. Domestic and communal relationships of its inhabitants were defined to identify sociospatial patterns of a sustainable community. Findings include the correlations between the formal and spatial organization of the home and patterns of occupation.

INTRODUCTION

The modernisation of rural communities into the urban ones may have many benefits in theory, but over time and with population growth, this tends to develop limitations. This is largely due to incompatible solutions imposed on these communities, resulting in their inability to adapt to them. To move forward, it is necessary to take a few steps back and examine vernacular architecture for a better understanding of how communities lived independently and built their own houses (Oliver, 1969). In as much as vernacular architecture in housing has often been associated with squatters and illegal settlements such as the favelas in Brazil, these self-built houses frequently offer insights into community spatial requirements. Indeed, learning from the past can encourage a stress-less human adaptability process (Roaf, 2010).

The Kampong Ayer, or ‘Water Village’, located in Brunei's capital city Bandar Seri Begawan, houses around 39,000 people in self-built homes on stilts that form a unique architectural heritage that has been occupied for over 1300 years. Thirty years ago, the ‘discovery’ of the urban poor’s ingenuity in building their own houses generated a significant amount of research interest and subsequent literature (Ward, 1982). Similarly, studies that covered the technical performance of this type of housing, such as thermal comfort, were undertaken separately. However, it is suggested that a combination of both technical and socio-cultural issues would be more effective (Evans, 1980). For instance, while the performance studies into technology developed to combat climate change have been successful, the technological capability of the community to fully utilise such technology is questionable (Hyde, 2008). It is suggested that the compatibility of technical and social solutions with regards to managing the urban poor needs to be in accordance with the local habits and preferences of the people (Labaki and Kowaltowski, 1998). Often we are unsure of what these local habits and preferences are. Nonetheless, a typical place that reveals such information is the house. As such, perhaps the first step towards understanding rural communities is to examine the role of the house and appreciate its significance to the community (Waterson, 1990). Gaining a deeper appreciation and understanding of the meaning and perpetual variables encapsulated in the house by examining patterns of daily domestic activities can give a clearer explanation of how it came to be rather than the end product itself (Rapoport, 1969).

Developing countries with similar climate and cultural values face common challenges with their comparatively larger population and often resort to high-rise housing. Brunei Darussalam, with a relatively small population of fewer than 400,000 people, has a less urgent agenda but equal concern for the sustainability of its future housing. In 1910 the attempt to relocate some residents of Kampong Ayer (around 10% of the total population) into housing estates on land began. However, as its population continues to grow and living on land becomes increasingly popular, a tailored sustainable housing approach for communities living on water may be needed to preserve and sustain Kampong Ayer. As the majority of the residents who reside there are low-income earners, it is of even more importance to resolve its housing issue (Sullivan and Ward, 2012).

In this paper the authors present an investigation into the evolution of spaces, from the 1950's to the present day, of six houses in Brunei Darussalam, by analysing the daily life patterns registered on the floor plans of each house using a system developed by the authors. As there is limited detailed evidence of the daily activities, which occurred in the houses historically, it was not be possible to make any definite comparisons. Therefore, most of the work described in this paper was based on the actual findings from the field investigations.

Background

According to the Brunei Malay Technology Museum, 1989, there are five basic house types found in Kampong Ayer. Of these, the plan layout of two houses, 'Tungkup' and 'Berlanggar', best showed similarities to the case study houses, as they bore a strong resemblance to the current houses (Fig. 1). These simple open plan layouts suggest a communal use of gathering space as is typical of Malay houses found in the Malay Archipelago region. Typical characteristics of this house type were considered to create a datum for this discussion. In reference to a typical Malay house (Fig. 2), it is suggested that the floor plans demonstrate its multi-functional purpose, influenced by the time of day and year, minimal physical partitioning and furniture, and with most activities utilising the floor (Lim, 1987). Physically, the interior spaces are not defined by walls and are instead distinguished by differences in floor levels, varying floor sizes, orientation and location.

METHODOLOGY

The houses were randomly selected and the house owners' were each required to sign a study participation agreement. Of the houses investigated, house 1, 2, 4 and 6 were found to have more traditional layouts, whereas house 3 and 5, built in the last four years, were found to have a 'modern' layout (Fig. 3). A summary of the characteristics of each house is given in Table 1. The investigation involved having the house occupants mark occupancy charts for each room in their houses, so as to map the frequency of and time when the rooms were occupied. The information marked on these charts showed the most commonly used rooms in the house as well as the number of people occupying the room at hourly intervals throughout the day, for period of 4-6 weeks.

Additionally, using Tinytag data loggers, the recording of internal temperature and relative humidity of the four most occupied rooms in each house was conducted simultaneously. To shed more light on the results of the occupancy investigation, interviews (partly based on findings from initial results of the study) with the house owners were undertaken. In addition to this, a survey was carried out with the intention of giving a general view on the living conditions of the people in Kampong Ayer. Some results from this survey as related to the selected houses are discussed later.

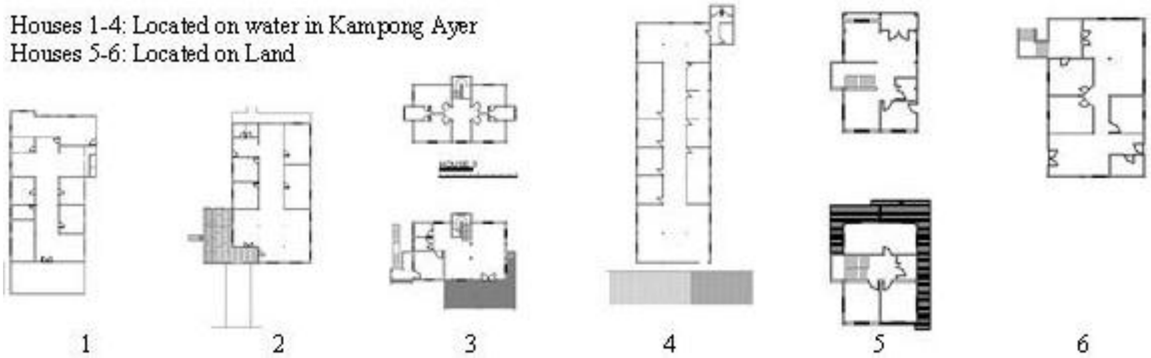

Figure 3 House plans of six houses (Source: House 1, 2, 4 & 6 from authors; House 3 & 5 from Public Works Department and Housing Development Department, Brunei Darussalam, respectively).

Table 1: Brief Descriptive Comparison of the Six Houses

HOUSES	1	2	3	4	5	6
Number of people living in the house	4	5	14	15	6	4

Number of families Living in the house	1	1	2	3	1	1
Self-build / New build	Self-build	Self-build	New build	Self-build	New build	Self-build

OBSERVATIONS

Sleeping arrangements were found to depend on the number of people living in the house and number of bedrooms available. For households with sufficient bedrooms, everyone was assigned to a group sleeping area. For instance, for a typical family living in a three-bedroom house, the parents shared a bedroom, while groups of the male children and female children had a room each. Babies and younger children often share a room with their parents whereas young male and female children can share a room only if there is no other room. Segregating the children at an early age is partly influenced by the Islamic religion - the main religion practiced in Brunei Darussalam. Often, in deciding who gets a bedroom, female children are given priority over male children. Such was the case in House 3 where a family of fourteen living in a four-bedroom house allocated rooms in the following manner: Bedroom 1 – parents; Bedroom 2 – three daughters; Bedroom 3 – eldest daughter, her husband and their two young children; Bedroom 4 – second eldest daughter who is engaged to be married (her future husband will share the room with her); Living Room - three sons (one son sleeps in the communal space in the bedroom lobby at night). It was found that an insufficient number of bedrooms compelled families make use of other rooms in the house for sleeping, commonly the living room or family TV area. The bedrooms have beds while the living room or family room will have mattresses on the floor, which are rolled up and put away during the day.

Areas for sharing meals varied in all six houses. House 1 had a dining area next to the kitchen area, used for the main meals. On the other hand, House 5 had a dining table in an area separate from the kitchen, which was also used for main meals. House 2, 3, 4 and 6 each had a small table in the kitchen where the families could gather at mealtimes. Sometimes this involved moving furniture to accommodate everyone. Occupants of House 1, 5 and 6 had all their meals at their table at regular times of the day, whereas occupants of House 2, 3 and 4 had irregular meal times with some meals taken in different parts of the house such as the family TV room. With the exception of House 3 where the head the family occasionally used meal times as an opportunity to hold family discussions, it was noted that meal times were viewed mostly as a time for eating instead of dialogue. In addition to providing space for informal dining, the kitchen was used for cooking and as such its floor area is sufficient to accommodate just this. Also, the kitchen is usually modified to accommodate kitchenware storage and large freezer units. As fresh meat is not readily available, families bought in bulk to store until the next shopping trip in the city.

Common to all six houses was the popularity of the family TV area as the main gathering zone for family members. This took place mainly in the evening, after dinner and the last prayer of the day, at around 8.00PM. Rarely used for informal family gatherings, the living room is mostly used to receive guests. During special occasions and events involving many guests, all the communal areas in the house are occupied to accommodate everyone - including in the corridors. Furniture is moved to create more open spaces and carpets are rolled out on the floor for guests to sit on. As with the sleeping arrangements, females and males tend to group separately further highlighting gender segregation in spatial use, as is influenced by Islam.

Traditionally, the front of the house has an outdoor area, the veranda, which is used for less formal gatherings or as an introductory area before entering the house. Usually, this is the first area to be renovated so as to extend the living room area. As a small roof or a large over-hanging roof already covers this space, it requires only three external walls, windows and a new entrance to do so. This newly extended room is commonly utilised as a living room or small shop (Fig. 4). In House 4, the existing living room is large enough to accommodate a small shop indoors (Fig. 4). However, the extension option was found to be more common possibly due to occupants wanting to keep indoor areas inaccessible to the public.

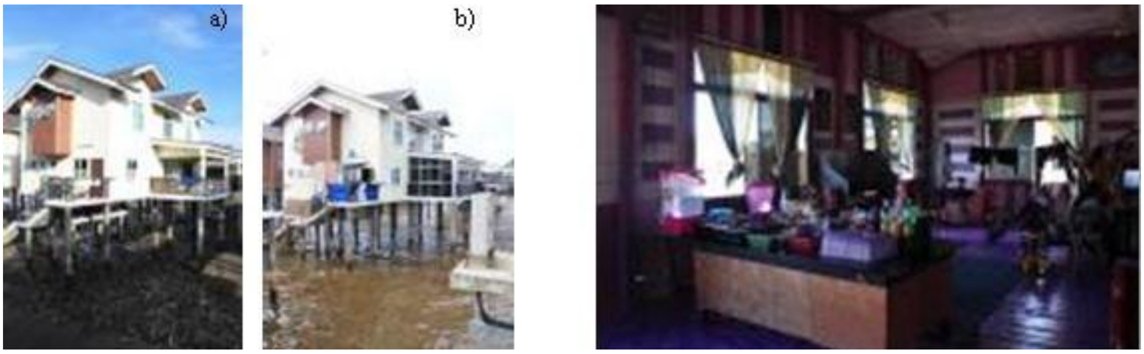

Figure 4 Left: House 3 before and after conversion of the veranda into a shop (a) December 2012 (b) January 2014. Right: Showing the living room in House 4 that has been modified to accommodate a small shop (Source: Author).

RESULTS FROM THE OCCUPANCY INVESTIGATIONS

Tables 2 and 3 show some results of the occupancy investigations. Table 2 reveals the bedrooms and the family TV room to be the most frequented spaces. Specifically, a large duration of the time spent in the bedrooms is spent sleeping (between 9.00PM and 5.00AM) but is also occupied for short afternoon naps and performance of daily prayers during the day. As was highlighted earlier, the family TV area is occupied more frequently than the living area as it is less formal and allows the families to gather there to rest, watch TV and carry out a variety of activities. Also shown is the amount of time spent in other areas in each house where/when each family conducts other daily activities.

Table 2: The Most Frequently Occupied Rooms in Each House

House	Three Most Occupied Rooms in Each House with Percentage of Occupancy (On average in a day) As recorded between 6th January 2014 to 13th February 2014					
	1		2		3	
1	Family TV	71%	Bedroom 2	67%	Dining	67%
2	Bedroom 1	92%	Family TV	71%	Bedroom 2	63%
3	Bedroom 1	100%	Bedroom 3	100%	Family TV	100%
4	Living	100%	Family TV	100%	Kitchen	100%
5	Bedroom 2	100%	Bedroom 3	100%	Bedroom 1	92%
6	Bedroom 1	100%	Living	96%	Family TV	88%

To get an indication of the thermal comfort conditions in the houses, the temperature and relative humidity measures of selected rooms in each house was recorded. As the houses are located within the warm-humid climate zone, discomfort is more likely to be as a result of relatively high temperatures and relative humidity levels. More often than not, the main means of relief for occupants in this climate is air-movement for physiological cooling (Koenigsberger, 1974). As is typical of the Malay House, the more traditional houses were found to be structurally responsive to the climate through the provision of lightweight construction (to prevent storage of heat in the fabric), large window openings to enhance cross ventilation and air-movement as well as wide overhangs/eaves that act as sun shading elements. Some of the bedrooms had air-conditioners - only used occasionally during the night. Thermal discomfort during this time was suggested to be due to the increased number of occupants within the spaces. While the more recently built houses feature fewer passive cooling controls, it is suggested that structural modifications, such as indoor partitions have contributed to inefficiency in maintaining comfort naturally. Also, as these houses were more compact in plan, their layouts have significantly reduced the opportunities for, and efficiency, of natural cross-ventilation. Additionally, the results from the recordings were matched against the CBE Thermal Comfort Tool for ASHRAE Standard 55-2010 to determine whether any of the readings were within the predicted thermal comfort zone. Table 3 presents a snapshot of recordings taken a selected typical day – temperatures that fall within the standard are highlighted.

Table 3: The Internal Temperatures/RH levels at 2.00AM, 10.00AM and 6.00pm intervals for three most frequently occupied rooms in each house as recoded on 1.02.2014 (where available).

House	Rooms	Internal Temperature ^{o}C and Relative Humidity %		
		2.00 AM	10.00 AM	6.00 PM
1 (on water)	Family TV	-	-	-
	Bedroom 2	-	-	-
	Dining	30^{o}C / 63.9%	27^{o}C / 77.1%	31^{o}C / 66%
2 (on water)	Bedroom 1	22^{o}C / 71%	22^{o}C / 71%	22^{o}C / 57%
	Family TV	25^{o}C / 86%	25^{o}C / 86%	28^{o}C / 75%
	Bedroom 2	25^{o}C / 87%	25^{o}C / 92%	30^{o}C / 65%
3 (on water)	Bedroom 1	19^{o}C / 59%	22^{o}C / 91%	26^{o}C / 80%
	Bedroom 3	-	-	-
	Family TV	25^{o}C / 64%	26^{o}C / 77%	27^{o}C / 78%
4 (on water)	Living	-	-	-
	Family TV	25^{o}C / 86%	27^{o}C / 77%	28^{o}C / 73%
	Kitchen	25^{o}C / 88%	26^{o}C / 85%	29^{o}C / 72%
5 (on land)	Bedroom 2	-	-	-
	Bedroom 3	-	-	-
	Bedroom 1	27^{o}C / 73%	27^{o}C / 78%	27^{o}C / 74%
6 (on land)	Bedroom 1	27^{o}C / 79%	27^{o}C / 78%	29^{o}C / 67%
	Living	26^{o}C / 83%	28^{o}C / 73%	29^{o}C / 68%
	Family TV	-	-	-

Although most of the readings shown fall outside of the thermal comfort zone of ASHRAE Standard 55-2010, it is suggested that the use of structural controls (large fenestration, orientation, space volume, floor area and in some cases mechanical ventilation) and self-adjustment mechanisms helps to make existing conditions tolerable. At first glance, the readings from the houses located in the water have lower temperature readings than the houses on land. It is suggested that this is as a result of the micro-climate conditions. As the surrounding 'ground' area the houses on water is less likely to retain heat, then it is less likely for the houses to absorb heat via radiation/reflection from the ground surface, as might be the case in the houses on land. During the study it was found that external temperature levels taken in both areas showed those on land to be higher than for that of the houses on water. However, the extent to which the comparison of water and land ground surfaces and their influence on the thermal comfort in the houses will require further investigation to reach a more valid conclusion.

RESULTS FROM THE SURVEY

Results from the survey regarding the houses revealed some information about the renovations of these houses (Fig. 5). A majority of the participants taking part in this survey, live in timber houses on water, and have at some point made renovations and extensions to their house - most of which are self-built and constructed with timber. Some have integrated other materials including brick and steel. Employing contractors or foreign labourers to build the extensions is becoming increasingly popular too, which is subsequently diminishing the timber-building skill amongst the local community.

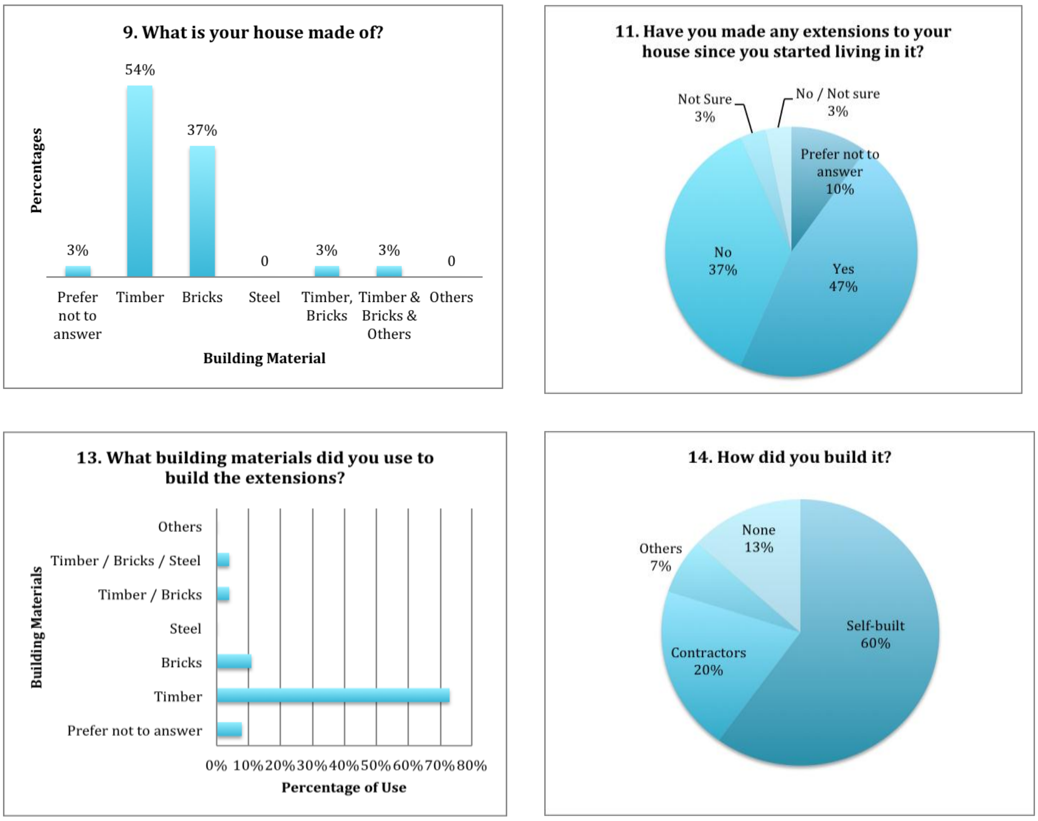

Figure 5: Results of Part: House; Questions 9, 11, 13 and 14.

DISCUSSION ON OBSERVATIONS AND RESULTS OF INVESTIGATION

For houses with larger families, limited sleeping areas and gathering areas leave occupants with the need to utilise other areas of the house for these activities. The living and family TV areas are normally used for sleeping by the older single male members of the family with the priority of occupation of bedrooms given to the married couples and female family members. This indicates a type of hierarchy within the families which is distinctly determined by age, gender and marital status.

It is suggested that the nature of ‘gathering’ has evolved due to the size of the kitchen. Traditionally, the open floor plan of the houses accommodated all household activities. All family members would gather in this open area where they would - together or in their own time - rest, sleep, pray, eat and talk. There was rarely any furniture in these houses and everyone sat on mats/carpets on the floor, which also helped to define space. This was useful during big occasions as they were able to fit large numbers of people in the communal areas of the open interior. In contrast to the set up in the houses today, internal walls and furniture have compromised the previously free-flowing nature of house and reduced its flexibility. While bedrooms are off limits to guests and visitors, all communal parts of the house are used; as such, furniture is often shifted to give an open space. The traditional way of gathering is still favoured and practiced in some houses in Kampong Ayer. The daily family gathering space in traditional open layouts was only ever in one space. In the current layouts the gathering area consists of two spaces; the living area (mainly for receiving guests) and the family TV area (for casual family gatherings). How often the living area was used depended on how frequently they had guests. The family TV area is mainly for watching television, meaning less interaction amongst family members.

From a structural viewpoint, traditional houses in Kampong Ayer, with their open plans and minimal internal partitions, were able to enhance the cooling effect of natural ventilation with the light, constant breeze flowing freely through the houses. Nowadays, the houses, and more so those on land, have evolved into complex layouts with more internal wall partitions. Although this gives more visual privacy within the house, opportunities for efficient natural cross ventilation may be compromised. Renovation of the veranda into another room may have also compromised the advantage of utilising it as a heat buffer. Nonetheless, despite the results from the internal temperature and relative humidity recordings showing that most of the conditions were outside the prescribed thermal comfort range, occupants still managed to feel comfortable with the minimal help of fans/air-conditioning units as a result of using existing passive controls.

With self-building skills becoming less popular in Kampong Ayer, the locals are seeking expertise elsewhere. Not only is this more expensive, but it also means that the ‘sense of community’ that is tied to self-help/self-build is disappearing. This can have a dramatic effect on the sustainability of the water village, as a huge part of their resilience in the past centuries has been through community cooperation. As most of the houses in Kampong Ayer today are originally self-built, its design intent stems from the house owners own desires and necessities. The contents of the houses and the modifications made to the houses over time are clear indications of the constantly changing life stages of each family. The flexibility of the houses in allowing the house extensions and renovations to suit the families’ changing structure has allowed them to remain comfortable in the same houses for many generations (Friedman, 2011).

As has been suggested in numerous other studies, the design of climate responsive houses is often ignored when developing mass-housing proposals and may be dominated by cost, availability of land and population as is common in the aforementioned high-rise typologies. Also, it has been noted that sociocultural issues tend to influence the occupancy and morphology of their houses. It has been suggested that more suitable approach would be to examine both technical and socio-cultural factors side by side so as to derive an approach that would lead to the future development and maintenance of sustainable communities in Brunei Darussalam effectively.

CONCLUSION

Communities usually survive most environmental challenges they face; as long as the adaptability period and means to adapt is within its capability and that there is cooperation amongst the community members to achieve a joint goal to survive. However, some challenges that prove to go beyond the community’s resilience can result in a defeated end. The people living in Kampong Ayer appear to want to continue living there as they have adapted well despite the challenges imposed on the village, such as scarcity of local materials, economics or employment. Their undeniably strong sense of independence and individuality, apparent in the make up of their houses, shows confidence in their spirit to be sustainable. However, the extent of their resilience is yet to be determined. There are certainly other factors influencing the sustainability of such a community, some of these may be future threats. On that note, this paper opens doors to investigate what the limits are to this community’s sustainability in this context.

How effective are ‘close to zero’ carbon new dwellings in reducing actual energy demand: Insights from UK

Professor Rajat Gupta, PhD

rgupta@brookes.ac.uk

Mariam Kapsali, MSc
OISD, Oxford Brookes University

ABSTRACT

In the UK, zero carbon will be the standard for new homes from 2016 and non-domestic buildings by 2019. However, it is increasingly recognized new buildings use at least twice the energy predicted by energy models and this gap is relatively poorly understood, thereby risking contravention of zero carbon policy. Yet there is relatively little understanding within policy and wider industry of what might be causing this gap.

This paper investigates the actual energy demand reductions achieved in three ‘close to zero’ carbon social housing developments in UK, through a systematic approach comprising building performance monitoring and post-occupancy evaluation of six case study dwellings over 1.5 years. The six case study houses cover a variety of built forms and different types of construction systems with similar occupancy profiles within the same development.

Findings from the first year of monitoring show that the actual energy use in the case study houses exceeds their design predictions by a factor up to 3. CO_2 footprint across the six houses differ by a factor of nearly 2 in some cases despite all the developments being designed to Code for Sustainable homes level 4 or 5. Consistently high indoor temperatures (>25^{o}C) are observed in the majority of the dwellings both in living rooms and bedrooms. Other issues include lack of user comprehension of mechanical ventilation and heat recovery (MVHR) systems and air source heat pumps, resulting from poor guidance during handover and inadequate commissioning of these systems.

To ensure that such low energy houses perform as intended, seasonal commissioning of services and systems is essential. Occupants need to be trained through graduated handover, supplemented by visual home user guides offering advice on using energy systems and controls. Otherwise there is a risk that UK Government’s zero carbon housing policy may get undermined.

INTRODUCTION

The UK government has passed a legally binding framework to reduce the country’s carbon emissions 80% below 1990 levels by 2050 (UKGBC, 2008). Zero carbon will be the standard for new homes from 2016 and non-domestic buildings by 2019. However, there is a growing concern within the housing industry that, in practice, even current energy efficiency and carbon emissions standards are not being achieved (Gupta and Gregg, 2012). It is increasingly recognized that there is a gap between actual energy use in building and the energy predicted by models (Gupta et al, 2013; Bell et al, 2010). This performance gap may undermine zero carbon housing policy and carry considerable commercial risk for the wider industrial sector (Zero Carbon Hub, 2013). Yet there is relatively little understanding within policy and wider industry of what might be causing this gap.

Rajat Gupta is Professor of Sustainable Architecture and Mariam Kapsali is a Research Associate in the Oxford Institute for Sustainable Development (OISD), School of Architecture, Oxford Brookes University, Oxford, England.

Research on the performance gap in the housing sector highlights the need for measuring fabric performance and reviewing the commissioning of services and systems (Wingfield et al, 2011), (Zero Carbon Hub, 2013; Gupta et al, 2013) but also points out the effect of occupant behaviour and understanding (Firth et al, 2008; Steemers and Yun, 2009; Gill et al, 2010).

This paper investigates the performance gap in six case study dwellings across three ‘close to zero’ carbon social housing developments in the UK. A Building Performance Evaluation (BPE) based forensic approach is adopted to evaluate the location and extents of the performance gap for these projects, followed by an in-depth analysis of the empirical findings to reveal the causes of the discrepancies. Findings reveal that fabric performance, installation and commissioning, usability of controls, occupant behaviour and understanding play an important role in influencing housing performance and are the root causes behind the performance gap.

BUILDING PERFORMANCE EVALUATION METHODOLOGY AND CASE STUDIES

Building performance evaluation (BPE) is the process of identifying and locating the gas between ‘as designed’ and ‘in use’ performance through a systematic collection and analysis of qualitative and quantitative information related to energy performance, environmental conditions, fabric performance and occupant feedback. The project is part of the National Building Performance Evaluation (BPE) programme funded by the Technology Strategy Board, the UK Government’s innovation agency. The programme involves both domestic and non-domestic buildings and aims to help the construction industry deliver more efficient and better performing buildings (TSB, 2012).

The six cast study dwellings are part of three exemplar social housing developments (A, B and C) located in South East England). The six case studies (two per development – A1, A2, B1, B2, C1 and C2) were selected to represent a variety of built forms and construction systems with similar occupancy profiles. Table 1 presents the background characteristics of the case studies and Table 2 presents an overview of their design specifications and construction details. Understanding the extent and location of the performance gap in these studies helps to identify ways to address the gap.

Table 1. Case Studies Information

	Development A		Development B		Development C	
Case study reference	Case A1	Case A2	Case B1	Case B2	Case C1	Case C2
Area	94 m²	94 m²	88 m²	123 m²	128 m²	146 m²
Typology	2 bed,mid-terrace	2 bed,mid-terrace	3 bed, end-terrace	4bed, mid-terrace	4 bed, mid-terrace	5bed, detached
Occupancy patterns	24h	24h	15:00-8:00	24h	13:00-8:00	13:00-8:00
Occupants	2 adults, 2 children	2 adults, 2 children	2 adults, 2 children	4 adults, 1 baby	2 adults, 3 children	1 adult, 5 children

Table 2. Design Specifications and Construction Details

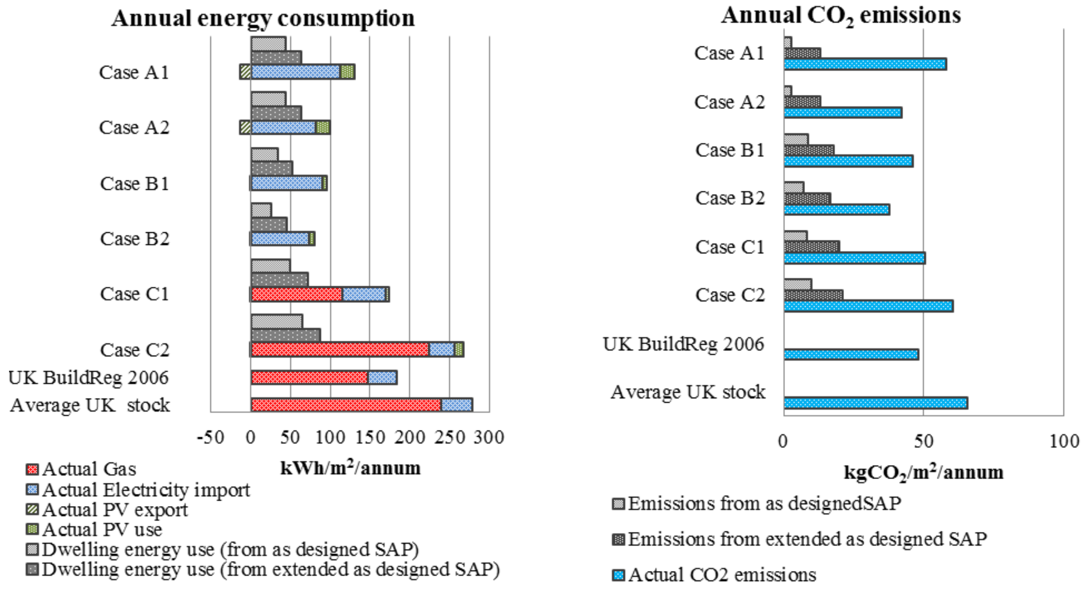
	Development A	Development B	Development C
Construction type	Timber frame with cast hempcrete	Steel frame with pre-insulated panels	Timber frame and brick
Target design rating	CSH Level 5	CSH Level 4	CSH Level 4
As designed U-values W/m²K	Walls 0.18 Windows 1.4	Walls 0.15 Windows ≤1.2	Walls 0.21 Windows 1.3
Space heating and hot water system	Exhaust Air Heat Pump (EAHP), underfloor heating, solar collectors	Air Source Heat Pump (ASHP), underfloor heating, immersion heater back up	Gas condensing boiler with radiators
Ventilation strategy	MVHR through EAHP	MVHR	MVHR
Renewables	4kWpk Photovoltaics	1.5kWpk Photovoltaics	1.65kWp & 1.88kWp Photovoltaics

ACTUAL ENERGY USE

Monitoring data for energy consumption are provided for the period from January to December 2013 as shown in Figure 1. Comparison of actual energy use with 'as designed' SAP[1] predictions reveals big discrepancies between them in all cases. These discrepancies are partly due to the fact that SAP does not cover all end uses of energy in dwellings. To overcome this, SAP predictions were extended to include electricity for lighting and appliances and energy used for cooking. Actual annual energy use exceeds the extended SAP prediction by a factor of 2 in Cases A1, A2, B1 and B2, by a factor of 2.5 in Case C1 and by a factor of 3 in Case C2. Actual annual CO_2 emissions are even higher compared to the extended SAP prediction in all cases. Cases A1 and A2 present the highest discrepancies, exceeding the values of the extended SAP model by a factor of 4.5 and 3 respectively. This is due to the houses being electrically heated.

Cases A1 and A2, although designed for CSH Level 5, consume more electricity than Cases B1 and B2 that have been designed for CSH Level 4. This is partly due to the low COP of the EAHPs in Cases A1 and A2 that has been measured to 1.4 instead of the design specification of 2.6. The design COP of the ASHPs in Cases B1 and B2 is 3.13. Cases C1 and C2 have a similar performance to a typical UK house, despite being designed to CSH Level 4.

There is also significant variation in the energy consumption of houses within the same development designed to the same standard and with similar occupancy patterns (Table 1). In Development A, occupants in Case A2 keep their thermostat at 19^oC and are more energy conscious than their neighbours who keep the thermostat between 25-27^oC. Occupant expectations and control over heating resulted in the annual CO_2 emissions and actual energy use of Case A1 being higher than that of Case A2 by a factor of 1.3. In Development B, annual CO_2 emissions and actual energy use in Case B1 are higher than those of Case B2 by a factor of 1.2 as a result of poor occupant understanding of the ASHP that led to reduction of the system's efficiency. The highest energy consumption is observed in Cases C1 and C2. Annual energy use of Case C2 exceeds that of Case C1 by a factor of 1.5. In both houses occupants set their thermostats as high as 30^oC throughout the day, but in Case C2 occupants tend to leave the windows open day and night even during winter (Figure 4) thus increasing the heat loss and the heating demand.



a) b)

Figure 1 (a) Comparison of actual energy consumption and (b) comparison of actual CO_2 emissions with SAP predictions and Extended SAP prediction across all cases (January – December 2013). Emissions factors: Electricity 0.445 $kgCO_2/kWh$, Gas 0.184 $kgCO_2/kWh$ (Carbon Trust, 2013).

[1] The Standard Assessment Procedure (SAP) is the methodology used by the UK Government to assess and compare the energy and environmental performance of dwellings.

CAUSES OF PERFORMANCE GAP

Fabric performance

The fabric performance of each housing development was forensically assessed using in situ U-value tests, air permeability tests and infrared thermography. The common emerging issues across the three developments are summarized in Table 3.

Table 3. Common emerging issues highlighted by evaluation of fabric performance

	Development A	Development B	Development C
Heat loss through party walls	×	×	
Heat loss through external walls	×		
Heat loss through window and door frames	×	×	×
Thermal bridges (thresholds, ceiling beams)	×	×	×
Actual U-values higher than design	×		
Loft insulation not well distributed		×	×
Actual air-permeability much higher than design	×	×	×

Wall insulation levels were found to be good in all cases. The findings from the in-situ U-value tests showed that in Developments B and C actual wall U-values are similar or even better than those specified at the design stage. However in all cases, thermographic images revealed heat loss and air leakage paths through door and window frames, cold spots in walls and thermal bridges across thresholds. Thermal bridges through ceiling beams and heat loss through party walls were also identified. This has implications for better detailing of joints and juctions by designers and careful implementation by contractors.

Air permeability tests revealed a noteworthy gap between 'as designed' and actual air-tightness in all case studies. All dwellings missed their design target (2-3 $m^3/m^2.h$) with air-permeability in most cases being twice as high as designed as shown in Figure 2. Such high values (5-6 $m^3/m^2.h$) question the actual need for an MVHR system since these have been specified for more airtight homes usually having air permeability below 3 $m^3/m^2.h$. Better air-tightness would have resulted from high quality detailing at key junctions, skirtings and service penetrations and careful workmanship around door and window thresholds and seals.

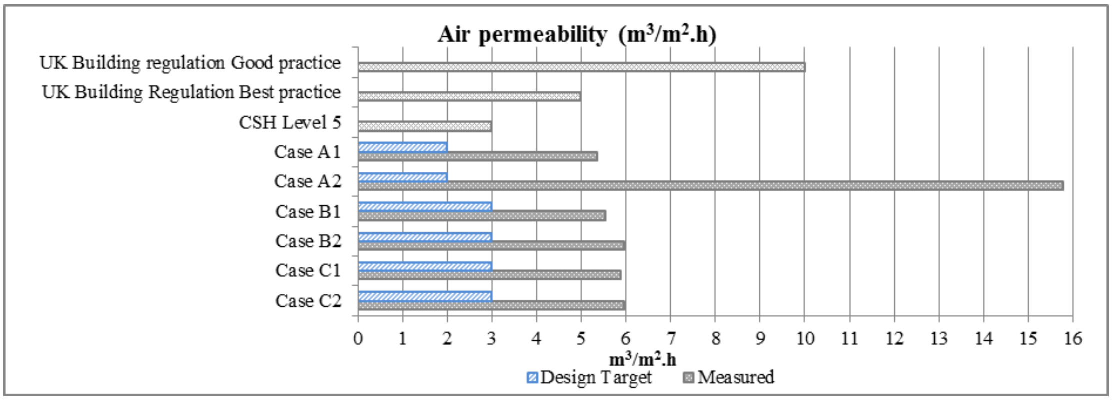


Figure 2 Comparison of measured and design air permeability.

Installation and commissioning of systems and services

A commissioning review is undertaken to ensure that the services and equipment's commissioning are complete and the design and operational strategy was capable of creating the desired performance and comfort.

The MVHR system installation and commissioning was found to be the most problematic issue in all six houses due to the developers' lack of experience with such systems. Improper commissioning and system imbalances were noted in all cases, breakdowns were reported in Cases B1 and B2, noise and cold draughts were reported in Cases C1 and B2 respectively. System imbalance due to poor commissioning and occupant intervention leads to increased heat loss and heating loads, increased energy use of the MVHR unit, system resistance, noise and cold draughts. In some cases (C1, C2) occupants had completely shut the supply terminals thus seriously undermining indoor air quality.

Commissioning of heating controls and room thermostats was also found to be problematic in Developments A and B. In Development A, commissioning check before the move-in revealed that the room thermostats had not been properly connected. In Development B, the wireless room thermostats had not been properly connected to the heating system resulting in the heating being constantly on leading to energy wastage. This was discovered during the study several months after the move-in following occupant complaints of lack of control over heating and of rooms being too hot. Poor commissioning of heating controls results in increased energy use and makes occupants skeptical of the low carbon technologies installed in the houses.

Usability of control interfaces

A review of the control interfaces investigates the relationship between the design and usability of controls and the potential effect they could have during the dwelling's occupancy (Bordass et al, 2007). Table 4 summarizes the key issues that emerged from the three developments.

Table 4. Common emerging issues highlighted by review of control interfaces

	Development A	Development B	Development C
Conflicting control strategies	×	×	
Oversimplified control interfaces	×		
Overcomplicated heating controls and zoning		×	
No indication of MVHR failure or maintenance	×	×	×
MVHR unit inaccessible, located in loft		×	×
Windows and doors intuitive, good fine control		×	×

Heating controls and thermostats were found to be problematic in Developments A and B. In Development B the designers' intention to provide occupants with good levels of control resulted in an excessive use of over-designed thermostats and zones that confuse occupants and complicate commissioning. On the other hand, oversimplified controls like the ones used in Development A, lead to similar results. Unclear, oversimplified or complex control strategies have a negative impact on energy use due to poor occupant understanding and control.

Provision of usable and accessible MVHR controls was an issue for all cases. The MVHR units in Developments B and C are not easily accessible as they are located in narrow loft spaces that hinder maintenance. In most cases, boost buttons do not provide an indication of system response and MVHR units do not give an indication of failure or maintenance. Poor control over ventilation and poor maintenance can lead to increased energy use of the MVHR unit and can also have a negative impact on indoor air quality and occupant comfort.

Handover process and user guidance: communication of design intent

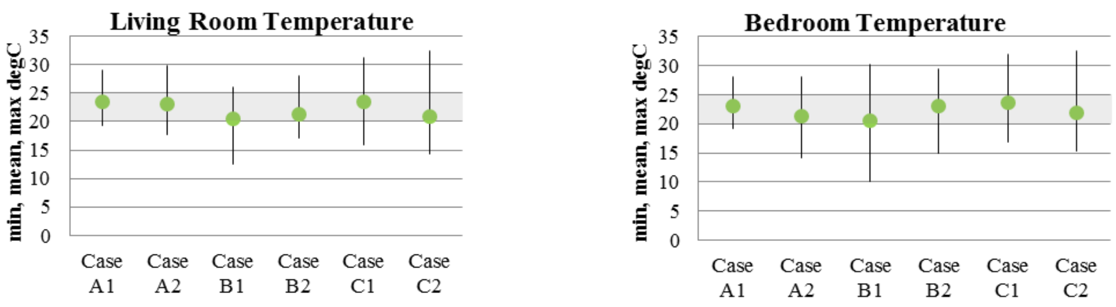
The handover homeowners receive before moving into their new home was observed and the documentation was reviwed to establish whether the information provided is sufficient in communicating the intent and operation of the new home without being overly technical or confusing.

The findings reveal that a phased approach, such as those followed in Developments A and B, is more successful for the handover. However, it would have been more beneficial if the handover also included discussion on the handover documentation (User Guide and O&M manuals) and hands-on application by the occupants. In Development C no phased approach was followed as the handover was completed in a day. Significant risk has been identified regarding the amount of information the occupants can absorb on the day of the handover. The review of Home User Guides showed that the guides generally contain extensive technical details, instead of providing occupants with clear guidelines on how to make better use of systems on a daily and seasonal basis.

Despite the differences in the handover process and guidance documentation, follow up conversation and interviews with occupants revealed that in all three developments some occupants have failed to understand the purpose and operation of the low carbon systems or have forgotten the information that was provided to them initially. Lack of occupant understanding is one of the reasons leading to higher energy use and poor performance of systems. This raises questions about the quality of the handover and the need for retraining the occupants.

Occupant expectations and satisfaction

Occupant behaviour and expectations. Internal temperature data (January – December 2013) reveal that demand temperatures in the houses are high as shown in Figure 3. This is closely related to occupants' high expectations of comfort. Overall temperatures are high with five out of six houses having mean living room temperatures above 21^{o}C and three out of six houses having a mean above 23^{o}C. Peak temperatures above 27^{o}C were also observed in the majority of the houses (five out of six). Bedroom temperatures present a similar trend with five out of six houses having mean bedroom temperatures above 21^{o}C. Cases A1 and C1 have the highest mean temperatures as the occupants use a lot of heating energy by keeping their thermostats around 25-27^{o}C throughout the day. In Case C2 occupants also keep their thermostat very high throughout the day (30^{o}C) but mean temperatures are around 21^{o}C because occupants keep their windows open for many hours during the day (Figure 4), thus leading to the high gas consumption shown in Figure 1. This level of demand is leading to a gap between design prediction and actual consumption in terms of both energy use and environmental conditions.



a) b)

Figure 3 Mean, minimum and maximum temperatures in (a) living rooms and (b) bedrooms (January – December 2013).

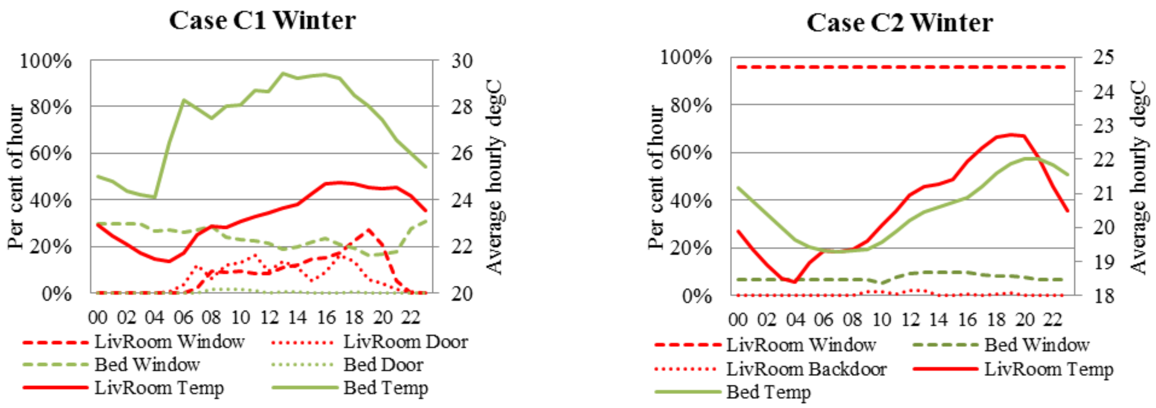


Figure 4 Hourly average temperatures and hourly percentage of window opening across a day (November – April) in Case C1 and Case C2.

Occupant surveys, interviews and walkthroughs. Occupant satisfaction surveys were carried out in all three developments using standardized occupant satisfaction questionnaires (BUS). Additionally, semi-structured interviews and walkthroughs were carried out with the occupants of the six case studies using the same templates. Table 5 summarizes the positive and negative occupant feedback from the survey and occupant interviews related to contols, comfort and satisfaction with space.

Table 5. Common emerging issues highlighted by occupant survey and interviews.

	Development A	Development B	Development C
Positive feedback			
Satisfaction with space and layout	×	×	×
Satisfaction with design and appearance	×	×	×
Satisfaction with light levels (natural, artificial)	×		×
Temperatures good overall	×	×	×
Negative feedback			
Poor control over heating	×	×	
Lack of understanding of heating system	×	×	
Lack of knowledge about MVHR	×	×	×
Poor control over ventilation		×	
Hot during summer		×	
Home User Guide considered complicated.	×	×	
Energy bills considered high	×	×	×

In all developments occupants are fairly satisfied with the appearance, design, layout and space of the houses. Also, daylight levels are appreciated in most cases. Most negative feedback involves the operation and control of the heating and MVHR system. Control over heating is considered problematic in Developments A and B that feature heat pumps and underfloor heating as occupants are not well familiar with such technologies and find the Home User Guide confusing. Control over ventilation is also considered problematic in most cases due to occupant confusion about the operation of the MVHR system. Moreover, energy bills are high in all houses althought all three developments designed to reduce energy use. Occupants in Developments A and B are very unhappy with their electricity bills which they attribute to the poor performance of the heating system. In Table 6 actual electricity and gas bills are between 3 to 20 times higher than the SAP estimated energy costs.. The combination of many new technologies, unfamiliar to both the occupants and the developers and owners, led to confusion and dissatisfaction in most cases.

Energy use in houses depends heavily on the occupants' perception of comfort and their attempts to attain comfortable conditions. Thermal comfort satisfaction is closely linked to the level of understanding and control over the heating and ventilation system. Resolving the issue of comfort and control effectively and understanding occupant expectations through follow-ups and training are essential for closing the performance gap and achieving better environmental conditions.

Table 6. Comparison of actual bills with SAP estimated costs and UK typical domestic energy bills

Cost (£)	A1	A2	B1	B2	C1	C2	UK typical [2]
Predicted (SAP) cost	70	70	330	336	259	315	
Electricity bills	1,440	1,200	1,300	1,100	700	960	424
Gas bills	-	-	-	-	720	1,500	608
Actual total cost	1,440	1,200	1,300	1,100	1,420	2,460	1,032

CONCLUSION

Using a mixed-methods socio-technical BPE approach, this study has identified the reasons for underperformance of 'close to zero' carbon new dwellings. The study has revealed that the actual energy use in the case study houses exceeds design predictions by a factor up to 3. Furthermore, actual energy use across the six case study houses varies by a factor 1.6, despite all the developments being designed to CSH Level 4 or 5 and having similar occupancy profiles. Fabric performance, commissioning of systems, usability of controls and occupant understanding and expectations increase the gap between actual and design performance. Discrepancies in fabric and system performance may result from difficulty of communicating design intentions and expectations, specification error or omissions and construction errors. Such issues could be avoided through rapid diagnostics onsite and better

[2] Typical UK domestic energy bills and consumption figures based on average household bills (Ofgem, 2011)

communication between all stakeholders. Installation and commissioning is clearly an area where increased training and awareness and checks will have a large impact on improving the performance of dwellings. In order to improve commissioning and maintenance developers and constructors need to ensure that their technicians receive adequate training. Seasonal commissioning also needs to be encouraged for houses with technologies such as heat pumps and MVHR systems.

The study also highlights the need for a detailed and coordinated services layout plan showing location of systems and controls that will help to solve issues of accessibility and will provide the basis for a clear strategy that the occupants need to follow. Combination of clear design intentions, intuitive and responsive control mechanisms and good occupant guidance and training will ensure better use of systems and increase the potential for energy reductions and improvement of environmental conditions. Findings indicate the need for graduated handover that involves hands on application by occupants, supplemented by visual home user guides offering clear guidance on the daily and seasonal operation of systems and controls. Guidance must be customized according to residents' background and abilities.

Learning from real-world case studies is an insightful way for understanding the reasons behind the energy performance gap in order to achieve low carbon housing in practice. This requires a formalized briefing, commissioning and feedback protocol, such as 'Soft Landings' (BSRIA, 2009), that has started to be used in domestic projects. This will help to ensure that these lessons are captured and fed back to the developers, constructors and designers. Otherwise there is a risk that UK Government's zero carbon housing policy may get undermined.

ACKNOWLEDGMENTS

We are grateful to UK Government's Technology Strategy Board's Building Performance Evaluation (BPE) programme for sponsoring these BPE research projects. Our sincere thanks also to occupants, client and project design teams for their help and support during the study.

A quiet revolution: Mapping energy use in low carbon communities

Professor Rajat Gupta, PhD

rgupta@brookes.ac.uk

Matt Gregg, MSc
OISD, Oxford Brookes University

ABSTRACT

Recent Government funding in the UK has enabled 22 low carbon community organisations to work with the private and academic sector to understand and reduce energy consumption in domestic and non-domestic buildings. This has helped communities prepare for policy mechanisms such as the national Green Deal programme which aims to improve existing housing and non-domestic buildings by offering up-front loans to be repaid by energy savings. This paper presents the role and application of a unique carbon mapping approach, which has enabled five of these low carbon communities to rapidly assess on a house-by-house level, the potential for improving the energy efficiency of their housing stock. DECoRuM, an award-winning GIS-based carbon counting model is used to measure, model, map and manage energy use and CO_2 emission reductions from approximately 1,300 houses across five communities, displaying estimates of energy use and carbon emissions before and after community action. Incremental packages of energy saving measures and low carbon technologies are assessed for their impact on CO_2 emissions to reveal further potential for large-scale refurbishment in the local area. Eligibility for the Green Deal is tested to show that on average 72 per cent of homes over all communities are suitable for finance. Through community events, results are visualised and fed back to the householders using colour-coded spatial maps along with thermal imaging. Findings from this study are relevant for policy-making and practitioners engaged in area-based carbon reductions.

INTRODUCTION

The UK is committed to reducing greenhouse gas (GHG) emissions by 80% from 1990 levels. In response to this commitment, the national Green Deal programme has been proposed to offer energy efficiency improvements to homeowners and businesses at little or no upfront cost with payment recouped through customers' energy bills (DECC, 2012a). The Energy Company Obligation (ECO), proposed to work alongside the Green Deal, will similarly support those experiencing fuel poverty and in hard to treat homes. In addition to the Green Deal, recent Government funding in the UK has enabled 22 low carbon community organisations to work with the private and academic sector to understand and reduce the amount of energy that is used in homes and buildings. One such programme, the Low Carbon Communities Challenge (LCCC), focussed on stimulating energy improvements of homes through capital funding of physical interventions to homes and buildings, behaviour change campaigns and low carbon living activities. The theoretical savings from the 8,206 installed measures and technologies for the entire programme is 3,062 tonnes of CO_2/yr (DECC, 2012b).

The Department of Energy and Climate Change (DECC) (2012b) provide an overall qualitative review of the LCCC impact. Gupta *et al.* (2014) applied a measurement, monitoring and evaluation (MME) approach to 88 households across six LCCC communities. Their findings show mixed results in

Rajat Gupta is Professor of Sustainable Architecture and Matt Gregg is a Research Fellow in the Oxford Institute for Sustainable Development (OISD), School of Architecture, Oxford Brookes University, Oxford, England.

terms of energy use across the households depending on a number of factors including the physical and technical interventions, and occupant behaviours and lifestyle. The detailed evaluations also uncovered unintended consequences associated with energy behaviours, such as increased use of washing machines and other such appliances due to 'free electricity' from low/ zero carbon technologies.

Geographical information systems (GIS) provide a platform for presenting findings in an aggregated form which can be visually effective in communicating results to householders and community groups. A number of GIS based studies focus on energy use estimations using a top-down approach. These include using remotely sensed anthropogenic heat to serve as a proxy to derive the spatial pattern of energy use (Zhou et al., 2012) or combining location, demographic and end-use data to enable energy consumption to be calculated and mapped (Pereira and Assis, 2013). In contrast to the above, the present study combines a bottom-up building characteristic data collection approach to estimate energy use and carbon emissions of approximately 1,300 dwellings over five communities, Community A, B, C, and D (anonymised as per communities' request) in England and Wales, combined with a top-down approach to analysis and geographical visualisation. This is demonstrated through the application of urban energy modelling using DECoRuM© (Domestic Energy, Carbon counting and carbon Reduction Model), to rapidly model, map, and measure energy use and carbon emissions on a house-by-house level. The following method calculates the carbon reduction impact of the LCCC and the impact of further carbon reduction measures for the five communities. The work presented in this paper is part of the Evaluating Low Carbon Communities (EVALOC) project which seeks to assess, explain and communicate the changes in energy use due to community activities within selected case study projects under DECC's LCCC initiative.

METHODOLOGY

The following steps are taken to map and assess the energy consumption, carbon emissions, and retrofit potential for the selected communities:

1. Data collection (e.g. home details, local climate data, etc.), modelling and mapping in GIS
2. Assessment of results, e.g., carbon emissions, before the LCCC and after the LCCC
3. Selected carbon reduction / Green Deal packages are applied to the neighbourhood and the results are calculated and mapped

The communities

Table 1 lists the five communities and some further details.

Community	Number of Households	Dominant Built Form
A	311	1930-49 semi-detached
B	242	1966-76 terraced
C	274	Pre-1900s terraced
D	184	Pre-1900s terraced
E	275	Pre-1930s terraced

DECoRuM model

DECoRuM is a GIS-based toolkit for carbon emissions reduction planning with the capability to estimate energy-related CO_2 emissions and effectiveness of mitigation strategies in existing UK dwellings, aggregating the results to a street, district and city level. The aggregated method of calculation and map-based presentation allows the results to be scaled-up for larger application and assessment. The background calculations of DECoRuM are performed by BREDEM-12 (Building Research Establishment's Domestic Energy Model) and SAP 2009 (Standard Assessment Procedure) both of which are dynamically linked to create the model. BREDEM is a methodology for calculation of the energy use of dwellings based on characteristics; it is suitable for stock modelling. It shares some features with the SAP methodology, but allows users to adjust inputs which are fixed in SAP (BRE, 2014). SAP, based on BREDEM is the Government approved method for the assessment of the energy and environmental performance of dwellings. Though not as robust as dynamic thermal simulation, the strength of DECoRuM is in the ability to rapidly process results for many dwellings and present them on an urban scale. The tool is useful for communicating energy related concepts and identifying potential areas for concern and further investigation, including simulation, house assessment and monitoring.

Some limitations include:

- Time required for data collection and entry; home questionnaires are helpful in reducing this initial effort.
- Behaviour related assessment is limited: occupancy times, heating schedules, window opening schedules, etc. are not available. Different scenarios must be calculated separately and cannot vary within a given timeframe; calculations are static.
- The model does not calculate where specifically a homeowner should insulate walls and whether internal or external insulation is ideal (insulation is simply either solid wall or cavity).

Data collection and modelling. In the DECoRuM model, CO_2 emissions are the result of heat loss calculations from fabric and ventilation, estimated energy use from heating, domestic hot water and electricity use as calculated using BREDEM-12. To inform the model, actual house characteristics are gathered from historic and current maps, on-site assessment, home occupant questionnaires, Energy Performance Certificates (EPCs), and literature describing home characteristics based on age and typology. As examples: occupancy, unless known, is calculated from floor area using the BREDEM-12 method; street-facing windows and frames are directly observed but all other unseen windows are assumed to be the same; wall construction and U-values (unless known, e.g. reported in EPCs) are based on the age of the home where construction methods are well documented (e.g. BREDEM reference tables). Verification is performed by calibrating the aggregated results to DECC's *lower level super output area* (LSOA) energy consumption data for England and Wales. LSOAs are zones made up of an average of 1500 residents or 400 households with relative social homogeneity, for which there are gas and electricity consumption figures reported (DECC, 2014a). Use of LSOA data for a similar purpose can be found in Booth and Choudhary (2011) and Williams *et al*. (2013).

Mapping the results. The results for each household are displayed on a map using GIS software; in this instance MapInfo. GIS allows any variable to be mapped for visual communication, e.g. kWh/year, CO_2 emissions/m^2/year, homes in need of cavity wall insulation, PV suitability, etc. Previously, DECoRuM maps have been used by the Grassroots Leads Energy Efficiency community group in Highfield, Bicester to provide residents with energy consumption information and to suggest energy efficiency improvement measures (Gupta and Cherian, 2013), and to present climate change impact and adaptation effectiveness to communities in the SNACC project (Suburban Neighbourhood Adaptation for a Changing Climate (Williams, *et al.*, 2013).

Carbon reduction measures. Previous research by the authors and others has demonstrated the development of mitigation measures and packages, which were found to be effective for similar home typologies (Gupta and Gregg, 2012; DECC, 2014b). This and other research (simulation and building performance evaluation) have demonstrated the effectiveness of specific mitigation measures for CO_2 reduction in homes. These include reduced U-values on building elements, high efficiency boilers, insulating hot water cylinder and pipes, and increased level of heating control. When creating packages, focus on a fabric based package is done to emphasise the importance of implementing fabric first (low tech demand reduction) measures and also due to its (generally) lower capital cost.

MAPPING LOW CARBON COMMUNITIES

Each of the 22 communities, as a part of the LCCC, received grants ranging from £250k - £970k to pay for physical interventions to homes and buildings (90%) and behaviour change activities (10%) (DECC, 2012b). **Table 2** lists the physical measures purchased for households against those which were mapped in DECoRuM. Community scale measures or non-domestic measures, e.g. wind turbines (Communities A and B), PV on community centres and schools (Communities D and E), are not listed because the contribution of these measures are not calculated in the household (demand side) energy consumption modelling of DECoRuM; in addition, LSOA, used to validate DECoRuM, only provides consumption values. With regard to household measures, not all households in the communities received physical measures and not all households that did receive measures are mapped. The impact of behaviour change will likely indirectly come out of the aggregated figure as the aggregated figure is validated by the LSOA, however, the MME method used in Gupta and Barnfield (2013) is essential for measuring the impact of behaviour change activities in detail.

Table 2. Physical Measures Applied to Households in Each Community (DECC, 2012b)

Community	LCCC measures (total households)	Measures (mapped)
A	(0)	PV (9), solar thermal (2) ASHP (2)
B	Cavity wall insulation (125), loft insulation (223), PV (12), solar thermal (6), ASHP (4)	Cavity wall insulation (10), loft insulation (28), PV (3), solar thermal (1)
C	PV (11), solar thermal (4), wood pellet boiler, ASHP (3)	PV (6), solar thermal (4), ASHP (3)
D	PV (53)	PV (53)
E	PV (8)	PV (4), solar thermal (1)

Communities before LCCC action

Occupant questionnaires (requesting specifically when measures were installed), EPCs (pre-2010) and LCCC household details were especially helpful in modelling the communities before LCCC implementation. Though occupant questionnaires or EPCs were not available for each household, these tools served to inform the model with regard to what measures did not exist in many households before the LCCC. Since measures were purchased and installed anywhere from 2010 – 2012, the maps of Pre-LCCC implementation are referred to as *Pre-2010*.

Communities after LCCC action

In the same way, the same tools were used to assess what measures are in place after LCCC implementation. These maps are referred to as *2012*. **Figure 1** shows the Pre-2010 and 2012 results from Community E. *After* the interventions made by LCCC programme in Community E, there is a mean annual CO_2 reduction of 536 $kgCO_2$/yr/household or 12 per cent in the mapped area in 2012. These results can be attributed to LCCC involvement, but not entirely, as not all mapped households were involved in the LCCC.

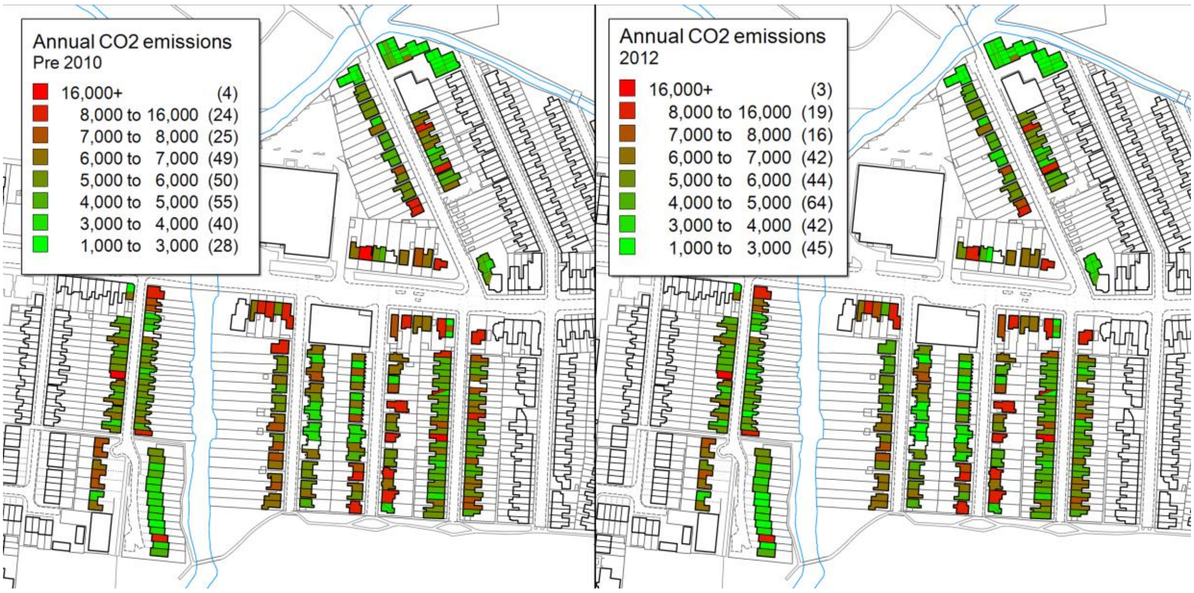

Figure 1 Pre-2010 and 2012 maps of annual CO_2 emissions for Community E.

Table 3 lists the communities and the results from the mapping for these two periods. Aside from other differing factors, Communities A and C are not served by the National Gas Network and are notably higher in annual emissions due to a majority of occupants utilising oil or electricity for heat.

Table 3. Mean annual domestic CO_2 emissions ($kgCO_2$/year) before and after LCCC programme

Community	Pre-2010	2012	2012 City Mean
A	5,969	5,286	Not available
B	4,564	4,046	4,179
C	9,298	7,111	Not available
D	5,753	4,889	4,895
E	4,574	4,038	4,454

Carbon reduction measures and packages

The model filters suitable dwellings for each retrofit measure based on the current (2012) condition of the dwelling, e.g. solid walled homes receive solid wall insulation and insulated cavity walls received no further insulation. Potential energy and carbon reductions are then calculated by the model for each household and then aggregated to realise community level impact. To meet the Government's carbon reduction target, most UK homes will require a package of measures (DECC, 2014b); therefore, the following typical retrofit measures were tested individually and also incrementally packaged. **Table 4** lists the packages that were developed for testing in DECoRuM; all measures are acceptable for Green Deal financing. Lowering the thermostat, a behaviour change measure, was also tested and presented to residents but not packaged. Primarily, the reason for this is that the packages were designed to reflect measures with capital costs so that the packages could be tested for Green Deal finance suitability.

Table 4. Carbon Reduction Packages

Package	Measures
Fabric improvement package	Wall insulation (cavity or solid), loft insulation, floor insulation, double glazing, draught proofing
Fabric and heating upgrade package	**Fabric package** + high efficiency condensing boiler, hot water cylinder insulation, pipework insulation, heating controls
Fabric, heating and electricity package	**Fabric and heating upgrade package** + energy efficient lighting and appliances, photovoltaic system, solar hot water system

An important key driver for refurbishment is capital cost. DECoRuM uses low and high estimates of the capital costs for each measure to indicate a likely range for the cost-effective carbon saving potential (the mean is taken from these two figures). The overall capital cost for community wide implementation of a certain package is calculated, based on the potential of each house within the community. **Figure 2** shows the mean capital costs and energy cost reduction potential for each package in the two most common house types in Community E. The Pre-1930s terraced housing represents 28 per cent of the dwellings in the mapped area and 1930-1949 semi-detached represents 18 per cent.

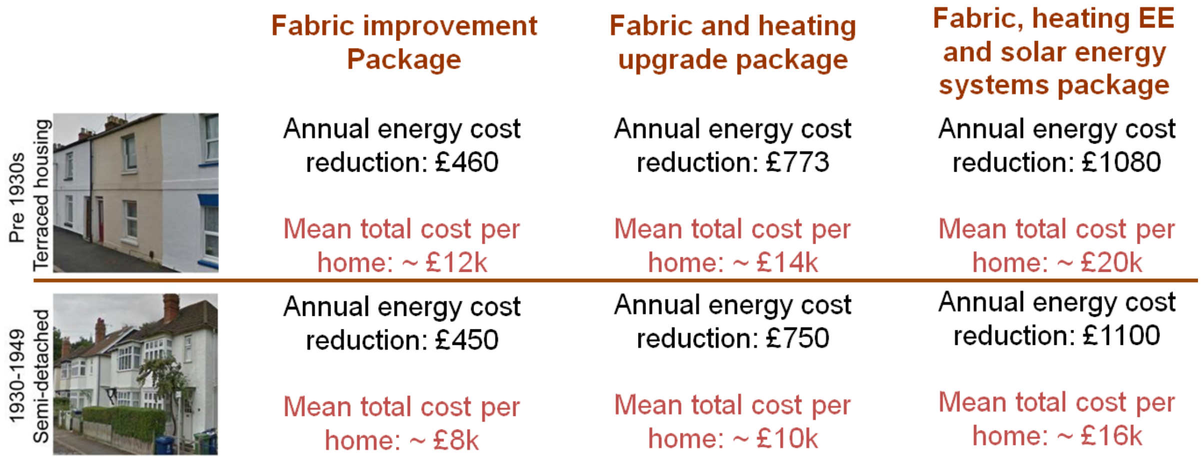

Figure 2 Package capital costs and reductions for Pre-1930s and 1930-49 house types in Community E.

The mean total cost for each home only considers those dwellings which could benefit from a measure in each package, though not all measures in the package need to be applied to qualify for the package in the model. Immediately as is seen in figure 2, Pre-1930s cost more to retrofit. This is attributed to the solid wall exterior of the house type, which will require solid wall insulation. The cost for solid wall insulation for each home is taken from the mean of external and internal insulation. Due to the nature of the data collection, especially where no questionnaires are filled, the model does not have the capability to assess whether internal or external insulation is a better choice for a particular dwelling. Annual cost reductions are a combination of a reduction in fuel costs and feed-in tariff (FiT) and Renewable Heat Incentive (RHI) (paid from April 2014) payments for PV and solar hot water respectively. Differing FiT payments, as per EPC grade, per house, are calculated into the total figure.

Carbon reduction packages and the Green Deal

Each carbon reduction package is then tested for Green Deal finance (theoretical) approval, specifically; will each package meet the *Golden Rule* on a house-by-house level? The Golden Rule is the central mechanism for determining which measures (to complete a package) are able to be financed through the Green Deal. The rule: “Estimated savings must be greater than or equal to repayments.” This, however, is not a guarantee but a calculated intent (DECC, 2012).

DECoRuM has the capability to calculate whether a package will meet the Golden Rule after measures are modelled and energy use reduction and energy cost reductions are calculated. The model calculates whether the annual fuel cost savings are less than the annual payback over the life of the measure(s). **Figure 3** shows the Golden Rule compliance for each package for Community E. As an example, a large portion of the terraced housing in the southeast section of the Fabric Package map do not meet the Golden Rule primarily because the cost of solid wall insulation and new double glazing together is too high in relation to the potential savings. In order to qualify some dwellings will need to consider alternative combinations of measures. It is also important to point out that the cost for solid wall insulation, as mentioned above, is an average fixed cost between external and internal wall insulation; opting for internal wall insulation would likely reduce the capital cost for the overall package. Alternatively, the strip of homes in the northeast section of the Fabric Package map (next to the legend) meets the Golden Rule. Most of these dwellings are 1930-49 semi-detached (**figure 2**) requiring cavity wall insulation, a less expensive measure.

Figure 3 Golden Rule compliance for each package in Community E.

DECoRuM modelling demonstrated a fairly wide range of Golden Rule compliance between the communities (**table 5** – the packages are numbered in the order they are listed in **table 4**). Communities A, B and C, as communities, appear to be easier targets for the Green Deal. Communities A and C specifically have more reduction potential, partially due to the size of the dwellings and the majority using oil for heating. Community B, on the other hand, for the Fabric Package, requires little up-front cost whereas all homes are cavity wall (many already insulated – table 2) and many already have double glazing (the second most costly fabric measure following solid wall insulation). Community D, comprised of 94 per cent solid wall terraced housing, presents a challenge in meeting the Golden Rule for the Fabric Package. Package 3 clearly becomes more difficult due to the cost of PV and solar hot water systems (poor solar orientation is also calculated into the reduction in solar systems impact). FiT and RHI payments do not count toward reduction of savings to calculate the Golden Rule. A dwelling could use the Green Deal finance to install PV and collect the FiT but if a home is performing poorly according to their EPC, e.g. worse than D, their FiT is reduced, thereby encouraging fabric improvement first (or in conjunction). The Green Deal also only covers a portion of the capital cost for PV depending on how much electricity is actually (calculated) used in the dwelling.

Table 5. Percentage of Homes in Each Community Satisfying the Golden Rule (per Package)

Community	Package 1	Package 2	Package 3
A	91%	91%	65%
B	100%	87%	13%
C	84%	79%	64%
D	29%	27%	11%
E	54%	48%	31%

DISCUSSION

Outputs from DECoRuM, maps of estimated energy use and CO_2 reduction potential of individual households, were used to provide energy feedback to householders (on a community level) through workshops, wherein the local community also had access to expert information and advice on taking action to reduce energy use through individual discussions and group presentations. The maps, along with thermal imaging surveys of the houses, used to make energy use visible by highlighting areas of heat loss and potential areas for fabric improvements, gave householders a clear view of the impacts different refurbishment measures and packages have had or may have on the energy performance of their house. The workshops also helped to gather more data from householders (using questionnaires), to further refine the model.

The communities are using the findings from the carbon mapping, along with thermal imaging and the MME studies to inform the householders in the community on effectiveness of work already done and also highlight areas for improvement. The carbon mapping is specifically useful for the community groups to pinpoint areas of high energy use, problem households and promising areas for Green Deal finance. The application of packages, the calculated impact, and costs, as shown through carbon mapping, establishes DECoRuM as a useful tool for Green Deal assessors, local authorities and the low carbon community groups intending to implement large scale retrofits.

It is important to remember that there are many combinations of carbon reduction measures and they do not need to follow the packages as defined in this study. It is likely that many more homes will be able to find a package that will fit their home and meet the Golden Rule. There are also a large number of ‘border line’ cases (houses which almost meet the Golden Rule). This highlights the importance of adopting a holistic approach that includes both technical improvements and behaviour change measures; one which the Green Deal is attempting to provide through energy saving advice (DECC, 2012a). This approach, where effective, would ensure that most of the predicted energy savings are achieved in practice and the Golden Rule will be met.

CONCLUSION

Carbon mapping has emerged as a valuable approach for strategic planning, evaluation and implementation of community and neighbourhood scale domestic refurbishments by rapidly measuring, modelling, and mapping and managing energy use and CO_2 emission reductions on a house-by-house level. Bespoke site specific mapping of current energy consumption and visualisation of the potential for energy savings can enable the uptake of carbon reduction measures. The model can help local authorities, community groups and householders to prepare for future change and policy mechanisms such as the national Green Deal programme and the ECO. The specific area-based approach can serve as a tool to scale-up the uptake of low energy domestic refurbishments, by providing Green Deal providers, local authorities, community organisations and householders with information on the technical and economic feasibility of deploying a suite of best practice refurbishment measures. Findings from this study are also relevant for practitioners and researchers engaged in tracking and assessing impact of large-scale area-based domestic refurbishments and the future effectiveness of the Green Deal after implementation.

Similar work includes the development of DECoRuM-Adapt, a next step for DECoRuM created to assess future climate impact, overheating risk and adaptation measure effectiveness. The assessment of the climate change risk allows for the further evaluation of mitigation measures to optimise the home's refurbishment to be thermally comfortable now and in the future (Gupta and Gregg, 2013). To further benefit research in this area, future work in urban modelling would include analysis of modelling outputs with socio-economic data to track the effect of refurbishments on fuel poverty.

ACKNOWLEDGMENTS

The authors would like to acknowledge the many residents of the neighbourhoods who returned energy questionnaires and allowed us to install temperature and energy data loggers in their homes. Thank you also to Laura Barnfield, Tara Hipwood, Chiara Fratter, and Bob Irving for assisting in the carbon mapping work, workshop presentations and performing the thermal imaging surveys. The research presented here is part of the EVALOC low carbon communities project [grant number RES-628-25-0012] which is funded under the EPSRC/ESRC Energy and Communities stream of Research Council UK's (RCUK) energy programme.

The Impact of Vegetation on Urban Microclimate to Counterbalance Built Density in a Subtropical Changing Climate

ABSTR ACT

The purpose of this paper is to assess the cooling effects of vegetation in urban microclimate, especially during daytime, to counterbalance built density in a subtropical climate. The findings contribute to a land-based mitigation strategy, trying to answer partially what a changing climate will mean for cities facing two mechanisms that can be superimposed: the global warming and the local heat-island effect, in the city os Sao Paulo, Brazil. According to the Brazilian Panel on Climate Change (PBMC), Brazil's climate will be warmer in the coming decades, with a temperature increase in all regions between 1ºC and 6º C by 2100, compared to the records at the end of the 20th century. The paper presents a brief review of planning with high-density and urban greening, having in mind that even low-density land use can contribute to urban heating, depending on the infrastructure development. In high-density cities, the most important vegetation effect is to prevent overheating in urban canyons, decreasing solar radiation absorption by shading and increasing evaporative cooling by the leaves and soil coverage. This way vegetation prevents overheating of buildings and other urban surfaces, contributing to better comfort conditions. Parametric studies exploring different scenarios of high-density urban blocks and greening have been carried out to investigate two different distribution of dense trees (LAI=4,6) to ameliorate urban microclimate using ENVI-met model 4 (preview), previously calibrated with field measurements of local climate and vegetation data. Aiming to benefit urban activities, air and mean radiant temperatures at the pedestrian level are compared. None of these will reverse long-term warming trends but, as we move from mitigation to adaptation, combinations of these strategies can slow the pace of warming over time and moderate urban warming, indicating a way forward for urban design in tropical and subtropical cities.

INTRODUCTION

Brazil has recently constituted the Brazilian Panel on Climate Change (PBMC). According to PBMC (2013), Brazil's climate will be warmer in the coming decades, with gradual and variable average temperature increase in all regions between 1ºC and 6ºC by 2100, compared to that recorded at the end of the 20th century. Brazil has its own voluntary commitments for emission reductions, as part of the National Politics for Climate Change, but adaptation measures for urban areas are still missing, and some local research groups are investigating this, aiming to support the review of the National Plan for Climate Change. Land use as a climate change mitigation measure, especially in urban areas, is underexplored; in this scenario we need more resilient cities and, for that, adaptation is crucial.

THE URBAN CLIMATE AND THE COUPLING OF GLOBAL AND LOCAL EFFECTS

Concerning the coupling of global and local warming effects, cities do not cause heat waves, but they amplify them. Because of the greater prevalence of mineral-based building materials, cities absorb and retain substantially more heat than rural areas characterized by more vegetative cover. Because of that the main reason for city warming is not the global warming itself, but the replacement of the vegetation for hard surfaces and the anthropogenic emissions (Stone, 2012).

One of the climate related land use implications is the urban heat island (UHI), which is more diverse than originally suspected (Arnfield, 2003). On the surface UHI is easy to understand and to visualize the results of urbanization. However, UHI is a multi-faceted phenomenon whose proper definition and physical basis is more complex. Proper understanding of the definition and types, dynamics and underlying physical processes of the UHI, however, is key to formulating mitigation measures (Roth, 2013). Besides differences based on the medium sensed (air, surface, even subsurface) and the sensing system employed (Arnfield, 2003), there is growing evidence supporting the existence of phase and amplitude departures in the UHI in tropical cities, in comparison with mid-latitude cities (Marques Filho *et al*., 2009; Chow; Roth, 2006). The UHI in tropical and subtropical cities is less intense than in higher latitude cities, and it is more pronounced during daytime and strongly regulated by the moisture content of the atmosphere and soil in adjacent rural regions (Roth, 2007). As well as in other tropical and subtropical climates, according to Ferreira *et al.* (2012), the UHI in the city of São Paulo has a daytime character, with a maximum intensity during afternoon (14:00-16:00 LT) and a minimum during morning time (07:00-08:00 LT) in almost all months monitored in 2004. The maximum UHI intensity varied from 2.6ºC in July (16:00 LT) to 5.5ºC in September (15:00 LT).

The role of density

Cities differ from their rural surroundings in a multitude of ways, many of them directly related to the surface energy balance and the formation of UHIs. Urban form is affected first and foremost by building dimensions and spacing, but also by the characteristics of artificial surfaces and by the amount of green space. The presence of a dense matrix of buildings promotes the creation of UHIs through a variety of processes, for example, the trapping of solar energy due to multiple reflection and absorption within canyons, the restricted sky view factor of deep and/or narrow canyons and reduction of wind speeds near the ground (Erell *et al*, 2011).

For several reasons, one of the current needs of urban settlements is a higher urban density, a topic that still causes some debate, but from mobility and urban climate points of view, low-density areas can be even worse. According to Stone (2012), areas of low population density may still effect a significant influence on UHI formation if they have extensive infrastructure development.

The urban climatic issues of heat, humidity, lack of daylight, solar access and urban ventilation is of topical concern to urban planners and governments, so, the need for appropriate designs for high-density cities is clear. Urbanization and higher-density living is an irreversible path of human development. Higher-density living will continue to be developed and will soon be the norm. The environmental dimensions of high-density cities, especially in tropical and subtropical climatic zones, are decisive. Buildings are fighting each other for natural light and ventilation. The provision of light and air can be difficult; a paradigm shift is required, new tools are needed, but high-density living is a definite possibility, although it is not an easy path (Ng, 2010). To increase ventilation, height variation should be considered as much as possible; the stepped height concept can help to optimize the wind-capturing potential as well as the view of sky component for daylight availability. Designed properly, the strategy of tall and thin has a better chance to capture daylight. Given the same building bulk, on average, daylight availability to windows can improve by some 40 per cent (Ng; Wong, 2005).

The role of Green

Planted areas in a city tend to reduce daytime maximum temperatures, reducing radiant exchange at the ground surface. The effect of vegetation on the atmospheric heat island is manifested not only indirectly, in the form of a reduction of sensible heat flux from the cooler surface, but also directly in the form of evaporative cooling. Most field studies support the argument that a lack of vegetation in the city would tend to result in elevated daytime air temperature, and concomitantly, that a large-scale planting campaign may lead to a reduction of the daytime urban heat island (Erell *et al*., 2011).

According to Chen and Wong (2010), in a built environment the UHI effect can be described as a conflict between buildings and the urban climate, and considering the positive impact of plants upon this conflict, a conceptual model was proposed by the authors to understand the interactions among the three critical components in the built environment: climate, buildings and plants. In order to uncover the benefits of greenery in a built environment, the microclimatic effects should be quantified. There are some possibilities to reduce ambient air temperature with plants: urban parks, road trees, landscape within the vicinity of buildings and rooftop gardens. In addition, the surface temperatures could be reduced with rooftop gardens or vertical landscaping.

In high-density cities, land is scarce and there is little provision of space for the incorporation of urban greenery such as urban parks and landscaping. The integration of greenery in buildings also faces many constrains (Chen; Wong, 2010), in spite of some cases of success, like in Singapore, with the adoption of Green Plot Ratio by the local legislation (Ong, 2002).

Duo to the combined effect of shade and evapotranspiration, air temperature reductions from 1ºC to 3ºC can be achieved under the canopy in green areas, depending on the climate and soil conditions. According to Wong and Chen (2009), from the planning point of view, it can be found that smaller green areas strategically arranged or grouped around buildings should be largely promoted. This does not mean that large urban parks are not effective in terms of improving urban climate, but they are considered as a luxury to a heavily built-up environment, especially if rapid urbanization is experienced.

Within this context and assuming that the densification is inevitable and desirable from the point of view of urban sustainability, especially in megacities like Sao Paulo, the purpose of this research is to assess the cooling effects of vegetation in urban microclimate, especially during daytime, to counteract an increasing built density in a subtropical climate. The findings contribute to a land-based mitigation strategy, trying to answer partially what a changing climate will mean for cities and aiming for a more favourable energy balance in cities facing two climate-change mechanisms that can be superimposed: the global warming and the local daytime heat-island effect.

URBAN AND CLIMATIC CONTEXT OF SAO PAULO METROPOLITAN AREA

São Paulo is located at 23°32'S, 46°37'W, 60 Km far from the sea with altitudes varying from 720m to 850m. The city experiences hot, humid summers with air temperatures varying between 22ºC and 30ºC and mild winters between 10ºC and 22ºC. The metropolitan region, the 3rd biggest in the world, with more than 22 million inhabitants, had in 2014 the warmest January since 1943, when climatic data started to be regularly recorded in the city by the National Meteorological Institute (INMET) and the warmest February, with a maximum air temperature up to 36,4ºC. In other cities, like Porto Alegre, the Southern state capital, January 2014 was also the warmest in almost 100 years.

Accordind to PBMC (2013), in the future, besides mean temperature warming, an increase of extreme events is expected. January and February 2014 presented air temperatures above those observed ever and humidity values below those historically found. Whilst the historical climatological averages for these months are respectively 21,6ºC and 21,8ºC, the mean values recorded in 2014 were 24,2ºC and 24,3ºC and the highest measured air temperature since the meteorological station of the Institute of Astronomy, Geophysics and Atmospheric Sciences of the University of São Paulo (IAG-USP) recordings started were registered in both months: 31,6ºC. While both months are generally characterized by high rainfall amount and average relative humidity of 83%, the 2014 first two months had lower precipitation rates and recorded lower values of relative humidity (75% and 73% respectively). Thus, for this study, the incorporation of these months in the simulation is intended to be representative of an extreme event, characterized by higher temperatures and lower humidity rates.

Megacities like São Paulo are vulnerable to global warming and local warming effects, driven by urbanization. The PMBC is especially worried about the fast pace of vegetation suppression in Sao Paulo, both in the interspace of buildings as well as in the outskirts of the city.

Comparing the city of Sao Paulo´s population density with other cities in the world (Fig. 1), it is observed that even with an average density of 73.87 hab/ha (IBGE, 2011), similar to other cities, the density of Sao Paulo´s densest district is one of the lowest. As the availability of transport and infrastructure should be directly linked to urban density, it would be possible to think that there is an equitable distribution of these infrastructures throughout the city, which is definitely not true. São Paulo has some areas with reasonable availability of transport that does not necessarily have high values of population density and vice versa.

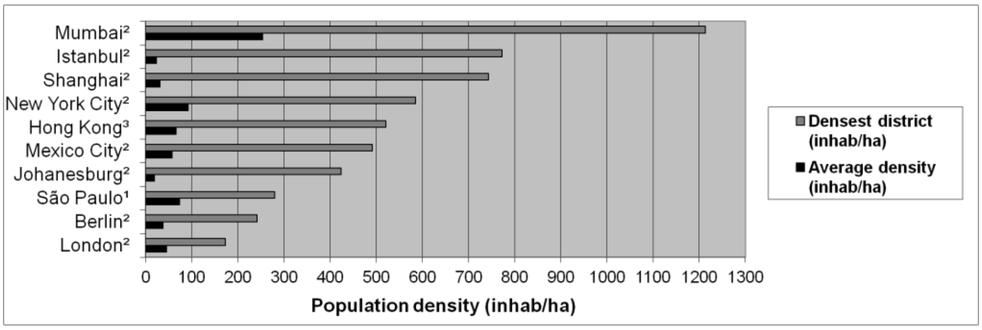

Figure 1: Big cities, their average density and densest districts.

Source: GUSSON, MADEIRA, DUARTE (2012) based on IBGE (2011), Burdett and Sudjic (2011) and Hong Kong Special Administrative Region (2012) data.

São Paulo is characterised by a heterogeneous urban structure, resulting from the rapid growth of the city during the 20th century. One of the effects of this growth is the social conflict of high-rise office towers and residential apartment buildings close to poor informal settlements (favelas). In addition, the distribution of vegetated areas is non-uniform in the city. While there are 35 parks, corresponding to 15 million m^2 (21% of the total area of Sao Paulo municipality), the downtown districts of Bras and Bela Vista are almost devoid of vegetation. Thus, few areas in the city are characterised by large amount of vegetation and street trees, usually in the wealthiest districts, mainly in the west zone of the city.

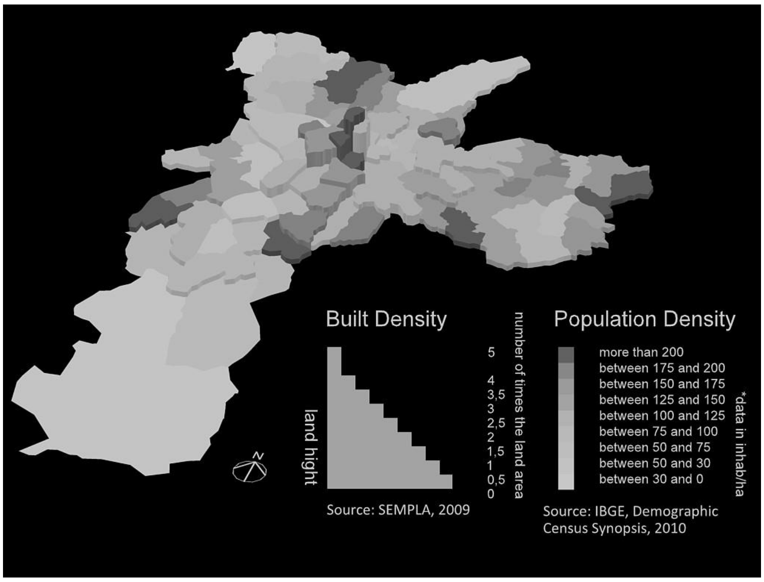

Figure 2: Built and population density in the city of São Paulo (by districts).

Source: GUSSON, MADEIRA, DUARTE (2012) based on IBGE (2010) and SEMPLA (2009) data.

The central area of São Paulo is formed by various districts, one of those is Bela Vista, chosen for this study due to its population density (the highest in the city) and for the built density (the 3rd higher), compared to a total of 97 districts in the municipality. Bela Vista shows the predominance of vertical residential buildings with heights varying between 10 and 20 floors. It also has one of the lowest green area per inhabitant, almost zero, according to Sao Paulo Environmental Agency.

FIELD MICROCLIMATE MEASUREMENTS

Microclimate monitoring was carried out from March 4th to April 29th of 2013 in the area of Bela Vista to register air temperature, relative humidity, solar radiation, surface temperature, wind direction and speed, aiming to previously calibrate the ENVI-met[1]4 *preview* for the parametric simulations. Figure 3 shows a nine-block area and in the middle of the central and densest block a Campbell Scientific meteorological station was set up in the ground floor of a residential building. In order to avoid obstructions for residents' circulation and for the equipment's protection, residents allowed the equipment installation in the building backyard, over grass and under a wooden pergola.

CALIBRATION AND PARAMETRIC SIMULATIONS IN ENVI-MET MODEL

The ENVI-met three-dimensional microclimate model was chosen for this study due to its advanced approach on plant-atmosphere interactions in cities. ENVI-met is one of the few models that seeks to describe the major climate processes acting in the urban environment, including turbulence, the turbulent transport of sensible and latent heat, the radiation fluxes within the urban structures and the influence of vegetation. The model simulates aerodynamics, thermodynamics and the radiation balance in complex urban structures with resolutions between 0.5m and 10m according to the position of the sun, urban geometry, vegetation, soil and various construction materials by solving thermodynamic and plant physiological equations (Bruse; Fleer, 1998; Bruse, 2012; Huttner, 2012).

For ENVI-met 4.0 *preview*, the forcing feature was incorporated and it is now possible to define the diurnal variation of the atmospheric boundary conditions and the incoming radiation. It also allows developing much more detailed weather scenarios for testing purposes and producing results that are in good accordance with field measurements (Jansson, 2006). The input data are shown in Table 1. The solar radiation calculated as a function of the latitude was adjusted to measured radiation by applying 1,4 octas for low clouds cover and 0,4 octas for high clouds cover. The adjustment factor for solar radiation was 1 (100%), in accordance with the measured data. The only additional climate data (not derived from local measurements) was that for specific humidity at 2500m, obtained from the local airport Campo de Marte (ca. 3,3km north of the site).[2] The soil temperature for the upper layer was measured using Campbell 107 temperature probe and humidity was estimated with Simple Biosphere Model – SIB2.[3] The model showed close similarity between adjusted and measured data, providing reliable results for the parametric simulations.

Table 1: Input configuration data applied in the ENVI-met 4 preview simulations

Start Simulation at day	26.04.2013
Wind Speed in 10m ab. Ground [m/s]	0.5
Wind Direction (0:N/ 90:E/ 180:S/ 270:W)	112.5
Initial Temperature Atmosphere [K]	300.44
Specific Humidity in 2500m [g Water/ kg air]	7
Relative Humidity in 2m [%]	50
Initial Temperature Upper Layer (0-20cm) [K]	291.76
Initial Humidity Upper Layer (0-20cm) [%]	50

For simulations, the starting day was defined based on pluviometric data collected from two fixed meteorological stations: one in the northern and other in the southern part of the city for the same period of Bela Vista measurements, which indicated the longest period with stable climatic conditions between April 26th-28th 2013, during autumn. Besides that, February 2014 was chosen to represent an extreme warm summer, characterized by higher temperatures and lower humidity rates registered in decades.

Initially a Base Case model was created and the input area domain was formed by 9 blocks of 100m x 100m (10.000m^2) each, which can be considered an average block size in Sao Paulo. In each block there are nine towers with 45m height (15 floors, average in Bela Vista), 20m x 20m each, representing a plot ratio of 5,4. The tower has a square shape plan that was planned to consider 4 housing units with 58m^2 each, per floor, and a population density of 3,5 people/apartment (total of 1764 inhab/ha).

Two other scenarios were created with different trees' distribution: a central park with trees covering an entire central block; and the same green area distributed in rows of street trees located in the perimeter of every block. In both cases, dense trees (LAI=4,6 m^2/m^2) and a soil type of sandy-clay-loam were chosen. Wind speed was kept constant in 0,5m/s in all scenarios, aiming to minimize convection effects and emphazise the effect of green and built density.

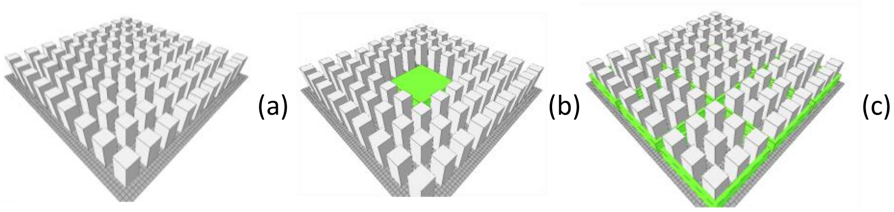

Figure 4: The three scenarios for ENVI-met model: (a) base case, only towers, (b) towers + central park, (c) towers + street trees

RESULTS AND DISCUSSION

All results are shown for 15h LST, coinciding with the maximum air temperature in all cases (Figure 5). As expected, in autumn, April 2013, with a mild climate in Sao Paulo, air temperature differences are minor, up to 0,5ºC, comparing the scenarios a and b, in and around the park, and about 0,3ºC comparing a and c. Concerning the distribution, the oasis effect is more pronouced in scenario b than c. In February 2014, the extreme warm summer this year, air temperature differences become more significant and the effect of vegetation is slightly more pronounced showing air temperature differences up to 0,6ºC comparing scenarios a and b and about 0,2ºC comparing b and c. On the other hand, the effects of the mutual shading of buildings and the vegetation contrasts with the warmer surfaces of the streets and the unshaded spaces between buildings, showing mean radiant temperature differences up to 13ºC in and around the park comparing the scenarios a and b, even during the mild April 2013. In scenario c, mean radiant temperature is lower along the shaded streets, although inside the blocks, scenario b performs better, configuring an oasis effect. Going to the extreme summer, February 2014, the picture is about the same, but with higher temperatures in the three scenarios, being mean radiant temperature in the scenario b about 10ºC lower than the scenario a. In scenario c the benefits of tree shading are evident on the mean radiant temperature along the streets, under the canopies, but the effect is local, and do not spread over the blocks (Table 2).

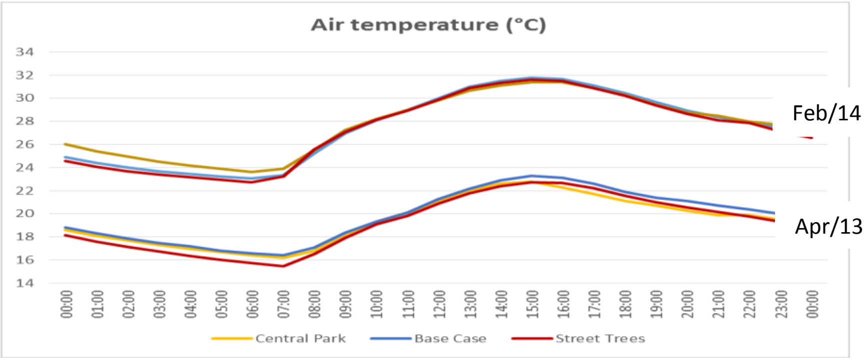

Figure 5: Air temperature results in both seasons, showing the highest air temperature at 15h LST.

Table 2: Simulation Results for 15h LST

	Base Case – only towers (a)	**Central Park Scenario (b)**	**Street Trees Scenario (c)**	**°C**
Air temperature – Apr/13				< 22,8° 22,9°C 23,0°C 23,1°C 23,2°C 23,3°C 23,4°C 23,5°C 23,6°C > 23,6°
Air temperature – Feb/14				< 31,4°C 31,6°C 31,8°C 32,0°C 32,2°C 32,4°C 32,6°C 32,8°C 33,0°C > 33,0 °C
Mean radiant temp – Apr/13				< 31°C 36°C 41°C 46°C 51°C 56°C 61°C 66°C 71°C > 71°C
Mean radiant temp – Feb/14				< 31°C 36°C 41°C 46°C 51°C 56°C 61°C 66°C 71°C > 71°C

Based on simulation results, an empirical adaptive thermal comfort index developed for local conditions was applied. The Temperature of Equivalent Perception - TEP (Monteiro; Alucci, 2011) was calculated based on the mean values for the central block in the three scenarios for the two periods, at 15h LST. Wind speed was 0,5 m/s, the same adopted for the simulation input.

Table 3 – Results for TEP = -3,777 + 0,4828 . Ta + 0,5172 .Tmrt + 0,0802 . Rh – 2,322va (oC)

	April 2013					February 2014				
Scenario	Ta (ºC)	Tmrt (ºC)	Rh (%)	v (m/s)	TEP	Ta (ºC)	Tmrt (ºC)	Rh (%)	v (m/s)	TEP
only towers	23,3	43,7	45,8	0,5	**32,6**	31,9	52,3	34,9	0,5	**40,3**
towers+ central park	22,8	33,2	48,1	0,5	**27,1**	31,3	43	36,4	0,5	**35,3**
towers + street trees	23	42,2	47,3	0,5	**31,8**	31,5	50	36,2	0,5	**39,0**

CONCLUSIONS

In both seasons, air temperature differences are small among the three scenarios, around 0,5ºC. In spite of that, the lower mean radiant temperature in the central park (scenario b) provoke an increase in comfort levels according to TEP, around 5ºC, characterizing what Erell *et al*. (2011) called park cool island, an oasis effect even in-between towers in a high-density context. On the scenario c, the effect is noticeable when compared to the base case (scenario a), but localized under the trees' canopies and the oasis effect do not spread over the blocks. None of these scenarios will reverse long-term warming trends but combinations of these strategies can moderate the extreme of climate events in cities.

The Life and Death of the Minnesota Experimental City: An Experiment in Utopian City Planning

Cindy Urness, MArch
[North Dakota State University, Fargo, USA]

Chitrarekha Kabre, PhD
[DCR University of Science and Technology, Murthal, INDIA]

ABSTRACT

Sustainability at the macro scale of settlement has been an aspect of the design of cities since our earliest history as urban dwellers (e.g. human settlements in ancient China, Egypt, Greece, India, Asia Minor, the Mediterranean world and South and Central America). The Minnesota Experimental City (referred to by its planners) was imagined initially by a university professor and a newspaper publisher, and was planned by working groups – meeting at the University of Minnesota - which included designers, planners, business people, government leaders, sociologists, educators, theologians, scientists, and economists, and ultimately supported in its early phases by both the federal government and the State of Minnesota. The goal was to plan, develop, and build – through a public/private partnership - a healthy environment for a new city of 250,000 people for northern Minnesota and to be constructed from the early 1970's to the mid-1980's. It would incorporate such technological innovations as car-free zones with people-movers, waterless toilets, a power-generating system fueled by both the burning of garbage in pollution-free furnaces and the use of windmills, and partially domed, climate-controlled, city centers. The goals of the city included life-long learning; social integration among and between religious, racial, age-specific and ethnic sub-groups; and values which looked not just forward but back to a feeling of community which emphasized "good food, good friends, and a good relationship to the earth." In essence, the Minnesota Experimental City embodied the principles of social, economic and environmental sustainability. This paper discusses the salient features of the Minnesota Experimental City and its relevance in the present context.

INTRODUCTION

As urban planners around the world confront the critical issues of the twenty-first century—expanding population, rapid urbanization, limited global resources, increased demand for food production, and protection of a fragile environment - this paper narrates the story of the Minnesota Experimental City (called MXC) – a livable sustainable new city of 250,000 people, planned for northern Minnesota in the central United States, intended to be constructed from the early 1970's to the mid-80's.

It's often the case that great big ideas like the MXC have larger-than-life characters behind them, and the MXC is no different. The story of the birth of the MXC idea is the story of Athelstan Spilhaus and Otto Silha – two men who met at the right time – (1965) - and in the right city and state – (Minneapolis, Minnesota – known at the time for its progressive politics) - each with a history of thinking creatively as they operated in their very different spheres – (Spilhaus, the world of science and education in his position of the Dean of the Institute of Technology at the University of Minnesota; Silha, the worlds of newspaper publishing and civic philanthropy). The MXC was planned by working groups which included designers, planners, business people, government leaders, sociologists, theologians, scientists, and economists. Their goal was – through a public/private partnership - to plan, develop, and build a healthy, sustainable environment for the city's inhabitants, which would incorporate such technological innovations as car-free zones with people-movers, waterless toilets, a power-generating system fueled by both the burning of garbage in pollution-free furnaces and the use of windmills, and a domed, climate-controlled downtown area.This paper will examine these forward-thinking technological innovations, but also the human-centered goals of the planners (among them futurist Buckminster Fuller, urbanologist Harvey Perloff, theologian Martin Marty, and economist Walter Heller) which included life-long learning; social integration among and between religious, racial, age-specific and ethnic sub-groups; and values which looked not just forward but back to a feeling of community which emphasized "good food, good friends, and a good relationship to the earth" (TIME, 1973).

It is helpful to understand the planning context in which these initial conversations between Spilhaus and Silha took place. The Housing Act of 1949 had launched the "Urban Renewal" movement in American cities. Neighborhoods considered "blighted" in dozens of cities across the country were cleared at federal and local expense, and land given to developers for redevelopment. The Housing Act of 1954 had made this redevelopment even more attractive to developers by providing FHA-backed loans to build housing. In 1956, the Federal-Aid Highways Act encouraged city and federal planners to construct new highways to provide easy access into central cities, often destroying healthy existing inner-city neighborhoods in the process. These actions, on top of the housing acts of the 30's and 40's which served to increase segregation and the growth of government-funded slum housing, along with the growth of suburban areas as city residents fled increasingly more troubled city centers, resulted in the sense that the American urban experience had failed. In 1961, Jane Jacobs in *The Life and Death of Great American Cities* began to raise strong questions about what had gone wrong at the hands of planners and government officials. There was a deep-felt concern that society was headed in the wrong direction in its ability to address the social issues of the day, e.g. segregation (of age groups as well as races), the environment, and education, but that all the tools were at hand to move in another direction.

By the mid-1960's, cities and their citizens were in turmoil. Polluted rivers were catching fire, spurring the birth of the environmental movement in the United States. This and the race riots that began in 1965 and continued through the remainder of the decade resulted in the sort of thoughtful – and urgent – discussions that Spilhaus, Silha, and leaders in business and industry in Minneapolis were engaged in, concerning the future of cities.

Add to this milieu the sense – based on evidence such as the successes of the Apollo moon shot program – that technological advances could solve our problems and move us forward. There was the sense also – a sort of World's Fair type of thinking – that the inventiveness and marketing know-how of the American people had not been applied to the problems of cities and housing (Spilhaus had directed the U.S. exhibit at the Seattle's World's Fair, and MXC planners were inspired by Moshe Safdie's Habitat housing complex built for Expo 67 in Montreal).

The Minnesota Experimental City was never built. The paper will look to answer the question, "why not?" and seek, also, to describe aspects of the city's design, features, and goals which might find new life in planning the healthy communities and sustainable habitats of today and tomorrow.

NEW TOWNS TO SUSTAINABLE TOWNS

The idea that we could re-imagine or re-invent cities to make them more "uplifting" places of habitation was, of course, not a new idea. Hippodamus (c. 498- c. 408 BC), a native of Miletus, Greece invented the art of planning cities and designed port towns of Piraeus and orthogonally planned towns such as Olynthus, Priene and Miletus. Conscious planning of cities reemerged in Europe during the Renaissance with prime objective to glorify a ruler or a state and partly aimed at improving circulation and providing military defense. From the 16th century to the end of the 18th, many cities were laid out and built with monumental splendor rather than health and comfort provisions for citizens.

The modern origins of urban planning lie in a social movement for urban reform that arose in the latter part of the 19th century as a reaction against the disorder of the industrial city. Many visionaries of the period sought an ideal city, yet practical considerations of adequate sanitation, movement of goods and people, and provision of amenities also drove the desire for planning.

New town developments have served many needs throughout history, including the following, according to William Alonso (1973): a) the acculturation and absorption of migrants, as in Israel and Australia; b) the development of frontier regions, ranging from tiny ones (Holland, Israel) to vast ones (the nineteenth-century American West, Siberia, and the center of South America); c) the exploration of concentrated resources (Ciudad Guayana, Venezuela and Kitimat, BC) and of extensive ones (central place systems such as the nineteenth-century American Midwest); and d) symbolism and politics (Washington, Brasilia).

In the United States, the Cities Beautiful movement, which architect Daniel Burnham was credited with founding, and which the Chicago Exposition of 1893 was credited with starting, influenced civic-minded citizens and planners in large cities and small towns across the nation. While the City Beautiful movement was based on the principles of Beaux Arts design, it really wasn't about beauty for its own sake, but for creating social order by instilling civic and moral virtue among the population. In 1906, Burnham and his assistant Edward Bennett designed a plan for the Chicago, which was the first comprehensive plan for the controlled growth of an American city. Happening at roughly the same time, and meshing with the same kind of intentions that the Cities Beautiful movement had was Ebenezer Howard's Garden City movement in England, founded in 1898, which was a reaction to the dirty, unhealthy conditions of cities caused by the Industrial Revolution. In the United States, bedroom suburbs such as Radburn, NJ, designed by Clarence Stein and the "greenbelt" towns continued the European Garden City tradition during pre-World War II years. In 1962, the modern new town community of Reston, VA, (Columbia, MD, came later) provided social and economic components of community as well as the simple physical aspects of the earlier new towns.

Table 1: Sustainable Urban Form Matrix

Design Concepts	Neo-traditional Development	Compact City	Urban Containment	Eco-city	MXC

Total Score	15 points	17 points	12 points	16 points	18 points

In the late 20th century the term sustainable development came to represent an ideal outcome in the sum of all planning goals. As advocated by the United Nations-sponsored World Commission on Environment and Development in Our Common Future (1987), sustainability refers to "development that meets the needs of the present without compromising the ability of future generations to meet their own needs." The latter point has been labelled as 'inter-generational equity'. More recently, sustainable development is defined as " a dynamic process which enables all people to realize their potential and to improve their quality of life in ways which simultaneously protect and enhance the earth's life support systems," (Forum for the Future). While there is widespread consensus on this general goal, most major planning decisions involve trade-offs between subsidiary objectives and thus frequently involve conflict. Jabareen (2006) delineates seven design principles for attaining the goals of sustainable urban development and identifies four urban forms that contribute to the overall sustainability of cities. Neo-traditional Development, Urban Containment, Compact City and Eco-City are the four identified sustainable urban forms comprised of combination of seven design principles or concepts viz a)

Compactness b) Sustainable Transport c) Density d) Mixed Land Uses e) Diversity f) Passive Solar Design g) Greening. The MXC epitomizes the design principles of sustainable urban development and is a forerunner to the present day eco-cities, as can be seen in how the MXC scores using Jabareen's (2006) Sustainable Urban Form Matrix, measuring the seven principles above, and comparing the MXC to the four sustainable urban forms listed, shown in **Table 1**.

OVERLEAP

By 1967, multi-disciplinary studies for planning the MXC were initiated at the University of Minnesota, under the direction of Walter Vivrett, professor of architecture and planning. Otto Silha was by now the chair of a Steering Committee of 23 well-known individuals from a broad variety of disciplines from around the nation. The word "overleap" was used to describe what the MXC hoped to achieve: "at once an advance into future possibilities and a break with past constraints" (Vivrett, 1972). It was determined that the best avenue for arriving at a concept for the MXC would be to initiate "workshops" which would focus on specific areas:

- Education - Health, medical and environmental health
- City-building technology
- Communications
- Waste management and pollution control
- Transportation (people, goods, and mail)
- Energy and energy transmission

The workshop participants, numbering almost 200 people, met for roughly three days each from late 1967 through early 1968. They were asked to identify, in their areas, what was "state of the art, and then identify major gaps and issues and areas for potential innovation – critical for a city that was truly "experimental."

One might discount all of this as the efforts of a few scholars and interested business people. By February of 1967, however, grants from three government agencies (Housing and Urban Development, Health Education and Welfare, and Commerce) and 10 corporations – totaling around $300,000, or more than $2 million in today's dollars – were in place to fund the planning stage of the project. Vice-president Hubert Humphrey had signed on as a supporter, as had the Minnesota State Legislature.

WHY A NEW CITY?

The concepts of dispersal and building-from-scratch were critical for the success of a new experimental city. Attempts to repair the existing fabric would present problems having to do with "local traditions, outmoded building codes, restrictive legislation, and the consequences of unplanned, unhealthy growth" (Spilhaus, 1968) in addition to the vested interests of local business and industry. A "dispersed" city, located no less than 100 miles from an existing urban city, would be able to offer the advantages of an existing city but – with a defined perimeter and surrounding reserved land – it could not suffer from unplanned growth. The "built-from-scratch" aspect would allow new innovations in services, waste-management, pollution control, and communication to be fully implemented from the start, and serve as a test environment for other new cities.

A third aspect of the initial concept was that of "urgent need" – the urgent need to build and populate an "instant" city fully and quickly so that it might soon function as the kind of sociological and technological laboratory – the core of the "experimental city" concept - that might lead the way for other new cities and the repair of the environment into the 21st century. It was estimated that the MXC would cost about $4 billion to build ($26 billion in today's dollars).

While it is interesting to focus on the technological and planning aspects of MXC, it is important to state that from an early point in the conceptual phase it was the community and human values that were stated as the main goals of the project – the phrase "people-oriented, technologically advanced" was often used as a descriptor. Spilhaus said, "We must not force people into what is technologically easy, but find a technological solution which is practical and closely meets their desires" (Spilhaus, 1968).

The overarching goals were these (Vivrett, 1972): “a. man can creatively mold his environment; b. he can, in a positive and constructive manner, unite the resources of private technology with public authority; and c. he can re-orient social, economic, and physical forces to serve people.” The futurist Buckminster Fuller, a member of the Steering Committee, discussed the role of a city of the future as being “metaphysical,” offering a forum for the exchange of ideas, learning and culture, and not just goods.

MXC PLANNING PRINCIPLES

It’s important to make clear that site selection was an important aspect of the planning process. A number of sites around the state of Minnesota were considered, with two sites selected as finalists, both of them about two hours north of Minneapolis-St. Paul in rural areas, and both of them in areas of the state that were struggling economically.The basic planning principle that the MXC was based upon was Walter Christaller’s “Central Place Theory” which was developed during the 1930’s in Germany. The theory consisted of two basic concepts – that of “threshold,” which is the minimum population that is required to bring about the provision of certain good or services, and that of “range,” which is the average maximum distance people will travel to purchase goods and services.

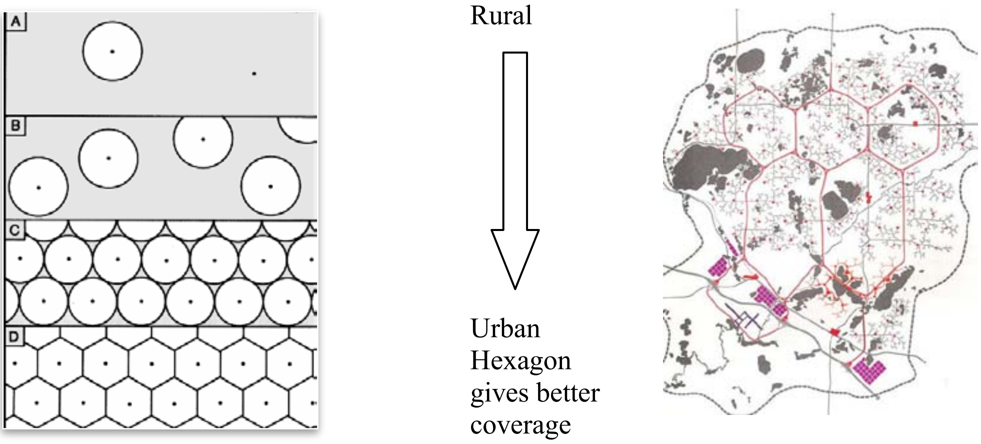

Figure 1 MXC development plan, combining hierarchical systems of centers with existing development patterns (Minnesota Experimental City Authority – Preliminary Report on Urban Design, 1973).

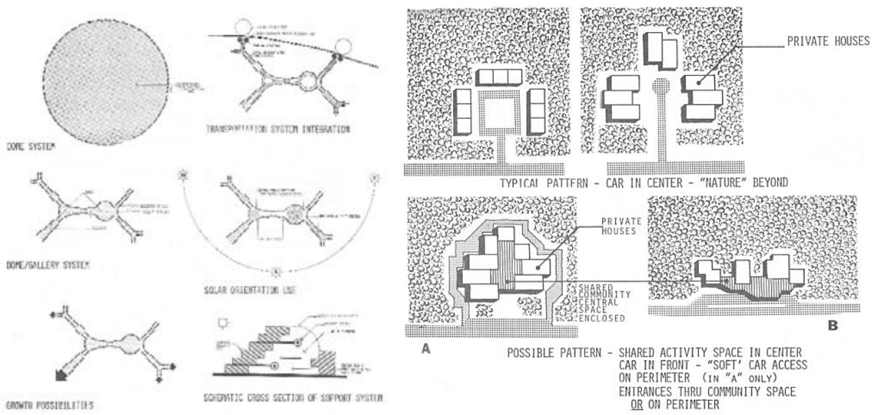

Figure 2 MXC development plans, combining hierarchical systems of centers with existing development patterns (Minnesota Experimental City Authority – Preliminary Report on Urban Design, 1973).

If you begin to “densify” areas of range you get a hierarchical system of centers, with the hexagonal shape ultimately giving better coverage than a circle. This system of hexagonal transportation networks was then laid out over existing potential communities in the initial master planning, as shown in **Figure 1.**

At the level of the community and neighborhood, as in **Figure 2,** built forms and development were laid out to maximize solar gain (images to the left), and to accommodate shared community space and close connections to nature (images to the right).

INFRASTRUCTURE AND SUPERSTRUCTURE

Technologically, the most important component of the MXC was its coordinated infrastructure and superstructure – its tunnel system, as in **Figure 3**. All transportation of goods and services, waste and utilities, and construction materials (small-sized components which could be assembled and disassembled for different configurations) would be handled through the tunnel system. Part of the tunnel system would be a network of environmentally-friendly features – solid waste would all be handled through an underground system that would allow for recycling of materials, the air would be scrubbed of pollutants, waste water would be reused for cooling and then recreation, and the infrastructure would do double-duty as superstructure.

People would arrive by vehicle at the edge of the city and would then be transported through a “pod” system of people movers, with semi-private “cabs” and the ability to select one’s own destination in a way that was more flexible than bus transportation. These cabs would provide door-to-door transportation to both low-density and high-density living and community structures, as in **Figure 4.**

It was very important to the planners that the communication network for the MXC also be part of the tunnel system. The substructure would be wired with coaxial cable to reach anywhere a telephone might conventionally be located. A wiring system to service radio frequency transmission would also be included. It was anticipated that the communication system would be used for high-speed connections to computers and video monitors which would be used for – among many anticipated uses - shopping, banking, crime prevention and the de-centralizing of learning and health care. It was planned that medical care would be made available through a series of care centers which would provide appropriate care at various levels, with computer connections back to central medical facilities for advice from specialists. Health care would be delivered as a “utility,” with easy access for all.

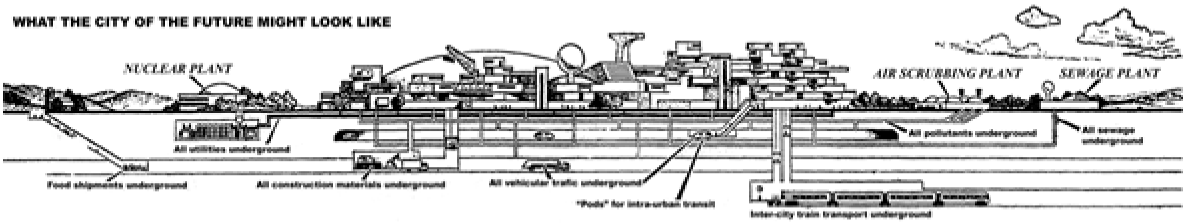

Figure 3 Cross-section of the MXC superstructure and tunnel system (New York Times, 1967).

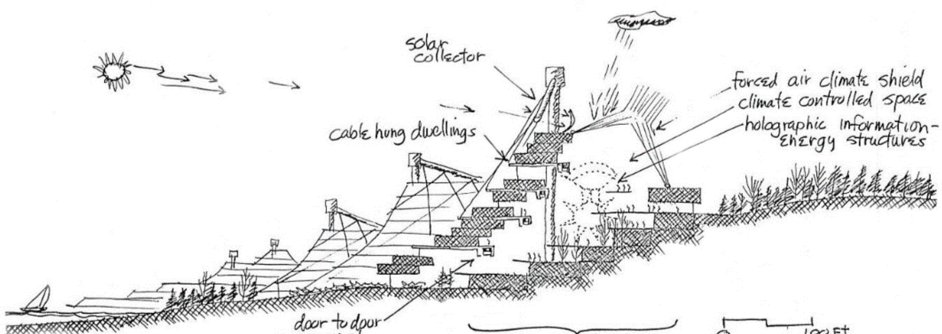

Figure 4 High-density community form, with maximized solar access and climate-controlled public space (Minnesota State Historical Society – MXC Authority Collection).

LIFE-LONG LEARNING

Perhaps one of the most interesting innovations in the MXC plan was in the area of education. The city would be constructed with no schools, but would instead serve as a life-long learning laboratory. Everyone would be a learner and everyone would be a teacher. Learning would occur everywhere within the city. There would be no schools, but instead learning centers located throughout the city in homes, businesses, and public spaces. These would include Beginning Life Centers for very young children, Stimulus Centers for films, tapes, sounds and spells, Gaming Centers for the study of complex realities in a simple fashion, Project Centers where people could work on experimental outcomes, Learner Banks where tools, equipment, print and non-print materials could be checked out, and Family Life Centers where families could learn together (Minnesota Experimental City Authority – Education, 1973).

FINANCING AND MANAGEMENT

With a price tag of over $4 billion, who was to pay for and manage the MXC? The planners of the project suggested several options for management. One would be to have a quasi-public, quasi-private corporation run the city as a public utility (similar to the model that was ultimately used at the London Docklands); another would be to view the city as similar to a large Disney-style hotel complex with lodging, shops, restaurants, and transportation systems, with public services possibly contracted out to private entities. In terms of who would pay the initial price tag for infrastructure, it was hoped that business and industry – recognizing the opportunity that the city would provide as a laboratory for new technologies of pollution control, transportation, communication, and construction - would be willing to invest in the up-front construction costs. Additional costs could be financed through bundled FHA mortgages.

FATE OF THE MXC

The initial project reports were completed in 1969, and the workshops continued their studies. The project lost a strong supporter at a high level when Hubert Humphrey lost his bid for the U.S. presidency in 1968, and MXC gradually lost local support as the state legislature tipped from more liberal to more conservative from 1968-1972. The University of Minnesota at the time was also substantially funded by the legislature, and as the legislative makeup changed, state government was less supportive of the University's MXC efforts. By late 1972, the final site had been chosen for the project. In January 1973, the final planning reports were issued. But by February of that year it was also the case that local politics had begun to signal the end of the project.

Locally, the MXC project - grounded in environmental innovation - became a victim of the concerns of those who treasured the local environment of Aitkin County, MN, the wooded, rural county which was ultimately selected as the site for the MXC. While many residents of the county welcomed the opportunities which the project would bring, many feared the loss of property and peacefulness. In 1973, TIME Magazine published an article called "The Newest New Town" which spoke positively about the prospects for the MXC. It was the last hoorah, followed by these grim headlines in the Minneapolis Star Tribune from February through May of 1973:

2/8 "MXC Prospects Not Bright in Legislature"
2/14 "Opponents Term MXC a Trojan Horse"
2/16 "MXC Threatens Good Hunting Area"
2/20 "Petitions Opposing MXC Presented to Governor"
3/13 "PCA Recommends Dropping MXC Plan"
3/28 "Senate Sub-Committee Votes to Cut Off MXC"
4/4 "House Sub-Committee Votes Against MXC"
4/5 "MXC Bill Dead"
5/24 "MXC May Be Moved to VA, FL, or OH"

Things were also happening in the larger arena that helped to seal the fate of the MXC. The country was involved in an unpopular war which escalated after the election of Richard Nixon in 1968 and didn’t end until 1975. From 1973 through 1975 the country experienced what some considered the most severe recession since WWII, with oil shortages, rising interest rates, and the reduction of real income and consumer spending. The notion that we could tackle any challenge if the ideas and the effort were there seemed like an idea whose time had passed. Locally, the MXC project - grounded in environmental innovation, with a tightly interwoven connection between human development and the landscape - became a victim of the concerns of those who treasured the local environment of Aitkin County, MN, the wooded, rural county which was ultimately selected as the site for the MXC. While many residents of the county welcomed the opportunities which the project would bring, many feared the loss of property and peacefulness.

CONCLUSION

Those who contributed to the imagineering of the MXC should recognize aspects of the design in today’s world. Forty years later, we live in a world where the environmental issues of air quality, resource management, and land use are more important than they have been at any time since the 70’s. On-line learning and high-speed internet communication were just speculation in the 60’s – now they’re part of how we learn and communicate. The type of large scale building and planning of “instant” cities that characterized the MXC is now happening in the construction of new cities in India and China. The “cradle to cradle” use of resources we saw proposed for the MXC is now an aim for consumers, industries and nations.

Criticism has sometimes been leveled at the MXC for its top-down planning approach, conceived by an “elite” group of academics and businessmen. Its approaches, however, to sustainable land use, net-zero energy use and waste management, communication, education and health delivery systems still constitute the “overleap” of innovation that was the MXC’s goal. Forty years later, perhaps, the open-source, bottom-up nature of current innovation might take some inspiration, especially in developing societies, from the ideas of an experimental city that was many years ahead of its time. While the “compact city” model is viewed by many as the best answer to a more sustainable urban future, perhaps the idea of smaller - yet dense – communities which are closely tied to nature is more compatible with the patterns that have satisfied our needs for communal habitation throughout history.

Towards the Improvement of Cooling Energy and seismic performance in Timber buildings using GIS and interactive Database

ABSTRACT

By increasing the thermal mass of building components, in order to improve its thermal inertia, the whole structure mass rises and therefore reduces structural performance of timber buildings in seismic areas. Italian codes establish restrictive limits for the design of building, particularly in southern regions because of a high seismic activity. In order to answer the question »How can the summer behaviour of timber buildings be improved without worsening their seismic performance?«, Fraunhofer Italia, Free University of Bozen-Bolzano and Trees and Timber Institute CNR – IVALSA developed the research project TIMBEEST, which combines quantities belonging to different engineering branches (energy and seismic) towards their best compromise.

Within this research project, Fraunhofer Italia developed an interactive tool composed of database and Geographical Information System (GIS). This tool stores and analyses data, as well as it allows researchers and professionals to manage and evaluate the interaction of energy and structural characteristics of timber building components during the design phase across the Italian territory.

Starting from energy and structural indicators (the Cooling Degrees Days for the Typical Reference Year and the Seismic Response Spectra, respectively) by a spatial discretization based on Italian Provinces, maps with a classification of the Italian territory were created. Such classification combines energy and seismic indicators to evaluate their impact on buildings.

In order to improve the passive cooling performance of timber buildings on the basis of the classification of environmental and structural indicators, enhanced building components has been developed and presented by the interactive tool.

INTRODUCTION

Italy is a country characterized by an intense and widely spread seismic activity (Civil Protection Department) and high temperature during summer (Pinna, 1978), especially in southern areas. For this reason the TIMBEEST research project studies strategies to improve of the summer behaviour of timber buildings across the Italian territory by using thermal mass without worsening their seismic performance.

Since 1970s, researchers have studied the effect of thermal mass on energy demand and cooling/heating peak loads (Robertson (1986), Brown (1990)). Furthermore, the improvement of thermal

Julia Ratajczak is a researcher at the Fraunhofer Italia Research, Bolzano-Bozen, Italy. Cristina Benedetti is a scientific consultant at the Fraunhofer Italia Research, Bolzano-Bozen, Italy. Irene Paradisi is a researcher at the Fraunhofer Italia Research, Bolzano-Bozen, Italy.

building performance through the optimization of thermal mass layer distribution and its effective thickness has been investigated (Baverstock (1986), Shaviv (1988), Kosny and Kossecka (1998), Al-Sanea and Zedan (2001), Paradisi et al. (2012)).

Timber technology presents an excellent structural performance in seismic areas, but its low thermal inertia (compared to clay block or concrete buildings) reduces the energy performance in cooling period. Because of the timber technology is rare or even absent in Central and Southern Italy, it is an opportunity to investigate the technological feasibility and effectiveness of timber buildings, considering both thermal performance and structural implications. Beside its specific goals, TIMBEEST research requires a huge effort in data management because of data intersection and influences from energy and structural branches. This project requires to be managed in flexible way considering continuous alignments and integrations and even changes. In order to satisfy those requirements, an interactive tool based on databases seems to be the best solution.

TOOL STRUCTURE

At building and city level many studies discuss methodologies to store, manage data and catalogue solution in order to create cognitive tools, which enables professionals to visualize data, provide a global interpretation of information and support the decision-making process. Within the available methodologies, the Geographic Information System (GIS), based on the geo-referencing process, and database can be used as a digital tool to provide a support for analysing and managing large sets of data.

The collection and spatial data analysis provided by GIS is necessary for advanced urban planning which focuses on specific topics, i.e. energy management (Fistola, 2010). Coors and Xu (2012) proposed an integrated approach for sustainable assessments of urban area in Stuttgart through GIS cartographies. Fabbri et al. (2012) used GIS tool to collect data regarding energy class of existing buildings in order to suggest a zone energy indicator for evaluating the city. Ascione et al. (2013) developed an analytical methodology combined with GIS, which aims at characterizing energy performances of new and existing buildings in order to allow sustainable planning for energy-oriented cities. The application of database in research projects has been used by Thomson and Hardin (2000), who showed that the efficiently handled data can substantially improve the quality of planning and decision-making process. Sala, Romano and Boganini (2011) developed an interactive database collecting different technologies and construction systems of Mediterranean areas in order to support professionals in the development of a complete project analysis in several specific areas. Moreover, Attia and Wanas (2012) created for the city of Cairo an online source database of building materials, building envelopes and their characteristics, which influence energy consumption in order to support professionals during the design phase. All these researches list up specific characteristics which belong to different branches avoiding their correlations and do not focus on timber buildings.

Based on previous experience of the interactive tool “Timber Construction” (iPad application, Benedetti, 2010), and considering the complex structure of TIMBEEST research project, interactive tools are identified as the best solution for dissemination purposes. Considering the potential of interactive databases and GIS to intersect data at different levels and manage information effectively, the TIMBEEST interactive tool has been developed in order to manage contents throughout all research phases. It is composed of the following parts: a) databases created by FileMaker Pro 11 software, which are structured in three main databases and several sub-databases linked together; b) external GIS database made using Quantum GIS software, which correlates analysed data to Italian territory in order to support databases in point a). A common User Interface (UI) provides a rapid access to the content of three research phases of TIMBEEST project and allows navigating through them easily. These research phases are: 1) state of the art (geographical context, environmental restraints and analysis of standard building components); 2) analysis and simulation of improved building components; 3) results and comparison of previous phases. Each of these phases is structured by the three sections throughout they are developed, which are: a) definition of the specific objectives; b) methodology; and c) collection and comments of the results (**Figure 1 a)**. The UI switches between research contents and sets of documents by navigational tabs, as shown in **Figure 1 b**.

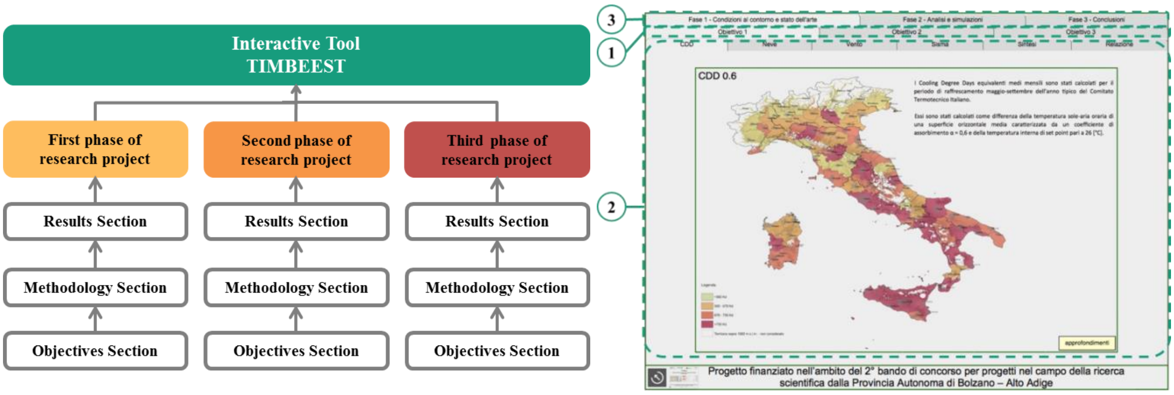

Figure 1 (a) Scheme of TIMBEEST interactive tool; (b) User interface for each phase of research project: 1) objectives; 2) methodology; 3) results.

OBJECTIVE AND METHODOLOGY SECTIONS

Objective section

The first phase of research project is focused on geographical context and environmental restraints, which affect thermal and seismic performance of buildings. Furthermore, the standard building components are identified and analysed. The objectives of the first phase are: a) to manage GIS data of physical features regarding environmental restraints such as equivalent Cooling Degree Days (CDD), horizontal elastic response spectrum (S_e), snow load (q_{sk}), wind load (p) and of a synthetic indicator, by mapping Italian territory at Province level; b) to manage energy and structural data of standard building components by the design of a database considering the most common timber technologies – Platform Frame (PF) and Cross-Laminated-Timber Panels (CLT) (Benedetti et al., 2010).

The second phase of research project develops and analyses improved building components by thermal mass in order to find the best compromise between summer thermal performance and seismic performance. Its objectives are: a) to outline suitable solutions for lightweights building components throughout a literature review regarding summer building performance and possible improvements in cooling period; b) to manage throughout a database energy and structural data of improved building components (with additional thermal mass); c) to summarize 256 dynamic simulations made by TRNSYS software for 110 capital cities of the Italian Provinces referred to standard and improved building components, respectively; d) to collect and visualize data of monitoring campaign of two Test Cells in order to validate thermal simulations; e) to manage 60 modal dynamic linear analysis of improved building components in order to evaluate the limit of thermal mass application in timber structures, which accomplish summer thermal improvement without worsening seismic performance of structure. The objectives c), d) and e) are going to be developed during the next months. Thence, the available results are not validated yet.

Furthermore, the third phase of research project will start at the end of year 2014 and it will include results of energy and seismic simulation and comparison of standard and improved building components in order to provide a quick overview of adopted solution.

Methodology section

The methodology section explains the procedures used to develop the scientific contents. This section corresponds to each objectives and it is integrated into the UI tabs (**Figure 1b, point 2**). Since the specific procedures exceed the goal of this paper, their details are not presented. It is possible to find such information in the research paper of Ratajczak et al. (2014). submitted to 30th International PLEA Conference 2014 and under the acceptance procedure.

RESULT SECTION

The result section visualizes specific phase outcomes in order to facilitate data analysis, to provide inputs for further steps of the TIMBEEST and to enhance the future implementation of the tool. These outcomes are gathered in result databases, and are correlated to different sub-databases and GIS database, as illustrated in the flow chart (**Figure 2**).

In detail each phase of TIMBEEST is made of different result databases, as many as the specific objectives. The following result databases are developed or will be implemented:

1. Result database of the first phase:
   a) database of standard building components;
   b) databases of geographical context and environmental restraints (GC&ER) at Province level.
2. Result database of the second phase:
   a) database of improved building components;
   b) database on thermodynamic simulation – has not been yet analysed;
   c) database of seismic dynamic simulation – has not been yet analysed.
3. Database of the third phase: has not been yet developed.

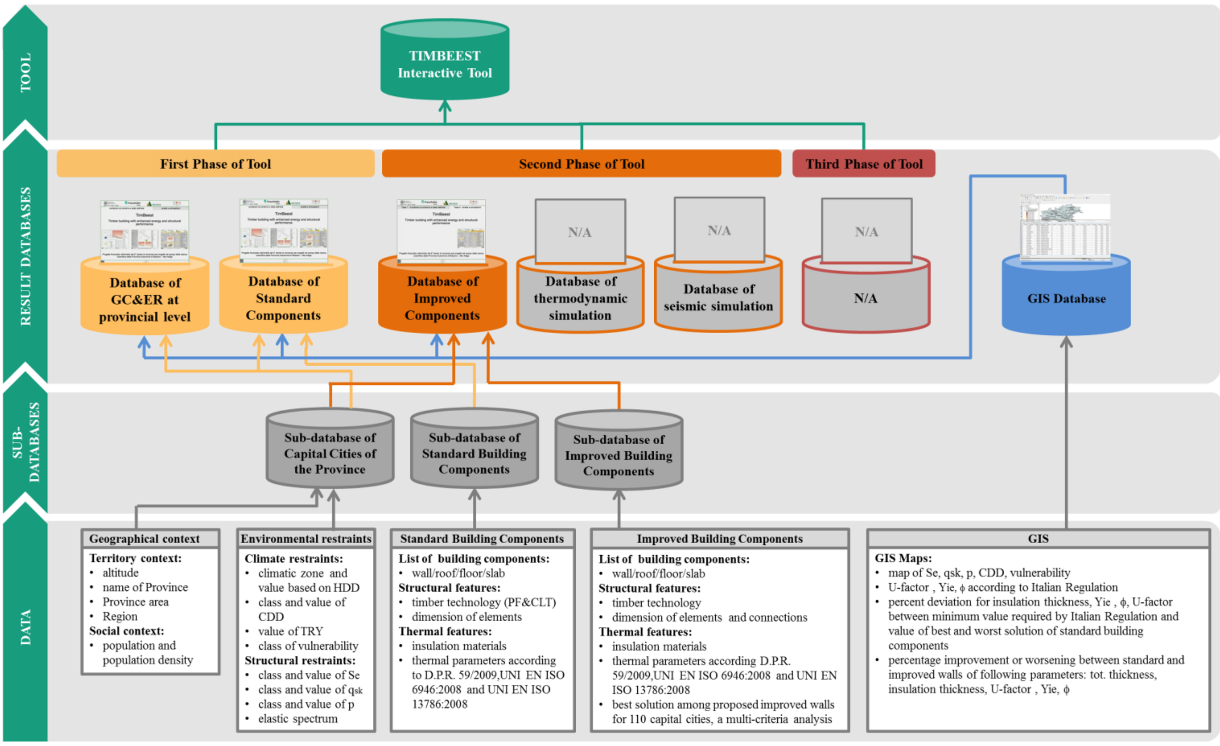

Figure 2 Flow chart of relations between sub-databases and result databases belonging to the first and second phase of TIMBEEST research project.

Because of the huge amount of data assigned to territory, the use of a GIS database is required to manage, analyse and visualize data as well as a GIS software **(Figure 3)** is needed to generate maps. The GIS database refers to the previously mentioned result databases.

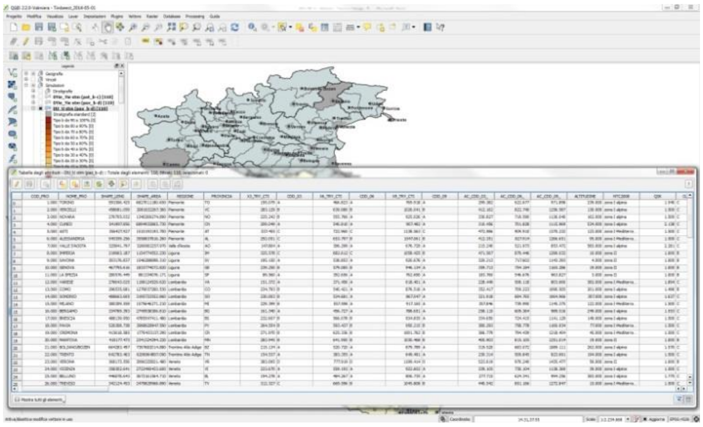

Figure 3 GIS database.

Considering the huge amount of data and interactions between them, the result databases is linked to different sub-databases in order to visualize data in one UI. The following sub-databases within the TIMBEEST interactive tool are presented: a) sub-database of capital cities; b) sub-database of standard building components; c) sub-database of improved building components.

The sub-database of capital cities (a) consists of geographical context data as: altitude, name of Regions, Provinces and capital cities, population number and population density of Provinces and capital cities; and environmental restraints data as: climatic zone based on Heating Degree Days, class and value of equivalent Cooling Degree Days, value of Test Reference Year, class and value of synthetic indicator, S_e, q_{sk}, and p. These environmental restraints data affect the thermal and structural performance of buildings.

Other two sub-databases (b and c) of standard and improved building components include information regarding type of building components and their structural and thermal features.

Result databases of the first phase

Figure 4 shows UI layout of the result database (1a), which is divided into topic area: 1) geographical context and environmental restraints; 2) building information; 3) structural features; 4) thermal features; 5) index of building components related to 110 capital cities of Italian Provinces. These information are visualized when a building component is selected from the index list.

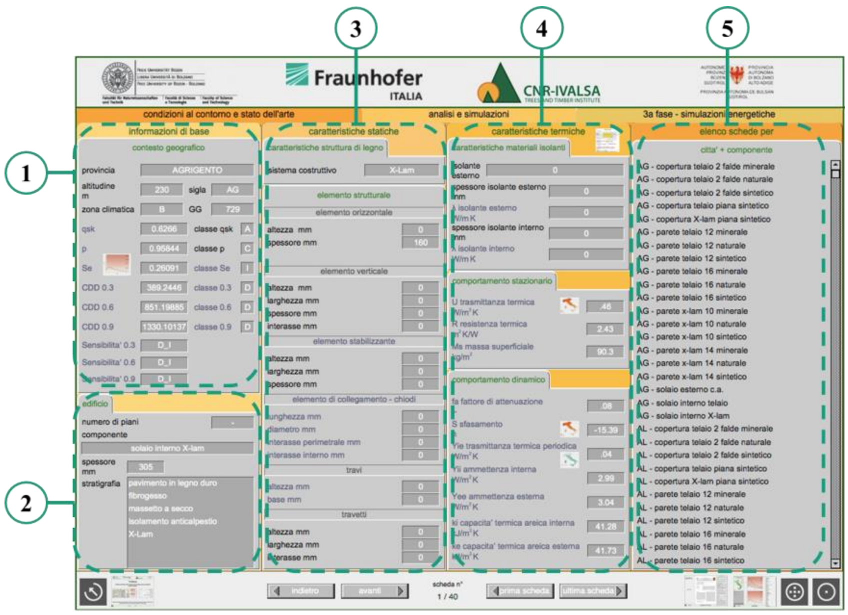

Figure 4 The UI layout of result database (1c) in the first phase of research project.

The first area regarding geographical context and environmental restraints **(Figure 4, point 1)** contains information and parameters related to capital cities such as: a) altitude; b) climatic zones and value based on HDD according to D.P.R. n. 412 26/08/93; c) class and value of snow load according to NTC 2008; d) class and value of wind load according to NTC 2008; e) class and value of horizontal elastic response spectrum according to NTC 2008; f) class and value of CDD referred to three different horizontal surfaces with absorption coefficient value (α, [-]) respectively 0,3, 0,6 and 0,9; g) class of synthesis referred to three absorption coefficient value. Furthermore, clicking on each parameter users can analyse GIS maps of Italian territory regarding q_{sk}. p, S_e, CDD and synthesis, which are structured as shown in **Figure 5a**: 1) GIS map with a legend and 2) description of parameter. The GIS maps are important to characterized territory and identify critical areas, for instance: the synthesis map allows highlighting the critical areas, affected by risks of overheating and earthquake.

Beside the seismic parameter Se a link to the GC&ER result database (1b) is integrated. **Figure 5 b** shows this result database, which provides information on: 1) map of seismic danger of the Italian territory evaluated under specific hypothesis by Istituto Nazionale di Geotecnica e Vulcanologia; 2) GIS map of related Region and the provincial classification of S_e; 3) graph of elastic spectrum, referred to capital city of the selected Province 4) graph of elastic spectrum with all capital cites presented in selected Region; and 5) environmental restraints – S_e class and value. The graph of elastic spectrum is elaborated using Simqke software developed by the University of Brescia.

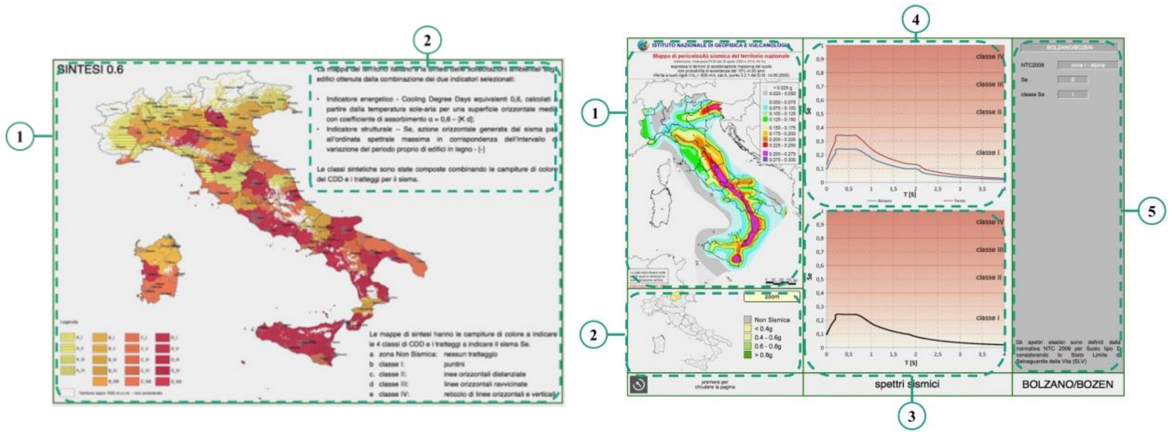

Figure 5 (a) The UI layout of the database of geographical context and environmental restraints at Province level; (b) Synthesis map.

The second area is dedicated to building information (**Figure 4, point 2**) and shows details regarding building components such as type of component (wall/roof/floor) in different technology PF and CLT, total thickness of component and list of layer composition. To enhance a comprehension of building component composition, the 2D drawings are visualized by clicking on text.

The third area is focused on structural features **(Figure 4, point 3)** and it is arranged in three parts: a) type of timber technology of selected building component; b) information regarding structural dimension of elements; and c) structural connections. Selecting building component from index list, the following information are provide for structural dimensioning: a) height and thickness of horizontal components; b) height, width, thickness and distance between elements (in case of PF) of vertical components; c) height, width and thickness for wall sheathing; d) length, diameter, and centreline spacing of screw connection; e) dimension of beams and studs. Furthermore, details regarding angle brackets, hold-down and screw connection for the following connection are specified: wall-to-concrete slab, wall-to-floor, wall-to-wall and beam-to-wall.

The fourth area presents thermal features **(Figure 4, point 4)** and provides the following data: a) thermal conductivity (λ, [W m^{-1} K^{-1}]) and thickness of different insulation materials (natural, mineral and synthetic) used in building component; b) thermal parameters, which are verified according to D.P.R. 59/2009 and UNI EN ISO 6946:2008 such as thermal transmittance (U-factor, [W m^{-2} K^{-1}]), thermal resistance (R, [m^{2} K W^{-1}]) and mass of component (Ms, [kg m^{-2}]); c) thermal parameters used for dynamic evaluation and verified according to UNI EN ISO 13786:2008 such as decrement factor (f, [-]), periodic thermal transmittance (Y_{ie}, [W m^{-2} K^{-1}]), time shift (ϕ, [h]), periodic thermal transmittance on interior side (Y_{ii}, [W m^{-2} K^{-1}]), periodic thermal transmittance on external side (Y_{ee}, [W m^{-2} K^{-1}]), interior areal heat capacity (k_1, [kJ m^{-2} K^{-1}]) and external areal heat capacity (k_2, [kJ m^{-2} K^{-1}]).

The fifth part **(Figure 4, point 5)** shows the index list of all building components, which are organized by capital city of the Province and type of timber technology.

In the result database (1a) of the first phase, next to U-factor, Y_{ie} and ϕ parameters, GIS maps are linked in order to visualize the minimum value required by Italian codes (**Figure 6 a, point 1**). **Figure 6 a, point 2, 3** shows two maps, which express the percent deviation for each parameter between minimum value and value of best and worst solution of standard building components in order to provide a range of variation. Furthermore, evaluations of all thermal parameters according to UNI EN ISO 6946:2008 and UNI EN ISO 13786:2008 using spreadsheet are integrated in database.

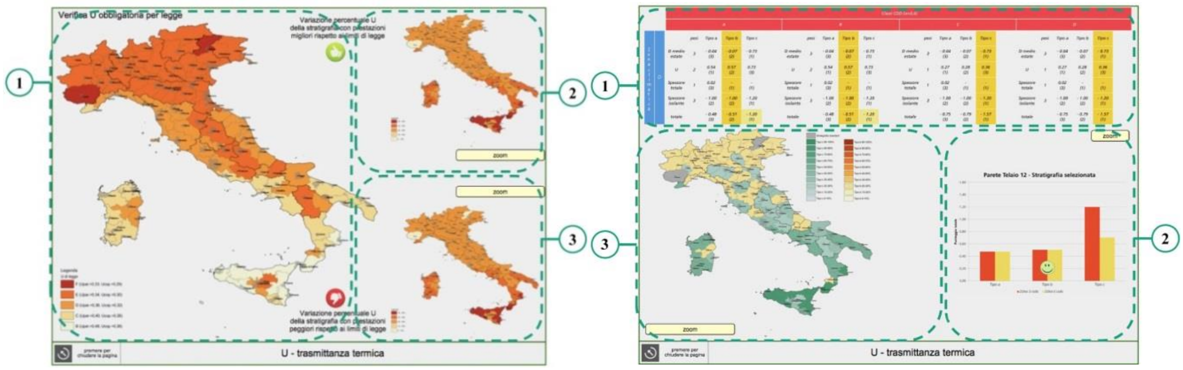

Figure 6 (a) GIS maps referred to thermal parameters; (b) GIS map referred to improved building components, and multi-criteria analyses.

Result database of the second phase

In the second part of research project improved solutions for building walls are studied. Four solutions for CLT technology and three solutions for PF technology are identified. The structure of the result database is the same of the (1a) one but the inserted data refer to other components. In order to find out the best solution for 110 capital cities among proposed ones, multi-criteria analysis is developed (**Figure 6 b, point 1, 2**). In order to combine the percentage improvement/worsening between best solution of standard and improved walls, the GIS database is used. This information are included into the result database (2a) of the second phase just next to thickness of insulation material, total thickness of the building component, the U-factor, the Y_{ie} and the ϕ (**Figure 6 b, point 3**). The layout of **Figure 6 b** allows having an overview of the best solution identified and its improvement or worsening through Italian territory. Furthermore, evaluations of all thermal parameters according to UNI EN ISO 6946:2008 and UNI EN ISO 13786:2008 using spreadsheet and comparison evaluation between improved solutions are integrated in this result database.

CONCLUSION

This research paper describes the structure of the TIMBEEST interactive tool. Since the research project is an on-going research till the first half of the year 2015, the database presented is not completed and is going to be continuously updated. Thereafter, the results of dynamic and structural dynamic simulation will be integrated in the database of the second phase in order to evaluate the percentage of gained improvement in structural and energy fields. Further steps will determine the environmental footprint of the improved building components to highlight the most sustainable solution towards the improvement of timber building performance during the cooling season. Beyond this information, the database of third phase should be developed entirely and it will aim at summing-up the research results.

The TIMBEEST interactive tool proved to be a useful support during different steps of research project. Data collected in various databases, but managed by one UI will allow researchers and professionals to manage and evaluate correctly and quickly the timber building components both from energy and from seismic point of view across the Italian territory during the design phase. Furthermore, considering future development of the project, researchers, who will be in charge of the development of new contents, can easily consult output data and even implement them. Such tool is used also as a controlling tool in order to check possible errors because of huge amount of data and intersection between them. Since the GIS software allows visualising data in the form of maps, errors are immediately highlighted in order to improve research methodology.

ABSTRACT

"Baixa Pombalina", the downtown and historic district of Lisbon is one of the most important pieces of urbanism and architecture ever built in Portugal, and is at present time a UNESCO World Heritage nominate. Those Buildings were built after the great earthquake of 1755, for housing, commercial, and services` functions. And they constitute a rational and functional approach for health and comfort to their residents, translating the state-of-the-art of architecture at the time, through the use of lighting and natural ventilation. In this research study, buildings of "Baixa" are observed as a scenario where residents of 21st Century live in spatial and built structures of 18th Century. This paper is about environmental controls within current thermal and lighting performance of "Baixa Pombalina" Buildings. It analyses the efficacy of those buildings from the passive design point of view, as well as the habits of its occupants in controlling and regulating the devices available in "Baixa" buildings at present time. A questionnaire model was developed to study bioclimatic performance of offices, and residences selected in "Baixa". And field work involved a survey where workers of fifteen offices and residents of five houses have participated. Results demonstrate that in buildings of Baixa, controls are used less interactively during winter season and more interactively during summer season. Results indicate that in the Lisbon climate, it is mainly during the summer season that controls have a major role in thermal performance of these inheritage buildings.

Keywords: Baixa Pombalina, Building Performance, Environmental Controls, Comfort and Occupancy.

INTRODUCTION

This Paper analyzes actions of control by current users in buildings of "Baixa Pombalina", which are inheritage buildings built in the 18th Century. The goal of this study is to understand these buildings and their diversed systems in the context of current habits of usage and control.

According to a current notion of Sustainability, construction shall ensure bioclimatic and global human comfort, in buildings and urban spaces; sustainable use of construction materials and environmental technologies in buildings (Pinheiro, 2006). The project and work of "Baixa Pombalina" fall in many contemporary concepts of sustainability. When Baixa buildings were designed, in the 18th Century, lighting, heating and cooling were essentially provided by natural light and ventilation. These buildings were built in a time before the use of mechanical lighting and HVAC systems, and are therefore Architecture with capability to ensure energy efficiency. However, during 20th Century, occupancy density was increased and HVAC mechanical devices were introduced, changing the thermal performance of buildings, and the actions and habits of its users before the available controls.

Author A is a Doctor graduated by the Department of Architecture, Civil Engineering, and Georesources of Instituto Superior Técnico of the University of Lisbon, Portugal. Author B is a professor in the Department of of Architecture, Civil Engineering, and Georesources of Instituto Superior Técnico of the University of Lisbon, Portugal.

This Paper provides an overview of actions taken by users: with regard to the use of controls introduced in these buildings, e.g. mechanical devices, as well as actions to use the original controls of these buildings, e.g. windows to regulate natural ventilation.

URBAN AND ARCHITECTURAL CONTEXT

"Baixa Pombalina" is located in the historic city center of Lisbon, near "Tejo" River and between hills. After the Great Earthquake of 1755, the area was rebuilt according to the 1758 Plan. And their buildings are called "Pombalino Yield Buildings" ("Prédio de Rendimento Pombalino"), and have similar architectural features and are grouped into blocks.

Figure 1 *(a) View of "Pombalino" Buildings of Baixa and (b) Aerial view of "Pombalino" blocks and (c) View from inside the inner yards of Baixa (photos: author).*

The block improves buildings' salubrity with wider spaces between buildings in order to ventilate and to illuminate. The use of the shape of rectangular block allowed two fronts separated by an inner yard, and also, a large perimeter of the façade. Blocks are of two types: The first are arranged longitudinally with the axis in the direction North-South, and occupy most part of the urban grid. The latter blocks are arranged transversely, with the axis in the direction East-West, in the Southern part of the Plan, interrupting the progression of secondary streets to Trade Square ("Praça do Comércio"). Directions have a torsion of 16,5º to the North axis, making the Southeast oriented façades differ in only 1º of the optimal benchmark tortion of 17,5º to the North axis, recommended by Olgyay (1963) for temperate climates.

An inner yard ("saguão") in the core of the block separates two rows of the lot. For reasons of salubrity, an inner yard was introduced in the block, three metres wide, allowing aeration by ventilation and natural lighting to the interior of buildings. The inclusion of the inner yard ("saguão") in the block allows a larger passive area, i.e., area that allows to be lit and naturally ventilated, according to the LT Method (Baker & Steemers, 2000).

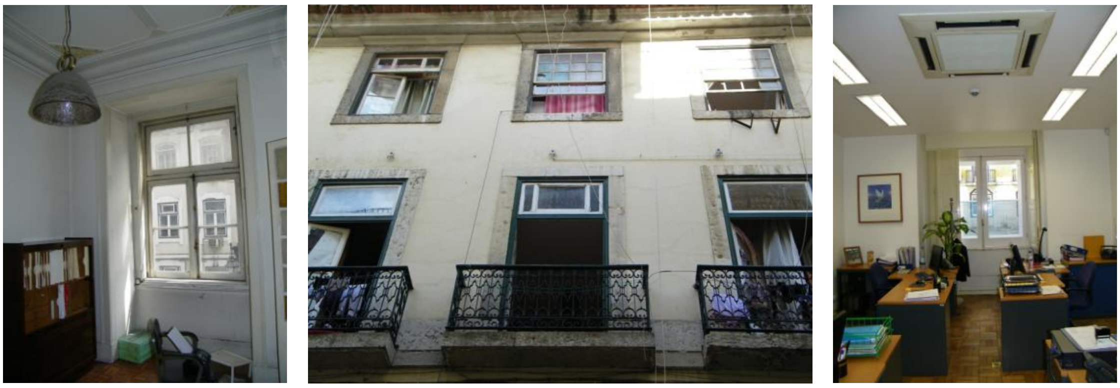

Figure 2 *(a) View of example of an exterior masonry wall and (b) Open windows of different types in a "Pombalino" building and (c) Example of the air conditioned system in offices in "Baixa" (source: author).*

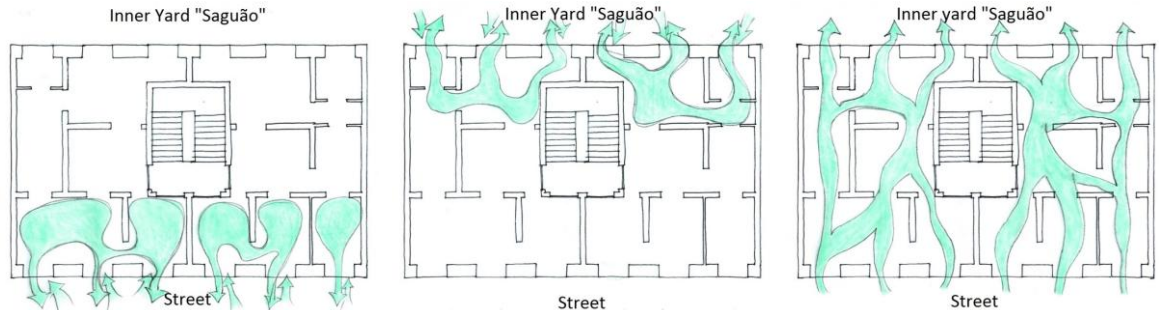
In buildings of Baixa, the main construction elements responsible for thermal inertia are the exterior walls, due to its thickness, the weight, and due to the inherent coefficient of thermal storage. Consisting of stone masonry wall with lime mortar coating, with approx. 0,60m total thickness (Mascarenhas, 2004), **illustrated in Figure 2a**.

According to an analysis carried out from the available drawings (CML, 2005) the original windows were double-hung sash windows, which allowed a position of fixed aperture, and casement windows which had top-hung casement windows. Window types allowed to diversify the type of ventilation. These types of window are **exemplified in Figure 2b**.

In some residences and offices of Baixa, air conditioning devices were introduced. Air conditioning systems were usually introduced in spaces of small or medium sizes, where each space division has its own device, **exemplified in Figure 2c.**



a) b) c)

Figure 3 *(a) Scheme Plan of single-side ventilation that occurs with the windows open in the street façades and (b) scheme of single-side ventilation that occurs with the windows open in the inner yard ("saguão") façades and (c) scheme of cross ventilation that occurs with open windows in the street and inner yard ("saguão") façades (source: author).*

Baixa's interior units consist of a row of rooms with windows to the side of the street, and a row of rooms with windows to the side of the rear, to the inner yard ("saguão"). Thus, Baixa's buildings provide the possibility of having naturally ventilated rooms, in a varied way. Having windows on one side and the other allows various combinations: To open windows on the street side (only), on the rear side (only), or both. And it opens up possibilities of practicing various types of ventilation – single-side, cross, stack effect, as well as night-time ventilation, **as shown in Figure 3**. The ventilation strategy is a major bioclimatic strategy currently recommended for the Lisbon climate (Gonçalves & Graça, 2004).

THERMAL ENVIRONMENT

Lisbon has a unique variant of the typical Mediterranean climate due to its proximity to the Atlantic Ocean (Ribeiro, 1987). In the center of Lisbon, according to the climatic normal, the monthly average temperature in January is 11.0 ºC and in August is 22.3 °C. The minimum temperature is -2.8 ° C in February and the maximum temperature is 39.5 °C in July. In what regards to relative humidity (RH), the minimum value is 60% in August, and the maximum value is 87% in December (IM 1981).

The following chart of **Figure 4 shows** monitoring values registered with datalogger devices during a year, of a selected building, used as office, and representative of the thermal environment of "Pombalino Yield buildings". Results are presented according to the months of the year. The following chart is organized by data logger device that have registered indoor temperatures in a room with mechanical system off, simultaneously with outside temperatures.

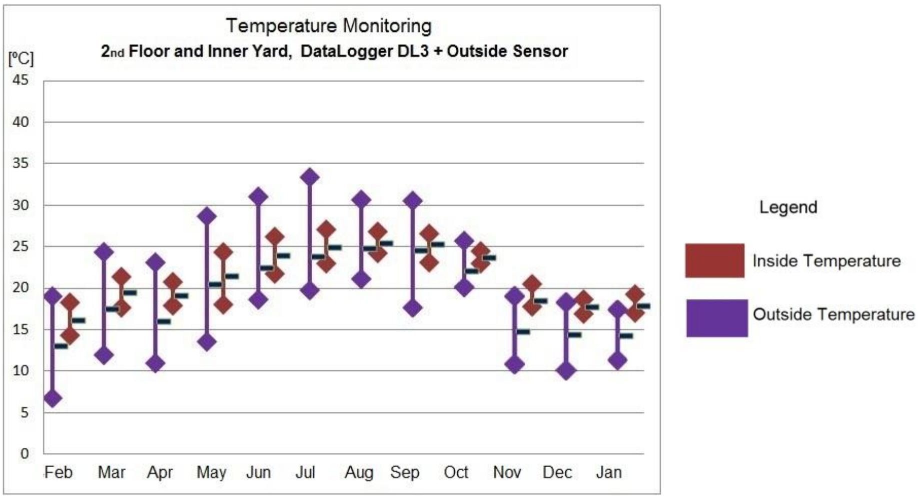


Figure 4 *Chart measuring averages, minimum and maximum temperatures registered in a room with mechanical system off, and outdoor spaces of the case study building.*

The previous graph in **Figure 4 shows** that when outside temperatures vary between 5ºC and 34,5ºC, indoor temperatures vary between 14ºC and 28ºC with the system off. It can be observed that during certain months of the year – from May to October - the average temperatures are within the range of 20ºC to 26ºC. - This means that during these months, average temperatures are within the limits of conventional comfort.

METHODOLOGY

A survey was conducted among subjects who live or work in Baixa, in Lisbon. The study was conducted in 20 fractions in 19 diverse buildings of Baixa, in housing and office spaces. Offices range from small private offices to large offices of Governmental Ministries and Institutes. 130 subjects were surveyed during the winter season, and 119 subjects were surveyed during the summer season, in a total of 249 subjects. 18 fractions were observed during each season of winter and summer of 2009. The variety of office and housing situations - in function, type of building, type of floor fraction, size, and location - is representative of the variety that exists in Baixa.

The evaluation was based on a survey, whose model was specifically developed for users of Baixa buildings, in Lisbon. The survey consists of a questionnaire to be answered based on their experience while users who live or work in those selected buildings.

In order to obtain an overview of actions of control applied by users, an analysis of frequency of actions applied by subjects surveyed was conducted, in what regards to:

1. Use of existing mechanical devices.
2. Opening windows, in duration, and spatial distribution.

And a comparison between the actions committed by users during the seasons of winter and summer was conducted.

In this sample, there is a higher percentage of respondents in the office function (95%) than in the residential function (5%). – Because there has been a greater availability from offices than by residences to participate in this study.

The study is focused on the use of windows and mechanical devices because those are the most used environmental controls that were observed in this study. Furthermore, currently most of Baixa's interior units have air conditioning. Although the use of shading devices was also observed during this research, this paper is focused on analyzing the use of windows and mechanical devices, being the main environmental controls used in buildings of Baixa at present time.

It was chosen to divide the study in winter and summer seasons, being the most representative of the opposite extreme situations that influence spaces during the year: Cold and dark compared to warm and bright climates.

DISCUSSION OF RESULTS

Heating and Cooling Mechanical Devices

The following **Tables 1 and 2 show** the frequency of periods of use of heating and cooling devices, in winter and summer seasons, respectively. Periods described correspond to a progression in time duration of use of mechanical devices.

Table 1. Frequency of Periods of Use of Heating Devices - Winter.

Periods	Frequency [%]
Never / NA	6,6 %
Punctually	9,9 %
Only on the coldest days	20,7 %
A few times per Winter	9,1 %
A few times per week	2,5 %
A few times per day	17,4 %
Almost always "on" during most of the Winter	33,9 %

Table 2. Frequency of Periods of Use of Cooling Devices - Summer.

Periods	Frequency [%]
Never / NA	2,6 %
Punctually	3,5 %
Only on the hottest days	9,6 %
A few times per Summer	2,6 %
A few times per week	1,8 %
A few times per day	25,4 %
Almost always "on" during most of the Summer	54,4 %

It can be observed in **Tables 1 and 2** that most of respondents turn on heating devices in Winter in the period "during most of the Winter", followed by "only on the coldest days". In summer, most of respondents turn on cooling devices in the period "during most of the summer", followed by "a few times per day".

Comparing both seasons, it can be observed that while in Winter the majority of respondents use the mechanical devices in the periods "almost always on" and exceptionally on ("only on the coldest days"), in Summer most of respondents use devices in periods "almost always on" and "a few times per day”, revealing the habit of having the cooling devices “on” during most of the Summer. Hence, one can conclude that the use of heating devices in winter presents different periods of use, depending on the type of building’s units. In a different way, in summer, the use of cooling devices is intensive, including AC devices (Air Conditioning devices, the most used), which are almost “on” during most of the season.

Natural Ventilation through opening of Windows

The following **Tables 3 and 4 show** the frequency of periods of opening windows, in winter and summer seasons, respectively. Periods described correspond to a progression in time duration of open windows.

Table 3. Frequency of Opening Windows in the Winter Season.

Period	Frequency [%]
Never	34,9 %
Punctually	43,7%
Morning / or Afternoon	13,5 %
Morning + Afternoon / or during the Night	6,3 %
Always	1,6 %

Table 4. Frequency of Opening Windows in the Summer Season.

Period	Frequency [%]
Never	16,4 %
Punctually	35,3%
Morning /or Afternoon /or Evening	21,6 %
Morning + Afternoon / or during the Night	21,6 %
Always	5,2 %

In Table 3, it can be observed that in the winter, the majority of subjects open windows “punctually” (43,7%) followed by “never” (34,9%). **In Table 4**, it can be observed that in the summer, the majority of subjects open windows “punctually” (35,3%) followed by isolated periods during the morning, or the afternoon, or in the evening (21,6%) or during all day or all night (21,6%). There are 16,4% of subjects that never open windows and 5,2% that has windows always opened.

The following **tables 5 and 6 show** the percentages of distribution of open windows, in winter and summer seasons, respectively.

Table 5. Distribution of Open Windows in Winter Season.

Distribution of Opening	During the Day	During the Night
Street and Rear	3,1 %	0 %
Only Street	44,1%	1,0%
Only Rear	12,6 %	1,0 %
No Opening	40,2 %	65,0 %
NA	0 %	33,0 %

Table 6. Distribution of Open Windows in Summer Season.

Distribution of Opening	During the Day	During the Night
Street and Rear simultaneously	13,9 %	2,9 %
Street and Rear alternate	7,8 %	1,0 %
Only Street	40,0 %	3,8 %
Only Rear	10,4 %	3,8 %
No Opening	26,1 %	45,2 %
NA	1,7 %	43,3 %

Table 5 shows that in the winter season, there is a large proportion of all subjects who does not open any window (40,2%). From those who open windows, most of subjects do it in the street side of their space (44,1%), followed by "only” in the rear side (12,6%). And it can be observed that subjects rarely open windows in the street and rear sides simultaneously (3,1%). A possible explanation is to prevent the drafts of cooling air and unwanted air in winter time.

It is observed in **Table 6** that in the summer, total of subjects open windows on street side primarily (40%), followed by "no opening" (26,1%) and "street and rear simultaneously" (13,9%). One possible explanation for the windows opening is to give rise to types of single-side ventilation or cross ventilation within the space allowing cooling and air renewal.

It is observed that generally, subjects do not open windows during the night in summer, which could be a strategy to cool the building fabric. This occurrence can be explained by the sample, which is mainly focused in the office function, where it has been observed that subjects do not leave windows open during the evening, i.e., outside working time. It has been described by subjects in residences that in summer, most of subjects have windows always open, during daytime and nighttime, as opposed to subjects in offices, that generally have windows open during daytime only.

These observed frequencies are partially explained by the widespread recurrence of mechanical devices, particularly during the summer season. This higher recurrence affects how windows are used. And to analyze these buildings' natural performance, it makes difficult to understand how the performance of these buildings would be without the use of mechanical appliances. One question that arises is whether if there were no air conditioning devices, how would be these buildings' use. And once not being able to use such devices, if there would be a more intensive use of other means that are available to regulate temperature, such as windows, shades or doors.

The observed use frequencies of mechanical appliances and windows can be explained by the sample, which is mainly focused in the office function and less in the residential function. The office function has a considerable density of occupancy and equipment producing internal heat gains, to which users respond turning on the mechanical appliances. This higher recurrence affects how the windows are used.

One can argue about the changing behavior of users of these buildings in the present context, where mechanical devices are available, as compared to the time when these buildings were constructed. Leads to formulate, as hypothesis, that users are not prepared to work with higher temperatures. Maybe because they are not used (anymore) to use all available controls: Users do not have a regular habit of opening windows. And in a simplified way, they are mainly restricted to the use of mechanical devices, neglecting the remaining environmental controls, such as windows or shading.

This complementarity of resources (natural + mechanical) is an important issue in the relationship between the regulation of mechanical equipment and windows. One may question whether this complementarity comes from compensation **-** triggered by the unnaturalness of mechanical controls, and one tries to compensate the thermal environment and air quality by opening windows, bringing natural air. Or one may ask if this complementarity is a correction **-** triggered by any fluctuation in temperature during the day, and while using mechanical controls, one tries to fix temperature by opening windows.

CONCLUSION

Regarding the thermal performance, it can be observed from analysis of the survey responses that generally:

1. Users turn on mechanical appliances in a greater frequency in summer than in winter;

2. Users open windows more often in summer than in winter.

3. Users open windows with greater distribution variety in the summer season than in the winter season.

After the analysis of results, it can be concluded about how buildings are used by users in each season:

4. In winter, subjects use less frequently heating devices, as well as the remaining elements to regulate temperature – They have a less interactive attitude - They use environmental controls to regulate temperature less frequently.

5. In summer, subjects use more frequently cooling devices, as well as the remaining elements to regulate temperature – They have a more interactive attitude – They use environmental controls to regulate temperature more frequently.

In winter, buildings of “Baixa”, in what regards to their controls are used less interactively. In this season, users use less frequently buildings’ original controls. And in the event of using controls, they use more frequently heating appliances. It must be noted that once, these buildings had fireplaces, that were meanwhile removed, and are now practically nonexistent. Over the years, the fireplace was replaced by heating devices.

In summer, architectural elements are used more interactively. In this season, most users use buildings’ original controls, such as windows. And users use more frequently cooling devices. It is observed that in summer, there is a greater effort than in winter, in using all means of temperature regulation available, such as windows. And in the event that users recur to air conditioning devices, they also use other controls to regulate temperature, such as opening windows (although it is not recommended to be used simultaneously because of conflict with AC). Architectural elements as a mean of temperature regulation are mainly used in the summer season. And it is an indication that under the climate of Lisbon, it is mostly in the summertime that controls have a greater role to play in these buildings in Baixa.

ACKNOWLEDGEMENTS

The authors wish to thank:

To all those who generously participated in the survey conducted in Baixa, providing their offices, their homes, and their time.

Development of a Window Opening Algorithm to Predict Occupant Behavior in Japanese Houses

Hom B. Rijal, PhD
Tokyo City University
rijal@tcu.ac.jp

Michael A. Humphreys
Oxford Brookes University

J. Fergus Nicol
Oxford Brookes University

ABSTRACT

We investigated window opening behaviour and the thermal environment over a period of more than 3 years in the living rooms and bedrooms of dwellings in the Kanto region of Japan. We collected over 32,000 data-samples from 243 residents of 121 homes. The proportion of 'open window' in the free running mode is significantly higher than that in the cooling and heating modes. The window opening is related to the indoor or outdoor air temperature. Window opening behaviour as predicted by logistic regression analysis is in agreement with the measured data. These findings can be applied to develop an adaptive algorithm for window opening behaviour in Japanese residences.

INTRODUCTION

Natural ventilation from opening windows has been decreasing in houses in recent years because of the increasing prevalence of mechanical ventilation and air-conditioning. However, temperature control by opening and closing windows can reduce environmental impact by minimizing the period of the year when air-conditioning is needed.

There has been more research into window-opening behaviour in offices (Rijal et al. 2007~2012, Yun & Steemers 2007, Robinson & Haldi 2008, Kim et al. 2009, Haldi & Robinson 2010) and university buildings (Suzuki et al. 2002, Umemiya & Yoshida 2004) than in dwellings (Dick & Thomas 1951, Asawa et al. 2005, Kubota 2007, Rijal et al. 2013). The findings from research in offices and universities cannot be assumed to apply to dwellings, where people's behaviour is less constrained. There is evidence that people respond differently in their own homes for a number of reasons, social, economic and cultural (Oseland, 1995). Thus it was necessary to conduct research also on residential window opening behaviour.

To explore window opening behavior and develop a window opening algorithm for Japanese residences, thermal measurements were made and an occupant behavior surveys conducted over a period of more than 3 years in the living rooms and bedrooms of dwellings in the Kanto region of Japan.

METHODOLOGY

Thermal comfort surveys and thermal measurements were conducted in 121 houses in Kanto region (Kanagawa, Tokyo, Saitama and Chiba) of Japan from 2010 to 2013 (Table 1). The detail of surveys 1, 2

A Hom B. Rijal is an associate professor in the Department of Restoration Ecology & Built Environment, Tokyo City University, Japan. Michael A. Humphreys is an associate of Oxford Brookes University and J. Fergus Nicol is emeritus professor at Department of Architecture, Oxford Brookes University, UK..

and 4 can be found in Rijal & Yoshimura (2011), Katsuno et al. (2012) and Rijal et al. (2014) respectively.

Indoor air temperature and relative humidity were measured in the living rooms and bedrooms, away from direct sunlight, at ten minute intervals using a data logger (Fig. 1). The globe temperature was also measured in the living room in surveys 3, 4 & 5. Outdoor air temperature and relative humidity were obtained from the nearest meteorological station.

The number of subjects was 119 males and 124 females. Respondents completed the questionnaire several times a day in the living rooms and twice in the bedrooms ("before go to bed" and "after wake-up from the bed") (Table 2). The thermal comfort survey was conducted several times a day using seven-point thermal sensation scales (Table 2). The window opening behaviour was recorded in binary form (0 = window closed, 1 = window open). We have collected over 32,000 samples.

Table 1. Description of survey

Survey	Survey period		Surveyed room	Measured variables*	Number of houses	Number of subjects			Number of votes	
	Start date	End date				Male	Female	Total	Living room	Bedroom
1	06-7-2010	18-7-2011	Living, Bed	T_i, RH_i	11	16	14	30	3299	2558

RESULTS AND DISCUSSION

3.1 Distribution of indoor and outdoor temperatures during voting

Table 3 shows the mean and standard deviation of the indoor and outdoor air temperature in each mode. Fig. 2 shows the monthly mean outdoor and indoor air temperature in FR mode in living room and bedroom. The mean outdoor air temperatures during the voting were 19.5 °C, 27.6 °C and 7.2 °C for FR, CL and HT modes respectively (Fig. 2). The mean indoor air temperatures at the time of voting were 24.2 °C, 27.3 °C and 19.2 °C for FR, CL and HT modes respectively. The Japanese government recommends the indoor temperature settings of 20 °C in winter

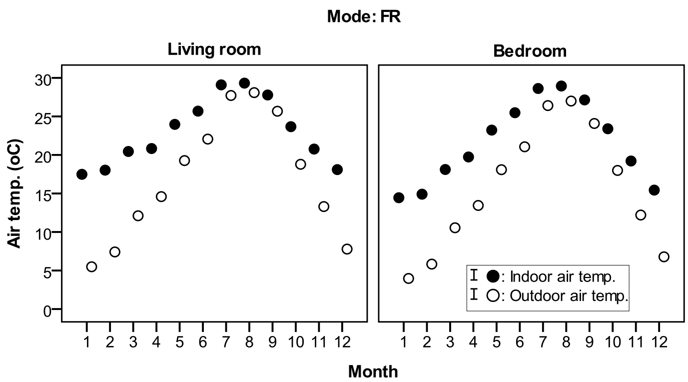

Figure 2 Monthly mean outdoor and indoor air temperature in FR mode.

and 28 °C in summer respectively. The results showed that the mean indoor temperatures during heating and cooling were close to the recommendation. The mean indoor and outdoor temperature difference was 4.7 K, -0.3 K and 12.0 K for FR, CL and HT modes respectively. The results show that the seasonal difference of the indoor air temperature is quite large, and that the data represent a wide range of outdoor temperature.

Table 3 Indoor air temperature and proportion of open windows in various modes

Mode	Room	Outdoor air temp. (°C)			Indoor air temp. (°C)			Window opening		
		N	Mean	SD	N	Mean	SD	N	Mean	SD

HT	All	2,982	7.2	4.2	2,960	19.2	2.9	3,050	0.00	0.03

N: Number of observation, SD: Standard deviation

3.2 Evaluation of window opening behaviour

3.2.1 Status of window opening (WO)

To understand the window opening behaviour, the mean proportions of ‘window opening (WO)’ are compared. Table 3 shows the mean and standard deviation of the windows open in each mode. The mean WO is 0.39, 0.03 and 0.00 for FR, CL and HT modes respectively. The mean window opening in living room is higher than in the bedroom (Table 3). Interestingly, the mean WO in UK office buildings was 0.70 in NV mode and 0.04 in AC mode (Rijal et al. 2007). The mean window opening in Pakistan office and commercial buildings was 0.33 in NV mode. The results showed that the mean windows open is close to the Pakistan value and lower than the UK value. We shall limit the analysis to the FR mode.

Season, month and time of the day

Seasonal and monthly difference in proportion of windows open in FR mode is shown in Fig. 3. The proportion of open windows (WO) is highest in summer and lowest in winter. The WO in autumn is significantly higher than that in spring. This is possibly due to the fact that people are more adapted in spring to the winter low temperature, and in autumn to the summer temperature. In reality, the indoor and outdoor air temperatures in autumn are higher than in the spring (Fig. 3(b)).

Evidently, the proportion of open windows gradually increases towards the summer months (Fig. 3(c)). Conversely, it gently decreases towards the winter months as indoor or outdoor air temperature varies (Figs. 2).

The data were divided into four groups, in ascending order of time. Interestingly, the proportion of open windows gradually increases during the morning, and then decreases towards the evening (Fig. 4(a)). Most of occupants open the windows in the morning and shut them at night. These trends are similar for all seasons (Fig. 4(b)).

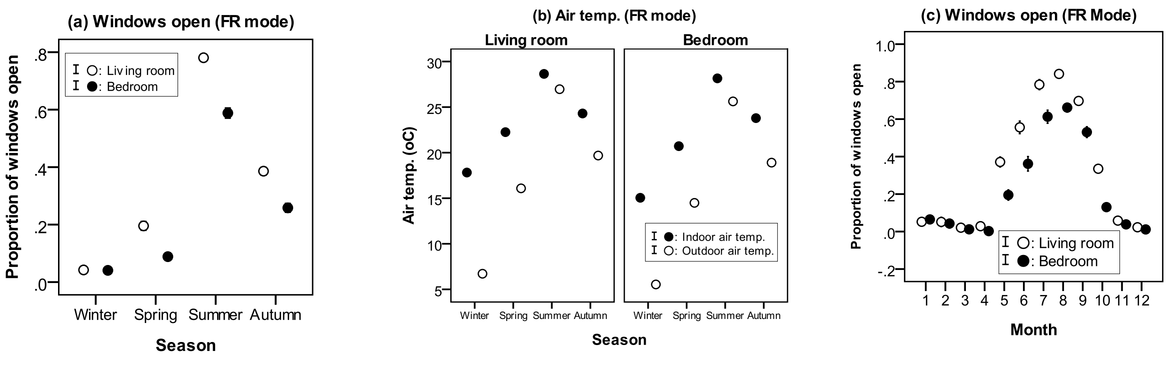

Figure 3 The proportion of open windows, indoor and outdoor air temperature (at 95% confidence level)

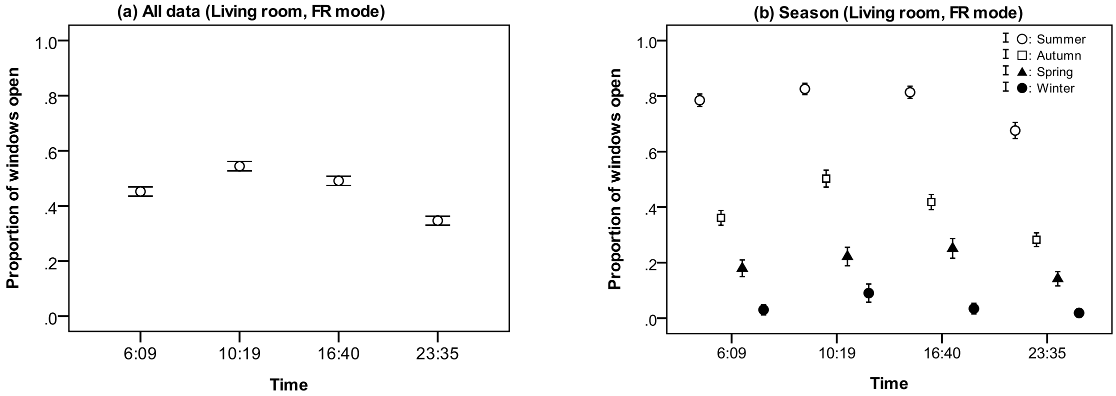

Figure 4 Proportion of open windows at 95% confidence intervals of time of day in living room.

3.2.3 Relationship between the open windows and air temperature

In FR mode the open window correlated better with the outdoor temperature than with the indoor temperature (Table 4). The correlation coefficient for the living room is higher than for the bedroom. From these observations, it can be inferred that the window opening is related to both indoor and outdoor air temperatures.

Fig. 5 shows the proportion of open windows and the corresponding temperatures. The data were divided into ten groups, in an ascending order of temperature. The proportion of the window opening rises as the indoor globe or outdoor air temperature rises. The proportion of window opening in the livingrooms is higer than in the bedrooms. When mean indoor air temperature is 27.1 °C, the proportion of open windows is 0.63 in living room and 0.51 in bedroom (Fig. 5(a)).

When the mean outdoor air temperature is 24.3 °C, the proportion of windows open is 0.71 in livingrooms and 0.58 in the bedrooms (Fig. 5(c)). These proportions are similar to the Pakistan study (Rijal et al. 2008), and significantly lower than that of the UK study (Rijal et al. 2007). This is perhaps because the indoor and outdoor air temperature in Japan and Pakistan are condiderably higher than that in the UK.

Table 4. Correlation coefficients in FR mode

Room	Items	Window: T_i	Window: To	T_i: T_o
Liivingroom	Correlation coefficient (r)	0.58	0.62	0.87
	Number of samples (N)	13,289	13,382	13,352
Bedroom	Correlation coefficient (r)	0.46	0.50	0.89
	Number of samples (N)	8,946	9,000	8,997
All	Correlation coefficient (r)	0.53	0.58	0.88
	Number of samples (N)	22,235	22,382	22,349

T_i: Indoor air temperature (°C), T_o: Outdoor air temperature (°C) All correlations are significant (p<0.001)

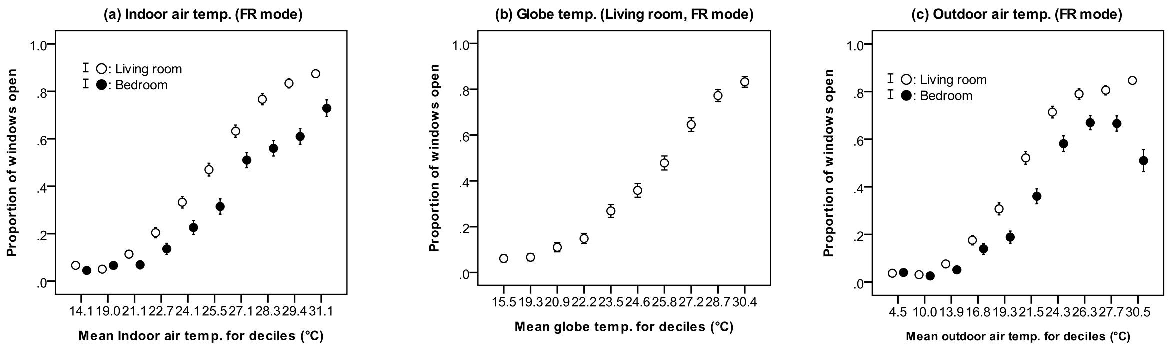

Figure 5 Proportion of open windows with 95% confidence intervals at deciles of temperatures.

3.3 Potential of the open window

3.3.1 Indoor air temperature

Fig. 6 and Table 5 show the seasonal variation in indoor air temperature for cases when windows are open and closed. The mean indoor air temperature for the window open condition is 27.7 °C in the livingroom which is significantly higher by 5.3 K, than for the window closed condition. In UK office buildings, the mean globe temperature for the window open condition is 23.4 °C which is 1.2 K higher than when the window is closed (Rijal et al. 2008a). Thus, the temperature difference between the cases of open and closed window in residential buildings is higher than that of the office buildings. The temperature difference is highest in autumn. In winter, the mean indoor air temperature for the 'open window' case is significantly lower than that of the 'closed window' case. The results showed that window opening is an effective way to control the indoor thermal environment.

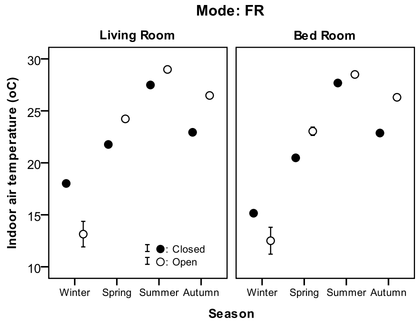

Figure 6 Seasonal variation of indoor air temperature for windows open and closed in FR mode.

Table 5. Indoor air temperature for windows open and closed

Season	Window	Indoor air temperature T_i (°C)									
		Living room					Bedroom				
		N	Mean	SD	t*	Open-Closed	N	Mean	SD	t*	Open-Closed

*All open/closed temperature differences are statistically significant ($p<0.001$)

3.3.2 Comfort temperature

The potential of the open window is further analyzed in the context of comfort temperature. The comfort temperatures were obtained by the Griffiths' method (Griffiths 1990, Nicol et al. 1994, Rijal et al. 2008, Humphreys et al. 2013, Rijal et al. 2014).

$$T_c = T_i + (4 - C) / a^* \quad (1)$$

T_c is the comfort temperature by Griffiths' method (°C), T_i is the indoor air temperature (°C) and a* is the regression coefficient (=0.50).

Fig. 7 and Table 6 show the seasonal variation in comfort temperature with windows open and closed. The mean comfort temperature for window open is 26.5 °C in living room which is 3.7 K higher than that of the case of window closed. Brager et al. (2004) found 1.5 K higher comfort temperature for the people with an access to window operation than the group

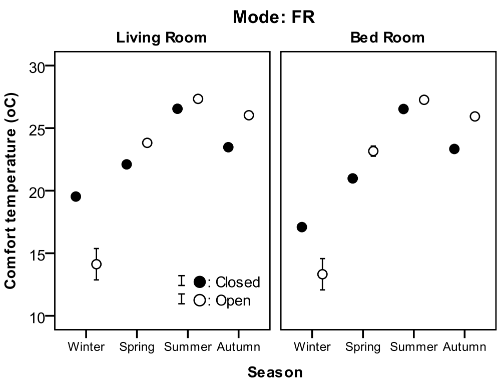

Figure 7 Seasonal variation of comfort temperature for windows open and closed in FR mode.

without in office buildings. The temperature difference is highest in autumn. In winter the mean comfort temperature for the open window condition is significantly lower than for the window closed condition. The results showed that window opening is effective to create the comfortable thermal environment.

Table 6. Comfort temperature for windows open and closed

Season	Window	Comfort temperature T_c (°C)									
		Living room					Bedroom				
		N	Mean	SD	t-value*	Open-Closed	N	Mean	SD	t-value*	Open-Closed

*All open/closed temperature differences are statistically significant ($p<0.001$)

3.4 Development of an algorithm to predict window opening behaviour

3.4.1 Logistic regression curves

In the previous section, we analyzed the window opening behaviour based on field data and confirmed some general behavioural trends, but no attempt was made to predict the occupant behaviour in housing (Rijal et al. 2013). Such predictions are needed for the thermal simulation of buildings.

Nicol and Humphreys (2004) made use of Probit analysis to predict occupant control behaviour in NV buildings. For mathematical convenience they used a Logistic distribution in place of the Normal distribution. The relationship between the probability of windows open (p) and the indoor or outdoor temperature (T) is of the form:

$$\text{logit(p)} = \log \{p/(1–p)\} = bT + c \quad (2)$$

$$p = \exp^{(bT+c)}/\{1+\exp^{(bT+c)}\} \quad (3)$$

and where exp (exponential function) is the base of natural logarithm, b is the regression coefficient for T, and c the constant in the regression equation.

We have adopted the same method here, using SPSS version 19 for the calculations. The Logistic regression equations, based on the indoor or outdoor temperature, are shown in Fig. 8. The following regression equations were obtained in between the windows open and the indoor or outdoor air temperature:

Living room

$$\text{logit(p)}=0.394T_i - 10.144 \quad (n= 13,289, R^2=0.34, S.E.=0.007, p<0.001) \quad (4)$$

$$\text{logit(p)}=0.372T_g - 9.659 \quad (n=9,833, R^2=0.29, S.E.=0.008, p<0.001) \quad (5)$$

$$\text{logit(p)}=0.258T_o - 5.675 \quad (n=13,382, R^2=0.38, S.E.=0.004, p<0.001) \quad (6)$$

Bedroom

$$\text{logit(p)}=0.291T_i - 8.100 \quad (n=8,946, R^2=0.24, S.E.=0.008, p<0.001) \quad (7)$$

$$\text{logit(p)}=0.206T_o - 5.113 \quad (n=9,000, R^2=0.26, S.E.=0.005, p<0.001) \quad (8)$$

All data

$$\text{logit(p)}=0.349T_i - 9.235 \quad (n=22,235, R^2=0.30, S.E.=0.005, p<0.001) \quad (9)$$

$$\text{logit(p)}=0.238T_o - 5.466 \quad (n=22,382, R^2=0.34, S.E.=0.003, p<0.001) \quad (10)$$

T_i: Indoor air temperature (°C), T_g: Globe temperature (°C), T_o: Outdoor air temperature (°C), n:

sample size, S.E.: Standard error, *p*: Significance level of the regression coefficient, R^2: Cox and Snell R^2.

A regression coefficient of 0.349 is obtained when the indoor air temperature is the predictor. This is higher than that obtained when the outdoor air temperature is used. In the Gifu region of Japan (Rijal et al. 2013), regression coefficients of 0.248 and 0.210 respectively were obtained with indoor or outdoor temperature. In Pakistan (Rijal et al. 2008) and in UK (Rijal et al. 2007) studies, regression coefficients of 0.176 and 0.354 respectively were obtained with indoor globe temperature is the predictor. In Kyoto (Majima et al. 2007) and UK (Rijal et al. 2007) data returned the regression coefficients of 0.119 and 0.181 respectively with outdoor air temperature is the predictor. The regression coefficient in the living room is slightly higer than the bedroom. The predicted window opening is well matched with measured values (Fig. 8).

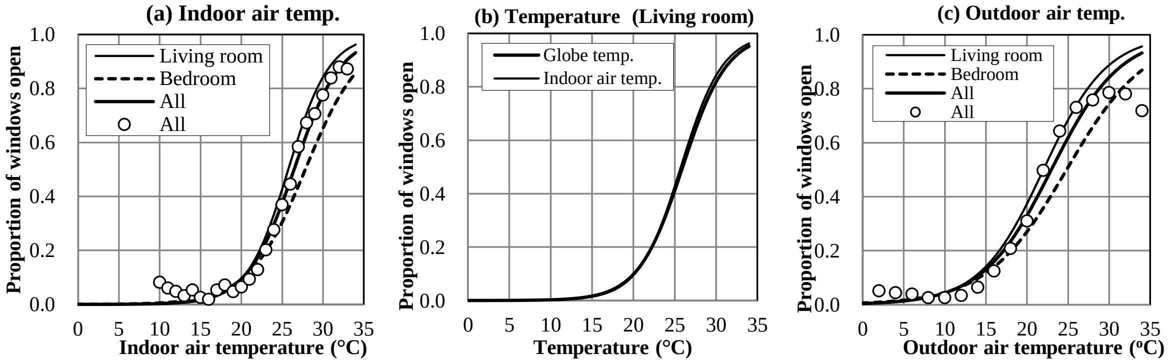

Figure 8 Comparison of measured (open circular dots) and predicted value (curved line) in NV mode. Measured values were grouped for every 1 °C for indoor air temperature and for every 2 °C for outdoor air temperature. The grouped data for samples less than 100 are not shown.

CONCLUSIONS

We have investigated the window opening behaviour and corresponding thermal environment over a period of more than 3 years in the living rooms and bedrooms of dwellings in the Kanto region of Japan and the following results were found:

1. The proportion of the window opening in the free running mode is significantly higher than that of the cooling or heating modes.
2. The window opening is related to the indoor and outdoor air temperature in the free running mode.
3. The window opening behaviour is predicted based on indoor and outdoor air temperature using logistic regression analysis. The predicted window opening matched well with that of the measured value.

ACKNOWLEDGEMENTS

We would like to thanks to all people who participated in the survey, to Kawamoto Industries, Ltd, Japan for their cooperation and to all students for data entry. This research was supported by Grant-in-Aid for Scientific Research (C) Number 24560726 and (B) Number 25289200.

ABSTRACT

The present work is to understand the impact of setpoint temperature and coefficient of performance (COP) of a cooling system on cooling energy consumption, and its effect on thermal comfort of occupants in office spaces for the different climate zones of India. The occupants' thermal comfort sensation is addressed here by the PMV (Predicted Mean Vote) index. The investigation of the mutual relationship between thermal comfort and energy demand is of the foremost importance to define the benchmarks for calibrating the energy use in office buildings. The first approach of this study is associated with the thermal comfort optimization and the second strategy includes energy consumption minimization while maintaining adequate thermal comfort. Results from the parametric energy simulation of a typical open plan office building are presented for different cases in order to evaluate the results with variations in cooling setpoint temperature and COP (an indicator of chiller performance). The results indicate there is a scope to reduce cooling energy consumption without compromising thermal comfort. India has a wide range of climatic conditions, hence this research comes up with a comparative analysis of cooling energy savings per unit increase in the cooling setpoint temperature for different climatic zones based on the system efficiency. Looking at the total energy use, this study suggests, the appropriate modulations in the setpoint temperature with respect to its climate zone.

INTRODUCTION

Any building requires energy for many functions like construction, operation and demolition. The main sector for energy consumption is building operation, of which HVAC systems form the most important end-use (Mathews, Botha, Arndt, & Malan, 2001). Buildings consume 33% of total energy in India and this is growing at the rate of 8% per annum (Rawal et al., 2012). Estimates reveal that, total built-up area will increase rapidly, as nearly 66% of the commercial sector is yet to be built by 2030 (Ramesh & Khan, 2013). Energy efficiency in buildings is a critical issue due to the increase in energy costs, energy consumption and the related environmental impacts, especially those related to global warming.

It is therefore, important to realize the energy consumption while regulating the indoor temperature. In the past, the thermal comfort standards was not analysed to optimize energy efficiency (Indraganti & Rao, 2010).Thermal comfort has a significant impact on the productivity of building occupants and it is also important to consider energy consumption with it. Recently, the idea of comfort and good living has been re-defined completely and the building industry responded to this new comfort expectation with vigor. In the last two decades, there has been exceptional increase in demand for air conditioned buildings as perception of comfort is changing rapidly. A building may be designed or retrofitted with energy efficiency measures resulting in substantial energy bill savings. These savings show great loss with respect to workplace inefficiencies, if the occupants are not comfortable(Mathews et al., 2001).

Most published research work deals with common "quantifiable" factors such as temperature, humidity and air velocity etc. However, the state of comfort depends on a wide range of factors, which are "not quantifiable" such as mental status, habits, education of the people etc. Among these factors, the one that is most studied is "acclimatization" to a particular climate. Various studies confirm that preferences/ acclimatization of people in different locations vary. This may result in people of warmer climate having a tolerance to higher temperatures as compared with people in colder region (Corgnati, Fabrizio, & Filippi, 2008; Indraganti & Rao, 2010; Mallick, 1996). There is a need to define comfort range of setpoint temperature according to the context of region and ambient temperature(Indraganti & Rao, 2010).This study attempts to understand the impact of variation in cooling setpoint temperature and chiller coefficient of performance (COP) on energy consumption as well as thermal comfort of occupants in office spaces.

India is a vast country with a variety of geographical features resulting in a multitude of climatic conditions. These have been simplified and categorized into five climatezones – hot and dry, warm and humid, composite, moderate and cold. Detailed characteristics of these zones are provided in the National Building Code of India (Bureau of Indian Standards, 2005). For this study, one representative city from each of these climate zones was identified: Ahmedabad, Chennai, Delhi, Bangalore and Guwahati.

METHODOLOGY

For the purpose of this study, a typical office building was modeled in Design Builder 3.0.0.104 using input parameters obtained through literature study.Simulations were run for five climatic zones mentioned earlier and the roof and floor were treated as adiabatic representing a typical intermediate floor.

Considerations

Thermal comfort depends on four environmental factors – air temperature, mean radiant temperature, air velocity and relative humidity. For the purpose of this study, only air temperature is being varied for the purpose of simulation study and the other parameters are allowed to float as per the variation in temperature. Although the operative temperature thermostat AC system gives more significant results for PMV values, air temperature thermostat is used for this study so as to match it with the conventional practice carried out in India. PTAC system is considered for air conditioning. As this system specification does not allow the humidty to vary considerably at a given temperature. Also variation is too less to impact the PMV values.

Runchart: To understand the influences of setpoint temperature and COP values on thermal comfort and enegy consumption, a pathway or a methodology was planned to gain the required results:

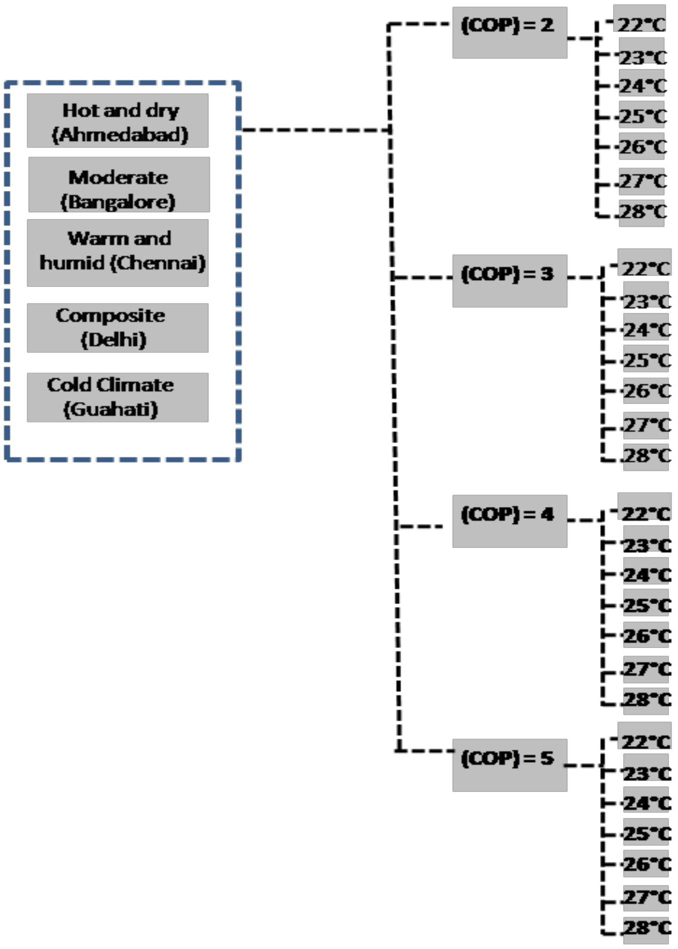

Figure 1 Run chart for simulations

It can be noticed that there are three major and intentional variables (outdoor temperature, COP values and setpoint temperature). For this study, two major outputs: cooling energy consumption and PMV index are analyzed that are obtained from design builder output data sheet.

RESULTS

To resolve the obtained results for comparission of each case, the cooling energy consumption is convertd into EPI (energy performance Index i.e. the ratio of total electricity used in a building to its total built up area. It is expressed as KWh/m^2/annum).

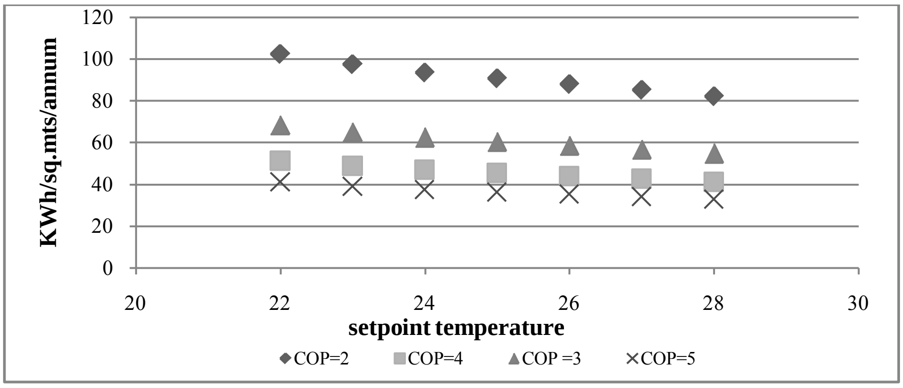

Figure2 *Energy Performance Index for Ahmedabad at particular COP value at Corresponding temperature*

Figure 2 Shows all cases are split into four distinct lines representing cooling energy on 2, 3, 4 and 5 COP value. The case with COP value 2 has the highest cooling enegy consumption and those with COP values 3 and 4 have the lower intermediate values and COP 5 being the lowest. Cooling consumption reduces as the COP value increases, however, this decrement varies drastically. Cooling energy consumption decreases significantly from COP 2 to 3 at particular temerature. The difference of almost 30 units (KWh/m^2/annum) is constant for each setpoint temperature for COP 2 and COP 3. The gradient slope for a single COP value having different setpoint temperature is steep till COP 3, and becomes gentler between COP 4 and the gradient line becomes almost straight for COP 5. This means that cooling consumption becomes nearly constant for higher COP value and there is not much net savings with increase in setpoint temperature. To quantify the same, there is a difference of 21 units of cooling consumption between setpoint 22˚C to 28˚C when COP is 2, however the difference get as low as only 8.0 units for setpoint temperature variations of COP value 5. So it is critical to decide the correct COP value as well for the desired setpoint temperature.

Table 1 EPI at particular Setpoint temperature and COP value for Ahmedabad

SETPOINT/COP	2	3	4	5
22˚C	**103**	68	51	41
23˚C	98	65	49	39
24˚C	94	62	47	37
25˚C	91	61	45	36
26˚C	88	59	44	35
27˚C	85	57	43	34
28˚C	82	55	41	**33**

The values in Table 1 show EPI (KWh/m^2/annum) at respective setpoint temperature and cooling system COP values. It can be seen that the EPI value decreases with increment in the cooling setpoint temperature as well as COP value. Maximum amount of cooling energy consumption per annum takes place at COP 2 and cooling setpoint of 22˚C. And the minimum cooling energy consumed annually for this case is 33 units, for COP 5 and setpoint 28˚C. There is also a reduction in cooling consumption of about 5.0 % annually with 1˚C increment in cooling setpoint. With an increase in COP value at the same setpoint, cooling consumption can be decreased substantially. It decreases by almost 30.0% when COP is changed from 2 to 3. However, chaging COP value from 4 to 5 leads to only 10.0% decrease.

Table 2 Percentage of hours falling under a given range of PMV value

SETPOINT/COP	-2.5	-1.5	-0.5	0.5	1.5	2.5	3
	-3	**-2.5**	**-1.5**	**-0.5**	**0.5**	**1.5**	**2.5**
22˚C	0%	0%	31%	62%	7%	0%	0%
23˚C	0%	0%	0%	70%	30%	0%	0%
24˚C	0%	0%	0%	45%	55%	0%	0%
25˚C	0%	0%	0%	44%	56%	0%	0%
26˚C	0%	0%	0%	1%	99%	0%	0%
27˚C	0%	0%	0%	0%	100%	0%	0%
28˚C	0%	0%	0%	0%	72%	28%	0%
	-3	**-2**	**-1**	**0**	**1**	**2**	**3**

Table 2 gives the percentage of hours out of occupied hours falling under particular bin of PMV value at a given setpoint temperature. It shows that at 22˚C and 23˚C setpoint temperature gives more than 60 % hours having PMV value in a range of 0.5 to -0.5. i.e., more than 60% of the occupied hours are comfortable for the occupants. The percentage gets reduced to 45% at 24˚C. It can be noticed that no matter 26˚C or 27˚C is maintained as indoor temperature 100% of the occupied hours fall under PMV value 0.5 to 1.5 i.e. uncomfortable thermal conditions. Table 3 shows a comparative analysis of different climatic zones of India on how much one can save on each degree rise of setpoint temperature. The table can be used by the occupant to interpret at what temperature it will make sense to reduce or modulate the indoor temperature and how much one can save against it with respect to the climatic zone.

Table 3 Shows percentage of reduction in cooling energy consumption at corresponding temperature in particular cities

Ahmedabad	Bangalore	Chennai	Delhi	Guwahati
-	-	-	-	-
7%	7%	6%	7%	6%
7%	8%	6%	7%	6%
6%	7%	7%	7%	6%
8%	8%	8%	8%	8%
9%	9%	9%	8%	9%
10%	9%	10%	9%	10%

Figure3 gives an idea of percentage of people dissatisfied with their thermal environment at each setpoint temperature considered in each particular city, representing respective climatic zone.

23˚C	84	56	42	34
24˚C	78	52	39	31
25˚C	73	48	36	29
26˚C	67	45	34	27
27˚C	61	41	31	25
28˚C	56	37	28	**22**

Comparison:

At the very first observation, comparing the case of Bangalore (Table 5) to Ahmedabad (Table 1), the highest annual cooling energy consumption at setpoint 22˚C for COP 2 is 103 units for Ahmedabad where as it is as low as 84 units for the case of Bangalore. By changing the COP value from 2 to 3, the reduction in cooling energy consumption is 29 units for Bangalore whereas the reduction is more significant (35 units) in case of Ahmedabad. For COP 3, there is a reduction of on an average 4 units per degree setpoint temperature in Bangalore. In case of Ahmedabad the difference is of 2 units. Bangalore and Guwahati (Table 6) shows a very similar consumption pattern for all temperatures and COP values with a difference of 3 to 4 units, Bangalore being the lowest. Likewise, Chennai and Ahmedabad shows similar trend of consumption, Ahmedabad being the highest of all the cities (Table 4).

CONCLUSION

The most important observation of this study is that, low cooling setpoint temperature does not contribute significantly in lowering the cooling energy consumption at higher COP value of the PTAC cooling system. This is, however, true only for systems with average or low efficiency. The study proves through quantification the importance of using appropriate COP for achieving cooling energy savings while maintaining thermal comfort.

The outdoor environment also plays an important role in determining the trade-offs between comfort and cooling energy consumption. For instance, it was observed that Ahmedabad and Chennai had the highest cooling energy consumption of 103 and 97 units at COP of 2 and setpoint 22˚C, whereas Bangalore, Guwahati and Delhi show almost 8 to 10 units less cooling energy consumption for the same cooling setpoint and COP values.

Another important observation for each city is that the comfort levels at 24˚C and 25˚C are more or less the same (more than 50% of the occupants feel neutral on PMV scale). 24˚C setpoint consumes almost 6 % higher cooling energy annually than 25˚C (Table 3) so one can make a decision of maintaining one degree higher and contribute in saving cooling energy consumption.

ACKNOWLEDGMENTS

The authors are thankful to Saket Sarraf for his help with the statistical analysis of the simulation results.

ABSTRACT

This study examined an active air-conditioning control system with SaaS-type BEMS (Software as a Service-type Building Energy Management System). The SaaS-type BEMS controls building facilities through the Internet and can be easily introduced to existing small or medium-size buildings. The objective of Active Air-conditioning Control(AAcC) is active energy saving by controlling the operation of indoor equipment and features a mechanism to prevent room environment degradation by utilizing people's action of turning on/off of the air conditioner. This paper presents the room environment and energy saving effect of the system in summer if introduced to the office room of a middle-size building.

INTRODUCTION

Reduction of greenhouse gas emissions and increasing energy saving have become major societal issues. Measures to combat the former and optimize the latter have become especially urgent in Japan. Energy saving by whole societies, regardless of size, has been promoted through energy-saving actions on various types of facilities and buildings. However, energy management systems have been rather slowly introduced to small and medium-sized office buildings. As an air-conditioning system satisfying the thermal comfort request of occupants while achieving energy saving, a personal air-conditioning method is expected. However, this method is mainly applied to a new building, and its application is limited.

The present study examines a novel AAcC system installed on a SaaS-type BEMS. The system is easily introduced to small and medium-sized buildings, since a virtual BEMS can be configured to the building's physical equipment settings.

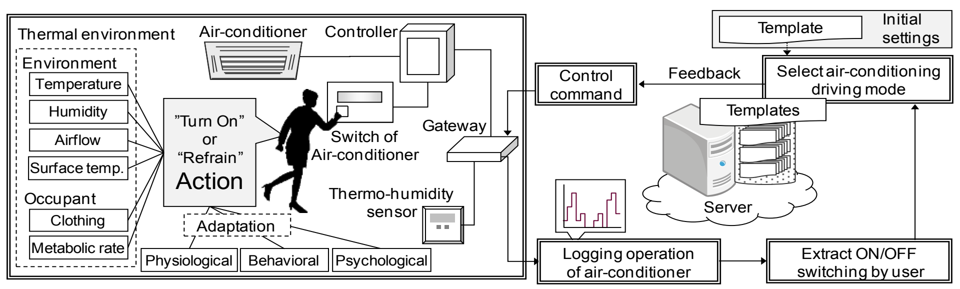

Figure 1. Active energy-saving air-conditioning control system.

Energy saving is achieved by active control of the indoor air-conditioning unit. The control system also reduces deterioration of the room conditioning by sensing the occupants' on/off switching of the air conditioning.Ultimately, the system should satisfy the thermal comfort requests of the occupants by feedback of their adjustment behavior, rather than by collecting the details of the occupants' attributes, thermal and comfort sensations, and psychological conditions.

In this paper, our proposed energy-saving system was evaluated in the office space of a medium sized building during the summer season.

OVERVIEW OF ACTIVE ENERGY-SAVING CONTROL FOR AIR-CONDITIONING SYSTEM

Figure 1 shows an operation diagram of the AAcC system. The system controls the air conditioning based on templates that describe ON/OFF commands for an air conditioner. It starts the control with an initial template. Then an appropriate template is selected in accordance with the template selection standard and is loaded to execute air conditioning control according to the ON/OFF commands described in the selected template. The template selection standard of this system is based on the number of switching-on/off actions of people in the room.

THE EXPERIMENT METHOD OF THE OFFICE IN SUMMER

A verification test was conducted in the period from July 8, 2013 to September 30, 2013 at a building N in Tokyo. Table 1 gives an overview of the building. There were nine indoor air conditioning units in the office room, one in each of three neighboring rooms, and one in a meeting room. The outdoor unit (1) covers all of these thirteen indoor units. Each air conditioning unit can be started and stopped independently.

Figure 2 shows the layout of the office room and the location of the indoor units, air thermo-humidity sensors, and globe thermo sensors. Since there was a building on the south-west side of the office, almost no direct sunlight entered the office except in some areas. Some windows of the office room had a window shade. A photograph and thermographic image of the room are given in Figure 3. The temperature and humidity were measured at five locations with wireless sensors and thermo-humidity sensors with a memory function, and the radiation temperature was measured at the room center with a globe thermometer. The number of manual switching operations of the indoor units and the total electricity consumption of the outdoor unit were also measured periodically by the SaaS type BEMS. Measurements were taken at intervals of 5 minutes.

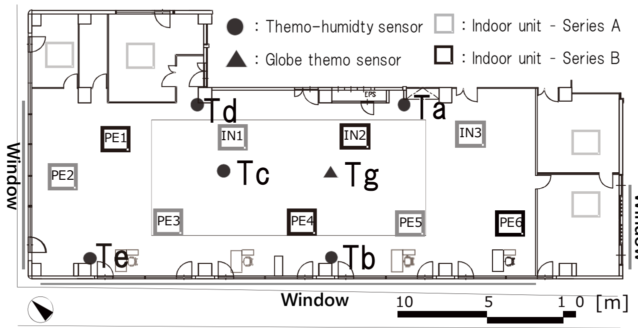

Figure 2. Position of indoor air-cooling unit and measurement points

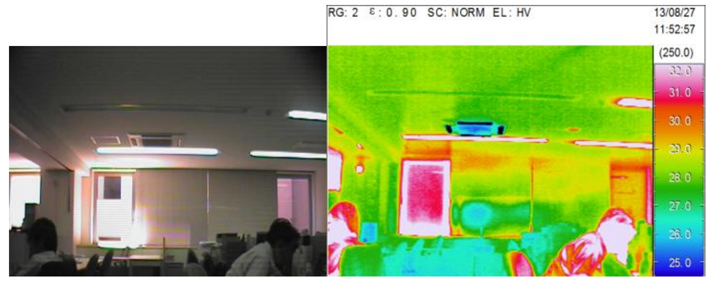

Figure 3. Infrared thermography image of South side

Next the air conditioning control method employed for the present experiments is explained. As shown in Figure 2, the indoor units were alternately grouped to Series A and Series B and each series was controlled separately. Simultaneous operation of Series A and Series B makes 100% operation and the operation of Series A only reduces the operation load by about 50%. Seven driving modes of different operation reduction rates were defined for intermittent operations of each series as shown in Table 2. The AAcC method switches the driving mode to a more energy-saving type when people in the room perform less temperature-adjustment actions and to a less energy-saving type when they perform more temperature-adjustment actions. Therefore, the driving mode changes according to the number of manual switching-on/off actions which are considered as the temperature-adjustment actions of the people in the room.

The present verification experiments used Mode 4 on the first day (July 8) to start the air conditioning of the office. On the next day, the previous day's status information of each indoor unit is analyzed at 0 o'clock to calculate the total number of manual switching-on/off actions of the people. When this total number is in the range from 0 to 74 per day the system changes the mode by one step to the energy-saving side, when in the range from 75 to 150 per day the system maintains the mode, and when it is more than 150 per day the system changes the mode by one step to the less energy-saving side. If no AAcC is made on the previous day, the mode selected on the last day that the control was made is maintained. Therefore, if the previous day is a holiday, the control is conducted in accordance with the control results of the last active air-conditioning controlled day.

THERMAL ENVIRONMENT AND THE RESULTS OF MODE CHANGES OF AIR-CONDITIONING OPERATION

Figure 4 shows the changes of the thermal environment of the office from August 19 to 21 in summer at an outdoor temperature over 30°C. August 19 was the first work day after the summer vacation. The indoor air temperature (hereafter referred to as room temperature) was controlled to be about 28°C with a variation of 2-3°C depending on measurement points, which caused the non-uniform thermal environment. The temperature change by switching on/off the air conditioning was 1-1.5°C on August 20 and 21. In the mode used on August 19, the air conditioning operations were stopped for a prolonged period and hence the temperature variation was expected to be large. However, the actual temperature variation was smaller at each measurement point than the variation on the next day having less energy reduction. This was because the people's temperature adjustment actions corrected the temperature variation. Figure 5 shows the mode change in the AAcC, indoor temperature (average over work hours), and outdoor temperature (in Tokyo) in July. There is no data for holidays, July 26, and August 7 and 27 when the AAcC was not performed. Figure 6 shows the total number of manual switching-on/off actions in a day in the area, except the meeting room, covered by the outdoor unit (1).

The room temperature was maintained at 26-28°C irrespective of the outdoor temperature. On the first day (July 8) of the AAcC, the number of switching-on actions of the people in the room was small, less than 75 per day. Therefore, the air conditioning mode was changed to mode 3 (reduction rate 50%) to save more energy. However, on July 11, the switching-on actions became more frequent and the mode returned to mode 4. On July 16 and 17, the mode was switched successively to mode 1 due to the small number of switching-on actions, and mode 1 was maintained on and after July 18. Since the number of switching-on actions was 151 or more per day on July 31, the mode was changed the next day to mode 2 to reduce the energy saving. The air conditioning mode was selected to be 3 or 4 in early July because of the record-breaking hot weather, but the outdoor temperature decreased in the middle of July and more energy-saving modes were used for the air-conditioning control.

In other words, the AAcC could follow the relatively slow change of the thermal environment caused by the influence from the outside environment.

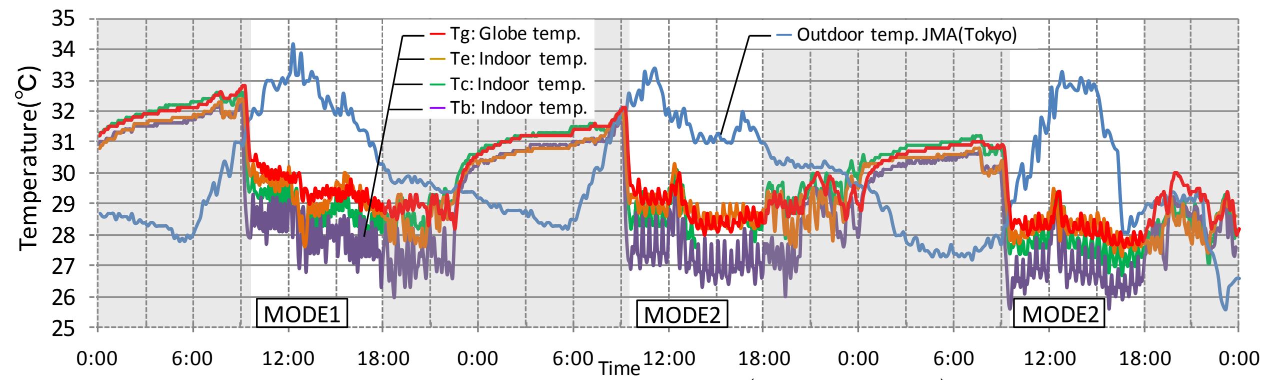

Figure 4. Thermal environment of office（19-21.Aug.2013）

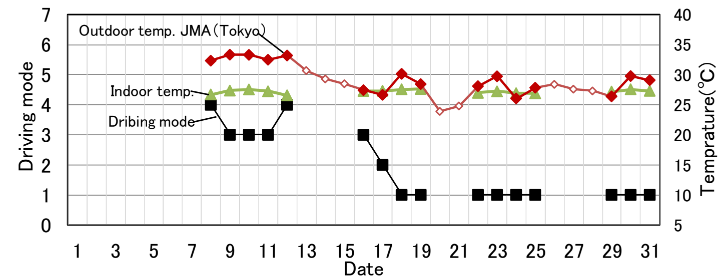

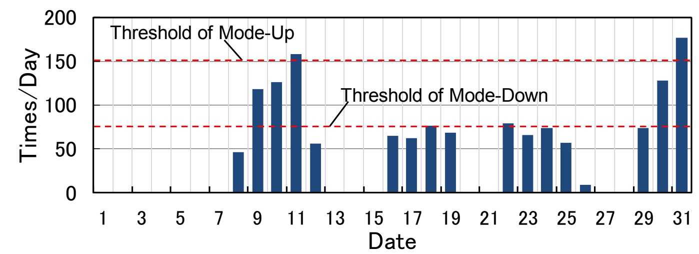

Figure 5. Thermal enviroment and Driving mode of office (Jul.2013)

Figure 6. ON/OFF action count (Jul.2013)

DIFFERENCE IN TEMPERATURE ADJUSTMENT ACTIONS IN DIFFERENT PLACES IN OFFICE

Figure 7 shows the total number of manual switching-on/off actions for each indoor unit over July 8 to 31 and August 1 to 31. The switching-on/off actions were more frequent on the perimeter side than on the interior side, and more on the east side than on the west side. This could be because the units on the perimeter side and those on the interior side were operated intermittently in the same mode and hence those on the perimeter side that could be easily affected by the outdoor environment were switched on/off more frequently. Also the number of switching-on/off actions was not the same for the indoor units on the perimeter side or for the units on the interior side. This could be because of the non-uniform thermal environment, difference in the each person's position, attribution, thermal sensation, comfort, and psychological conditions.

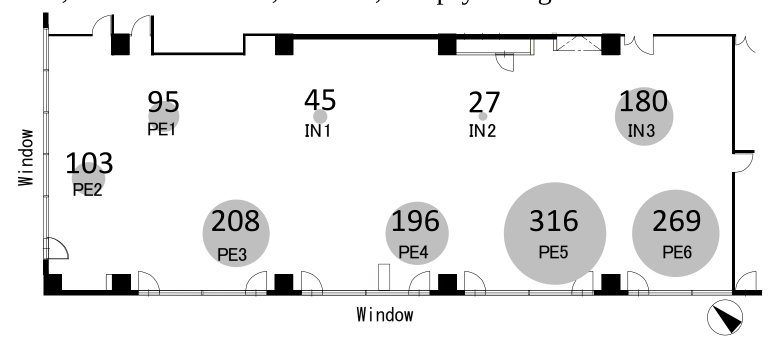

Figure 7. Count of switch every indoor unit (Jul.2013)

RESULTS OF INDOOR UNIT OPERATION SUPPRESSION AND ENERGY CONSUMPTION REDUCTION

Table 3 shows the expected reduction rate[Note1)] of the intermittent operations and the actual reduction rate calculated from the actual air conditioning operation hours.

The reduction rate difference [%]= Expected reduction rate [%] – actual reduction rate [%] in each mode

Table 3 Reduction rate of A/C indoor unit of office area

Month	Days of Auto Control (day)	Estimated Rate (%)	Usage of Room (h)	Usage of A/C (h)	Run. Rate of A/C (%)	Reduction Rate of A/C (%)	Outdoor Temp. JMA(Tokyo) (°C)
Jul.	11	64.4	82.5	38.4	46.6	53.4	27.3
Aug.	15	60.5	112.5	57.1	50.8	49.2	29.2
Sep.	19	65.8	142.5	60.0	42.1	57.9	25.2

The air conditioning driving mode changed every day according to the feedback from the people's temperature adjustment behaviors. The mode change in July, August and September when the AAcC was conducted was recorded. The data in the first week of July were omitted since this was the period for the AAcC to meet the condition As a result of the measurement, the expected reduction rate in July was 66.4% and the actual reduction rate was 53.4%, smaller than the expected rate due to the people's temperature adjustment. The expected reduction rate and the actual reduction rate were both smaller in August than in July but larger in September. This could be because the outdoor temperature in August was high and that in September was lower than in July and August. Since the difference between the expected and actual reduction rates was 7.9-11.3%, one can see that the people's temperature adjustment actions changed the mode by 1 step and the office was controlled in this mode range. To reduce this difference, the threshold (total number of manual switching-on/off actions) of the mode switching to higher energy consumption should be set to a small value. However, this may cause excessive air conditioning with higher energy consumption. It is therefore important to select an appropriate threshold.

Table 4 shows the comparison with the power consumption in 2010 when the air conditioners were kept switched on at 28°C. The energy consumption of each air conditioner was not measured in 2010 but the total consumed energy and the working hours of the indoor units were measured. The power consumption of the indoor and outdoor units was estimated from these measurements[Note2)]. The total consumption energy of the air conditioning estimated from each of the units was 11,945kwh, about 4% deviated from the actual measurement value 12,402kwh, indicating that the estimation was effective. It is concluded from this result that the energy consumption in the office room in 2013 was reduced by 46% in 2010 by the AAcC. The outdoor temperature was lower by 0.7°C in July, 0.4°C in August, and 0.1°C in September than in the same months in 2010. However, the influence of this difference is small since the change in the energy consumption of the outdoor unit due to the outdoor temperature change is 180.1kwh/month-°C. The office was used for 58 days in July, August and September both in 2010 and 2013. Although the number of people decreased by 10%, the use condition was almost the same in both years.

Table 4 Power reduction result (Jul.-Sep. 2013 vs Jul.-Sep. 2010)

Division		Control method	Jul.-Sep. 2013 Active air-conditioning control	Jul.-Sep. 2010 Temperature-constant control (28°C)		Reduction rate
			Measured	Measured	Estimated*	
Outdoor unit(1) (office area)						
	Indoor unit working time (h)		3420	6374	-	
	Detail	Office area (9unit) (h)	2788	5631		50%
		Other (4unit) (h)	632	743		15%
	Indoor unit (kWh)		256		476	
	Outdoor unit (kWh)		4118		7676	
	Power consumption (kWh)		4374		8152	46%
Outdoor unit(2) (Meeting room area)						
	Indoor unit working time (h)		1476	3866	-	62%
	Power consumption (kWh)		1448		3793	62%
Total						
	Air-conditioning electric power consumption (kWh)		5822	12402	11945	53%

* The estimated values of each electric consumption is estimated from indoor unit working time of 2010 based on air-conditioning electric consumption per indoor unit working time of 2013.

The above facts indicate that the major causes for the energy consumption reduction were the suppression of the air conditioning operations during the office hours as shown in Table 3, and prevention of forgetting to stop the air conditioners after office hours or unnecessary operation of them by the automatic termination of the air conditioners after office hours, which had been controlled manually.

CONCLUSION

In this study, an active air-conditioning control (AAcC) system was introduced to an office room where there were multiple indoor air-conditioning units and analyzed based on verification experiments conducted in summer with the focus on the thermal environment and the temperature adjustment actions of people in the room. By incorporating occupants' switching on/off action into the system, this control method enables the automatic control of air-conditioning along with the thermal comfort request of occupants. Major results are as follows.

1) The AAcC was conducted at a preset temperature of 26°C in an office room with multiple indoor units, which were alternately grouped into two. After the air conditioning mode is stabilized, the mean room temperature was maintained at 26-28°C irrespective of the outdoor temperature. The temperature variation at the sensor positions due to the start-stop operations of the indoor units was 1-1.5°C and the room temperature variation across the office room was about 2-3°C.
2) The air conditioning operation reduction rate for the office room was 53.4% in July, 49.2% in August, and 57.9% in September.
3) The results indicated that the AAcC of the office area in 2013 reduced the energy consumption by 46% from the consumption in 2010. The major causes for the large reduction are the suppression of the operation of the air conditioners during the office hours and the prevention of forgetting to stop the air conditioners after office hours.
4) The number of manual switching-on/off actions varied from place to place in the room and differed between the perimeter side and the interior side. It was therefore found that people's preference on the thermal environment could be deduced from their air conditioner adjustment actions.
5) In the air-conditioning control according to the number of people's switching-on/off actions, the AAcC could follow a change in the thermal environment caused by the influence of the outdoor temperature.

The above results showed that the AAcC based on the number of people's air conditioner adjustment actions realized air-conditioning control appropriate to the thermal environment of an office room with multiple air conditioners.Since the number of switching-on/off actions was counted every day, the system could follow only a slow thermal environmental change over two or more days. It was also clarified that holidays needed to be taken into consideration. Also, each indoor unit should be controlled separately to compensate for the variation of the thermal environment across the room.

The change-following performance should be improved by using a shorter period of the feedback from the number of manual switching-on/off actions in people's temperature adjustment behavior or by using the weather forecast data, and a system of applying the AAcC to each of the indoor units separately.

Note 1) The expected reduction rate was calculated from expected working hours of the air conditioners in office hours (7.5h). The expected working hours of the air conditioners were given by summing up the expected working hours calculated from every day's air conditioning modes.

Note 2) The power consumption per operating hour of indoor units, that of outdoor units, and that of air conditioners is calculated from the measurement results in 2013 (July to September) and from the total working hours of indoor units in 2010. Since the specifications of the indoor and outdoor units are different in the office area and in the meeting room area, the power consumption was calculated separately for each of the areas.

THERMAL COMFORT IN HOUSING OF THE METROPOLITAN AREA OF THE VALLEY OF MEXICO

Carla Figueroa-Villamar, PhD. Aníbal Figueroa-Castrejón, PhD. Gonzalo Bojórquez-Morales
[Universidad Autonoma Metropolitana] [Universidad Autonoma Metropolitana] [Universidad Autonoma de Baja California]

ABSTRACT

This research is based on the principles of adaptive focus. In this document, the results of the field research on thermal comfort regarding housing produced in series are presented. The survey was conducted in the municipalities of the Metropolitan Area of the Valley of Mexico that have presented the most urban growth in the last 10 years. Measurement times were determined according to bioclimatic analysis: cold, warm and transition. The environmental variables, such as dry bulb temperature, wet bulb temperature, black globe temperature, relative humidity and wind speed in the living room of the houses, were measured while, simultaneously, 426 surveys about thermal sensation were conducted to the inhabitants. The questionnaire was performed according to ISO 10551 and ASHRAE 55 Regulations. The annual neutral temperature in naturally ventilated houses in the Metropolitan Area of the Valley of Mexico is 21.3ºC and extensive thermal comfort limits are 16.0ºC and 26.7ºC. The Mexico's Energy Efficiency Standard in residential buildings, NOM 020 ENER-2011, suggests that the ideal temperature for interiors is 23°C, which is inconsistent with the neutral temperature resulting from the investigation; therefore, considering it favors the use of artificial devices for air conditioning and the energetic cost of housing.

INTRODUCTION

The purpose of the neutral temperature and ranges of thermal comfort in the housing of the Metropolitan Area of the Valley of Mexico, allows the development of tools and information that is useful for the planning and designing of houses which promote the thermal comfort wellbeing of residents. The perception of thermal comfort is important for carrying out activities without compromising the physical and mental performance of the subjects, however, if the thermal environment does not provide the right conditions, the subjects can take action to adapt or reduce the length of their stay in that space (Bojorquez Morales, 2010).

The ASHRAE 55-2004 Regulation incorporates the method for determining acceptable thermal conditions in naturally ventilated environments. This method was based on work done by de Dear and Brager (1998), in which several climatic zones were analyzed, each in different countries and buildings. However, data from countries in Latin America and Mexico are not included. In order to establish standards for thermal comfort, in the last years there have been investigations on thermal comfort in countries that were not included in this rule; Japan (Bahadur, 2013), China (Wang, et al., 2010), and several cities with warm weather in Mexico (Gomez Azpeitia, et al., 2009).

This investigation is based on the focus of adaptation, since it allows to evaluate, both, the subjects' perceived thermal sensation in a natural environment and the psychophysiological reactions generated to feel comfort.

The climate analysis determined the study periods: cold (December-January); warm (May); and transition (October-November, March). The field work consisted in conducting surveys, regarding thermal perception, to residents of municipalities with the highest urban expansion in 10 years. During the three periods, 377 observations were obtained.

METHOD

The investigation was divided in three stages: 1) Site Analysis, in which the urban growth in the Metropolitan Area of the Valley of Mexico (MAVM) was diagnosed to determine areas of study, and a description of the climate to show environmental conditions was made; 2) Correlational Study, in which the measurement periods, variables and instruments were defined; and the questionnaire and the sample was designed; 3) Data Analysis, which was by an unconventional method of regressional statistics by layers.

1. Site Analysis

The selected municipalities are the top ten municipalities with the highest population growth in the last ten years. As shown in Table 1, the number of houses built is greater than 5,000. The condition in order to be among the selected was that the average annual temperature could not present variations greater than 1°C. The field study was conducted in houses produced in series of the municipalities of: Tecamac, Nicolás Romero, Cuautitlan Izcalli, Tultitlan and Huehuetoca.

Table 1. Location Description

#	LOCALITIES	# HOUSING	LATITUDE (N)	LONGITUDE (w)	ALTITUDE (m.a.s.l.)	LOW TEMP.	AVERAGE TEMP.	HIGH TEMP.
1	Tecámac	132,275	19°39'24"	99°01'02"	2,340	6.9	15.6	24.4
2	Nicolás Romero	15,012	19°34'52"	99°16'42"	2,360	6.9	15	23.1
3	Cuautitlán Izcalli	11,964	19°42'16"	99°13'09"	2,365	7	15.6	24.1
4	Huehuetoca	7,653	19°41'03"	99°07'36"	2,245	6.1	14.9	23.5
5	Tultitlan	7,305	19°50'55"	99°12'45"	2,258	6.1	14.8	23.5

Table 1 shows the location of the municipalities, minimum temperatures, average and annual maximums, as well as the number of built houses which were produced in series.

2. Correlational Study

The questionnaire on thermal sensation was designed according to the ISO 10551 Regulation, using the 7-point scale (Table 2); and proposed in the study "Thermal comfort and Energy Savings in Affordable Housing in Mexico" (Azpeitia Gómez, et al., 2009), based on the previous rules.

Table 2. Thermal sensation scale by ISO 10551

#	VALUE	COMFORT VOTE
7	3	Hot
6	2	Warm
5	1	Slightly warm
4	0	Neutral
3	-1	Slightly cool
2	-2	Cool
1	-3	Cold

The survey was conducted on healthy subjects from 15 to 60 years of age, with average levels of clothing from 0.30clo to 1.5clo. The subjects were grouped into three levels of physical activity: passive or resting, from 0 to 75W/m^2, moderate with 76W/m^2 to 180W/m^2 and severe, greater than 185W/m^2; simultaneously the surveys were measured by the following variables: dry bulb temperature (TBS), wet bulb temperature (TBH), black global temperature (TGN), relative humidity (RH) and wind speed (VV); the measurements were performed with a heat stress monitor, which according to the ISO 7726 (1998) Regulation the information obtained is classified in Group I.

To determine the study periods, de Dear's and Brager's (1998) neutral temperature equation ± 2.5K was applied to normal weather of the before mentioned municipalities. The periods are shown in Table 3. The study sample was determined by the amount of affordable housing built and the total population of people of the ages between 12 and 60 years of the MAVM. It was decided, based on statistical data, that the sample should include at least 120 people per measurement period. The selection of subjects who were surveyed was random within housing developments, and deterministic, since the subjects were the ones who chose to part take or not part take in research.

Table 3. Measuring periods

ZONE	PERIODS	MONTHS	# OF SAMPLE
MAVM*	Transition	October November March	152
	Cold	December January	135
	Warm	May June	139

*Selected locations of the Metropolitan Area of the Valley of Mexico

For the conducting of the surveys, students of the Universidad Autónoma Metropolitana were trained and trial surveys were conducted to improve the application method and become familiar with the measuring equipment. Fieldwork was conducted from 09:00 hrs. to 19:00 hrs. and the data collected on site were captured using an Excel database to facilitate statistical analysis.

3. Data Analysis

The statistical method of analysis, was a nonconventional method of linear regression by layers, developed by Gómez-Azpeitia et al. (2007), was based on Nicol's (1993) proposal. The main difference with the conventional method is that prior to obtaining the regression, the sample is grouped by levels of perceived thermal sensation. After obtaining the average values of temperature (TMean) and standard deviation of the responses for each level of perceived thermal sensation, distribution ranges are establishes for each response category from the value of the corresponding TMean and adding or subtracting 1σ, representing 68% of the population whom expressed the same thermal sensation; the adding procedure is repeated, this time by adding or subtracting 2σ, representing 95% of the population.

Finally, the linear regression is done with the series of values of TMean, ±1σ and ±2σ of each thermal sensation. The intersection of each of the regression lines with the ordinate four (corresponding to the thermal comfort sensation) determines the value of the neutral temperature, as well as the limits of the comfort zone. In this method, what determines the validity of the regression, is the determining coefficient resulting of the straight line (R^2); this value ranges from 0 to 1, while it is closer to one, the value obtained has more representation on the sample, in other words, greater validity.

Figure 1 shows the graphs obtained from the data analysis collected from the field work done under the above mentioned method; TMean regression lines are observed, ±1σ and ±2σ, like the intersection of these, with the value of 4 for the ordinate *y*, which gives origin to the neutral values of temperature and thermal comfort range.

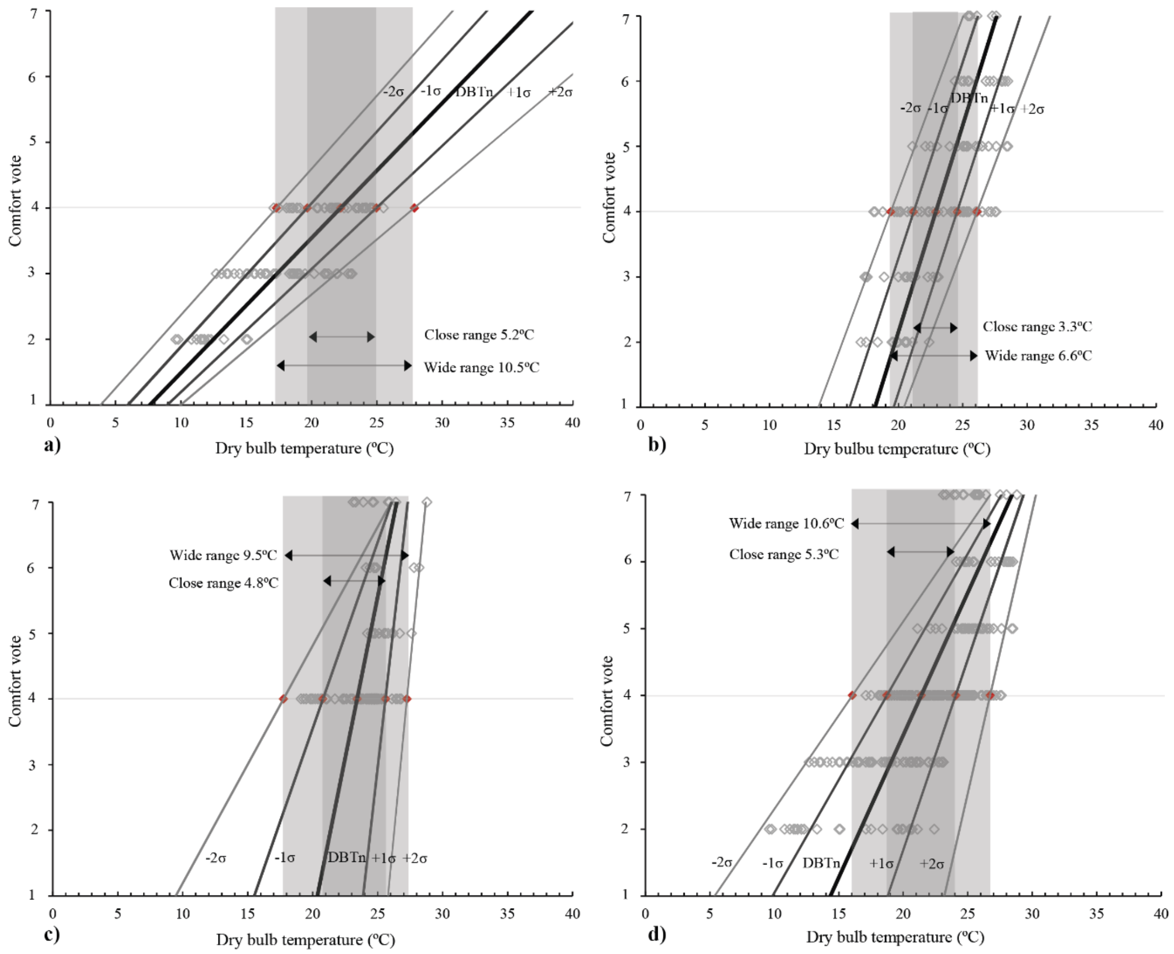

Figure 1. Determination of Tn and the comfort ranges by non-conventional method of statistical regression by layers in Metropolitan Area of Mexico. **(a)** Cold period **(b)** Transition period **(c)** Warm period **(d)** Annual

Figure 1a shows that the regression lines of -2σ y -1σ visually are parallel to the average line of regression, however, they are slightly convergent as the sensations increased from 2 to 4, which represents that the thermal perception of temperatures less than 22.2°C is similar in all the sensations. Lines +2σ and +1σ have the same behavior but with steeper slopes, indicating that when the temperature is above 22.2°C the capability of adaptation is reduced during cold sensations. Figure 1b shows some observations outside the limits of comfort sensations 6 and 7 to the limit +2σ, which indicates that most subjects have a preference for temperatures below 27.2ºC. The regression lines ±1σ and ±2σ are divergent in regards to the mean regression line as the cold sensation increases, which indicates that subjects are better able to adapt to these conditions in the warm period.

In Figure 1c, the regression lines -2σ y -1σ are visually parallel to the average regression line, however, are slightly convergent as the sensation increases from 6 to 7, the opposite occurs with the regression lines +2σ and +1σ which are slightly convergent to the sensations of cold; indicating that when temperatures are below 22.9°C the subjects show less adaptability to the sensations of heat, and the opposite occurs when they are higher. Figure 1d shows that the regression lines of ±2σ and ±1σ are divergent to the regression line Tn average as the thermal sensation of cold increases, which indicates that each year there is more capability of adaptation to these conditions; however sensations 3 and 2 show greater scatter in the data, which is possibly due to clothing levels and metabolic activity of the subjects; the levels of activity in these sensations were: 40% while resting, 55% in moderate work and 5% during intensive work; while 80% of the subjects were dressed between normal and snug (from 0.60 to 1.0clo).

RESULTS

The resulting values of the above analysis are presented in Table4; the neutral temperature, reduced and extensive limits of the thermal comfort zone and degrees of openness each study period has are shown. It is observed that the lowest value of Tn is the transition period, this is because in these months the weather has greater fluctuation, making it difficult for subjects to adapt to the thermal conditions; the highest value is observed in the cold period, which means that subjects have greater adaptation to thermal conditions that occurred in this period, which is consistent with the mild climate of the MAVM. The neutral temperatures resulting from the analysis in each period have a difference = or <5%; however, as shown in Table 4, the lowest value of Tn is given in the annual evaluation, since this one takes into account all the observations.

Table 4. Comfort temperatures and ranges determined in the field study

ZONE	PERIOD	Tn	COMFORT CLOSE RANGE Lower Limit	COMFORT CLOSE RANGE Upper Limit	COMFORT CLOSE RANGE Rank	COMFORT WIDE RANGE Lower Limit	COMFORT WIDE RANGE Upper Limit	COMFORT WIDE RANGE Rank
MAVM*	Transition	22.9	21.1	24.5	3.4	19.4	26.1	6.7
	Cold	22.2	19.6	24.9	5.3	17.3	27.8	10.5
	Warm	23.4	20.7	25.6	4.9	17.7	27.2	9.5
	ANNUAL	**21.3**	**18.7**	**24.0**	**5.3**	**16.0**	**26.7**	**10.7**

* Selected locations of the Metropolitan Area of the Valley of Mexico

Table5 shows the comparative analysis of neutral temperatures obtained with the equations proposed by different authors; it is apparent that in all the periods the neutral temperature resulting from this research is more the others, therefore, suggests an adjustment to the models of assessment of thermal comfort for the mild climate of the MAVM. However, the Tn results of de Dear's and Brager's (1998) equation, has a smaller difference of 1°C with the results obtained, which is an indicator for validating data through the application of ASHRAE Standard55- 2004.

Table 5. Comparative chart of comfort temperatures calculated by different authors

ZONE	PERIODS	To*	Neutral Temperature (Tn) Humpreys	Neutral Temperature (Tn) Auliciems	Neutral Temperature (Tn) Griffiths	Neutral Temperature (Tn) de Dear & Brager	Neutral Temperature (Tn) Field Study
MAVM	Transition	14.3	19.7	22.1	19.8	22.3	**22.9**
	Cold	11.6	18.2	21.2	18.3	21.4	**22.2**
	Warm	17.5	21.4	23.0	21.5	23.2	**23.4**
	ANUAL	15.1	20.1	22.3	20.2	22.5	**21.3**

*To: monthly average outdoor temperature

Finally the method was applied to determine the acceptable thermal conditions in naturally ventilated spaces (ASHRAE Standard55- 2004). Figure2 shows the analysis through period of acceptable operating temperatures. It is observed that the thermal conditions of the houses fall in the range of 90% acceptability of this standard.

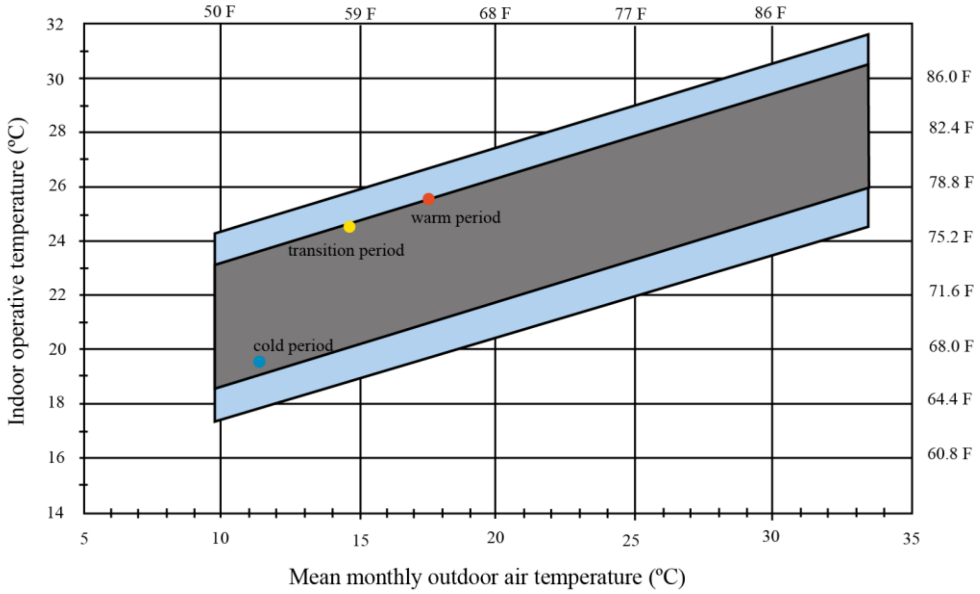

Figure 2. Acceptable operative temperature ranges by study period in naturally ventilated housing in MAVM (ASHRAE Standard55, 2004).

CONCLUSIONS

The ability to adapt to the thermal environment of houses built in mass production in the Metropolitan Area of the Valley of Mexico, is now higher; considering that 94% of the subjects said that the environment of their home was acceptable; nevertheless, only 48% said they felt comfort, possibly due to physical factors that were not evaluated in this investigation.

The annual neutral temperature in housing produced in series with natural ventilation in the Metropolitan Area of the Valley of Mexico is 21.3ºC, with a narrow range of ± 2.7ºC thermal comfort, for that reason it is suggested to make the appropriate amendments to Mexico's Energy Efficiency Standard, NOM 020-ENER-2011, which suggests an internal temperature of 23°C, hence, favors the use of active devices to acclimatize spaces. .

Finally, the study validates the use of the adaptive method of ASRAE 55- 2004 Standard to determine the thermal comfort conditions of the houses in the Metropolitan Area of the Valley of Mexico.

ACKNOWLEDGMENTS

This research was supported by the PROMEP project, "Lineamientos para el confort y desempeño energético de la vivienda urbana" ("Guidelines for the comfort and energy performance of urban housing"). I would like to extend my gratitude to the Universidad Autonoma Metropolitana, to all those who participated in the study and made possible its progress, to the people who conducted the surveys and partook in the fieldwork and to my partner, April Rueda, for her important collaboration and support in this investigation.

ABSTRACT

This article presents the verification of a mathematical model for predicting the luminous efficiency of light-pipes, based on the principle of unit hemisphere and solid angles. For this, light-pipes were simulated in the software photopia and essayed under real sky conditions. The adopted method in this research is theoretical deductive, developing a luminous efficiency predictive model of light-pipes and its complementation by the lumens methods. In order to verify the results, an empirical inductive method was applied, considering physical models under real sky conditions. In addition to the empirical results, simulations were carried out in raytracing software Photopia. The first method calculates the value of the relationship (LPE) between the availability of light in the central point in the output section of the light-pipe and that in the horizontal plane of its entrance. The high correlation found between results from the measured data and results from the proposed luminous efficiency predictive model of light-pipes (LEPMLP) with the results obtained from the software Photopia, in terms of estimated values of light-pipes efficiency (LPE), showed that it is a reliable tool and is easily applicable for dimensioning this kind of system for taking advantage of daylighting in everyday architectural and building design practice, allowing to deliver daylight to rooms without direct contact with the external environment.

INTRODUCTION

The global scenario has been changing with the exigencies of the environment resources, which were used by past generations inconsequently. Currently, the concern for the planet and future generations puts emphasis on the use and development of efficient products that consume or use clean or renewable energy. In this context, light -pipe systems are developed to conduct the daylight to internal environments far from the envelope, as, for example, rooms without direct contact with the external environment or in undergrounds.

Consiering the advances in researches, new technological innovations have been developed to bring daylight to indoor environments. A variety of devices aimed at lighting were designed and researched to improve the quality of daylighting to increase user acceptance and provide tools for designers to specify and size these systems.

Kocifaj et al. (2008) observe that beginning research on products of light had interest in the innovative system, seeking to eliminate the deficits and gaps offered by conventional systems openings. In the beginning, installed systems have been researched and prototypes as a "black box" comparing the performance of the system as a whole with other systems. Within this group are works such as: Al-Marwaee & Carter (2006), Oaklley et al. (2000). In a second step the interest of the academic community becomes more specifically to the driver turning his scientific interests to the efficiency of those seeking to unravel the behavior of light to be conducted this phenomenon and propose predictive models resulting in the prediction of the efficiency of light transmission along the conductor and several theoretical predictive mathematical models and semi- empíricos.Esse in the case of papers presented by Swift & Smith (1995), Swift et al.(2008) and Luz et al (2010). Finally, recently, in the third stage of the research for the products of light, the interest is focused on the transport of light from the diffuser (commonly placed at the exit of the pipe-line) to the work plan or a point in this internal environment.

These searches are resulting predictive mathematical and computational models of the luminous efficiency by providing data on the luminous flux emitted by the environment in pipelines, and distributed illuminance on the working plane in lux. This allows the comparison of these systems with artificial lights and allows you to choose when you design with precise image scaling of the lighting system, allowing the association between daylighting and artificial lighting. The predictive models of light pipe efficiency have been developed by several researchers. S-DPF e E-DPF (Zhang, Muneer &Kubier, 2002), Universidade de Liverpool (Carter, 2002), Luxplots (Jenkins & Muneer, 2003), CIE Method (CIE 173, 2006). Dutton and Shao (2007) validate the software Photopia as a tool to predict the performance of pipelines, comparing this with six existing predictive methods (Wittwer, 1986; Swift & Smith, 1995; Edmonds, 1995 and Zhang et al, 2002, Jenkins & Muneer 2003, and Carters, 2002). This work presents the verification of a mathematical model for predicting the luminous efficiency of light-pipes (LEPMLP), in comparison with the results of raytracing simulation on Photopia software.

The LEPMLEP was based in the principle of projected solid angle or unit hemisphere. This principle is used by many graphic methods in order to obtain infor the sky component. Allowing the determination of its value even in situations in which the area of the luminous source is constituted by irregular forms (Hopkinson et al., 1975).

The objective of this paper is the use raytracing simulation (Photopia) to verify a mathematical simplified model that friendly estimates the light-pipe efficiency (LPE). For this, light -pipes were simulated in the software Photopia and tested under real sky conditions.

PREDICTIVE MODEL OF LUMINOUS EFFICIENCY OF LIGHT-PIPES (LEPMLP)

It was adopted the condition of uniform sky as source of daylight. The input section of the light-pipe is considered an emitter plane, which luminance is gathered in a horizontal unobstructed plan (considering a real situation).

The developed model predicts the value of the light-pipe efficiency (LPE), which is the ratio, in percentage, of illuminance in the output section and the available illuminance in the input section. The ratio is obtained through the sum of the illuminances in the output section of the light-pipe, arising from the luminance of the input section, as well as from the luminance of the reflected images in the mirrors, considering the successive losses due to absorption in the multiple reflections through the light-pipe.

The adopted procedure to consider the contribution of each image of the primary source (input section) is the projection of the images in the unit hemisphere considering the solid angle constituted by the input section and the centre point of the output section of the light-pipe. It's to say that luminance of the input section and its reflexions in the mirrors are delivered to the unit hemisphere.

The projected luminances in the unit hemisphere are in solid angles, constituting with the light-pipe vertical central axis angles (θi), which are the vertices of rectangles triangles, which base is the segment [(b.i)+b/2], where b is the input section length, and the height (h) is the length of the light-pipe. The value of the angle θi is determined by Equation 1.

$$\theta_i = atg\left[\left(i + \tfrac{1}{2}\right) \cdot \tfrac{b}{h}\right] \qquad (1)$$

where: i is the number of reflexions in the length of the pipe-light, or in other words, the number or images projected in the unit hemisphere; b is the input section length; h is the length of the light-pipe.

The projected luminances in the unit hemisphere produce circular sectors in the base of such hemisphere, which areas (Ai) (annulus) are defined by Equations 2 and 3.

$$a_i = \sin\theta_i \cdot r \qquad (2)$$

$$A_i = (a_i^2 - a_{i-1}^2) \cdot \pi \qquad (3)$$

where: Ai is the apparent area of the annulus; ai and ai-1 are the radius of the concentric circles determined by the projected luminances; r is the radius of the hemisphere (in this specific case, r=1).

Figure 1. Projected luminances in the unit hemisphere

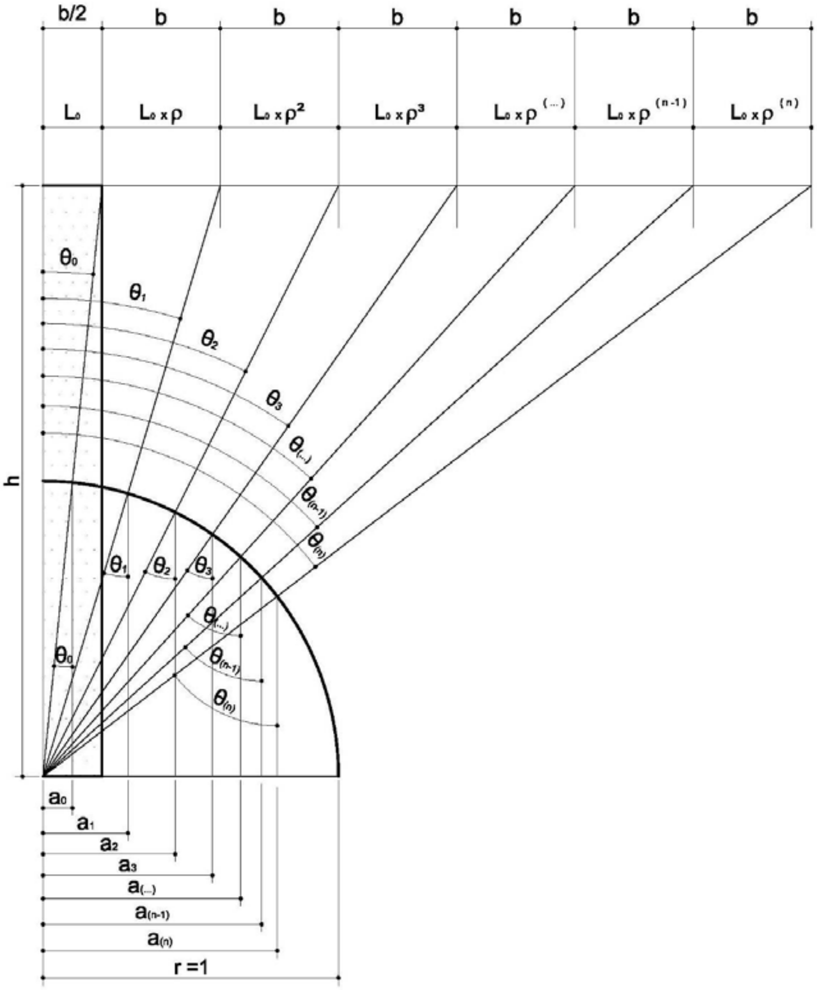

Figure 2. Annulus

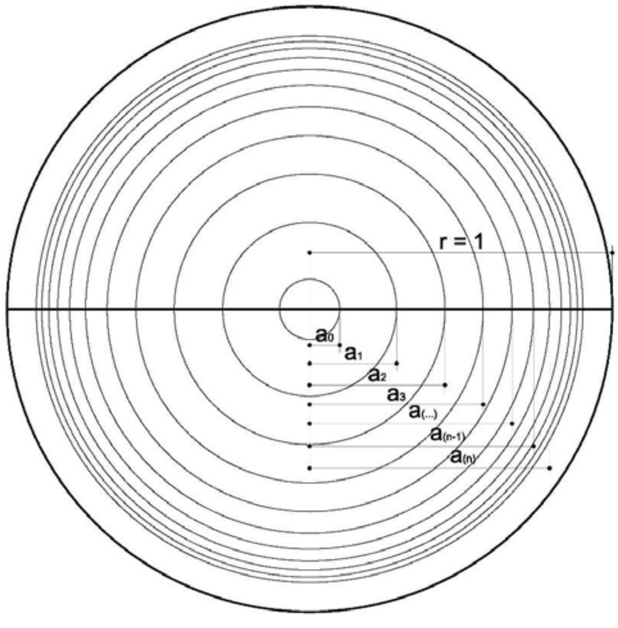


The illuminance Ei is the contribution of each annulus. The sum of Ei for all annuli is the illuminance gathered in the central point of the output section, or it is to say, in the central point of the unit hemisphere. Ei is determined through Equation 4.

$$E_i = A_i \cdot L_0 \cdot \rho^i \qquad (4)$$

where: Ei is the illuminance of the annulus; Ai is the area of the annulus; L0 is the luminance in the light-pipe input section; ρ is the light-pipe internal reflectance. Considering the previous four equations, one may obtain the equation 5.

$$LPE = \frac{E_p}{E_{ext}} = \frac{\sum_{i=0}^{n} E_i}{\pi \cdot L_0} \qquad (5)$$

where: LPE is the light-pipe efficiency; Ep is the light-pipe output section illuminance; Eext is the available illuminance in the unobstructed horizontal plane; Ei is the annulus illuminance; L0 is the light-pipe input section illuminance; n is the number of the emitter plane reflections.

Mathematically, substituting equation 1 into 2, one obtains Equation 6.

$$a_i = \sin \cdot atg\left[\left(i + \tfrac{1}{2}\right) \cdot \tfrac{b}{h}\right] \qquad (6)$$

Substituting equation 6 into 3, one obtains Equation 7 and Equation 8.

When i = 0;

$$A_0 = \sin^2 \cdot atg\left(\tfrac{1}{2} \cdot \tfrac{b}{h}\right) \cdot \pi \qquad (7)$$

When i > 0;

$$A_i = \left\{\sin^2 \cdot atg\left[\left(i + \tfrac{1}{2}\right) \cdot \tfrac{b}{h}\right] - \sin^2 \cdot atg\left[\left(i - \tfrac{1}{2}\right) \cdot \tfrac{b}{h}\right]\right\} \cdot \pi \qquad (8)$$

Substituting equations 7 and 8 into 4, one obtains Equation 9 and Equation 10.

When i = 0;

$$E_0 = \sin^2 \cdot atg\left(\tfrac{1}{2} \cdot \tfrac{b}{h}\right) \cdot \pi \cdot L_0 \cdot \rho^0 \qquad (9)$$

When i > 0;

$$E_i = \left\{\sin^2 \cdot atg\left[\left(i + \tfrac{1}{2}\right) \cdot \tfrac{b}{h}\right] - \sin^2 \cdot atg\left[\left(i - \tfrac{1}{2}\right) \cdot \tfrac{b}{h}\right]\right\} \cdot \pi \cdot L_0 \cdot \rho^i \qquad (10)$$

Substituting equations 9 and 10 into 5, one obtains Equation 11, in order to predict the light-pipe efficiency (LPE).

$$LPE = \sin^2 \cdot atg\left(\tfrac{1}{2} \cdot \tfrac{b}{h}\right) + \sum_{i=1}^{n} \left\{\sin^2 \cdot atg\left[\left(i + \tfrac{1}{2}\right) \cdot \tfrac{b}{h}\right] - \sin^2 \cdot atg\left[\left(i - \tfrac{1}{2}\right) \cdot \tfrac{b}{h}\right]\right\} \cdot \rho^i \qquad (11)$$

The absolute values of LPE, obtained by equation 11, can be also considered in percentage values, as it is commonly used with the daylight factor (DF).

SOFTWARE SIMULATION

Photopia is a general 3D luminaire design and analysis program specifically designed for non-imaging and illumination optical systems. Photopia's calculation basis is probabilistic raytracing, using real lamp geometries and measured intensity distributions, as well as measured directional reflectance and transmittance data for luminaire materials. User specified analysis settings allow for quick or detailed analyses of the luminaire design. In addition, all calculated output is available for viewing as calculations are in progress via a display update facility. In this way, a user can observe evolving output as a function of a specified percentage of the total analysis process.

Photopia includes "lamp" models for use in modeling daylight input into devices such as skylights, light pipes, solar collectors and room windows using daylight control systems. These source (lamp) models are based on the IESNA RP-21 daylight equations that model the absolute illuminance from the sun (solar disk) at various altitude angles and the sky for various sky conditions and solar altitude angles. The sky domes include variable luminance values across the hemisphere as described in RP-21. The sun models include a 0.53 deg. spread in their beam to model the actual angular size of the solar disk, averaged over its elliptical orbit. The combination of both the sun and sky dome models produces a total illuminance onto the daylighting device area that is intended to match real outdoor conditions. Keep in mind that real conditions can vary widely and the RP-21 equations represent average conditions. Such variability is what makes consistent physical measurement of daylight devices such a challenge and is one reason why daylight simulation is desirable.

Using the daylight source models is different than using the electric lamp models in Photopia's library since the daylight models illuminate the outside of a device to get light into it instead of illuminating a luminaire from within.

The default sky dome models are configured so that they uniformly illuminate about a 4' diameter area. Because of the way the light is emitted from the sky dome patches, light does spread beyond this 4' circle but it fades to a much lower level. In order to fully illuminate your device and also maximize the portion of sky dome rays that enter your device this model should also be scaled up or down depending on your device size relative to this 4' circular reference.

Since the sun and sky dome models will produce some rays that don't enter the daylight collection device, the complete model generally needs to include a shield so that the output of the device is isolated from the source models' stray light. The sky domes are relatively large in diameter since they need to generate a relatively even illuminance over an area large enough to accommodate the daylighting device. They concentrate most of their light toward the center of the hemisphere, but some light also strays away from the center. Only that light falling near the center of the hemisphere accurately models the way light is received from the sky dome.

The sky domes are relatively large in diameter since they need to generate a relatively even illuminance over an area large enough to accommodate the daylighting device. They concentrate most of their light toward the center of the hemisphere, but some light also strays away from the center. Only that light falling near the center of the hemisphere accurately models the way light is received from the sky dome. A lot of the light generated by the sky dome will not enter the daylighting device so it is also important to trace a large number of rays so that good resolution in your results can be obtained.

The efficiency (LOR) shown in the Photopia report will be the ratio of the lumens exiting the skylight divided by the total lumens produced by the sun and sky dome models. The total lumens produced by the sun and sky dome models is very large compared to the total number of lumens that are actually incident onto the daylight device. A more appropriate measure of the device efficiency is the ratio of the lumens exiting the device divided by the number of lumens incident onto it.

The studies presented by DUTTON & SHAO (2007) showed good results in using this software for predicting the performance of pipelines bright light compared to existing mathematical models. The simulations presented here, aimed to predict the transmittance of light through light pipes. For both pipe-lines were simulated with 36 input section ranging from 10cm, 20cm, 25cm, 30cm, 40cm and 50cm and lengths ranging from 1m, 1.5m, 2m, 3m, 4m and 5m.

DATA TREATMENT

Photopia provides a photometric report in which the luminous flux emitted by the luminaire is given. This report also shows the efficiency of the light, but in the case of the pipeline. This efficiency is false because the Photopia calculates it based on total luminous flux produced by the light source, in which case the pipe-line is the celestial vault. Thus, the value of the efficiency of a lamp is always the ratio between the total fixture lumens coming out of the total lumens generated by the sources (lamps) . In the case of designs that use daylight, this result does not match the efficiency of the lamp itself, in order that the source light does not emanate from within the machine but from outside. Thus, as only a small fraction of this light is captured through the pipe-line, the calculated result is usually negligible.

Therefore, it is necessary to know the value of the luminous flux that actually enters the pipe-line so that one can calculate the correct efficiency. To calculate the luminous flux entering the pipe-line light is necessary to calculate the horizontal illuminance at the opening of the pipe-line (lm/m^2) and multiply it by the area of the opening.

Photopia provides an Excel spreadsheet for this calculation. This is the "Daylighting Calculator" option that is on the menu "Help". This tool provides two options for sky condition , with sun or no sun and two choices of units of measure to be chosen , the international system and the Imperial system for the simulations was chosen the international metric system , the units are in meters , lumens and lux . For these simulations we used the "Enter Altitude Solar" option because this option, simply enter the angular position of the sun and the area of the inlet opening of the collector, the spreadsheet calculates the luminous flux entering the pipe-line.

The Daylighting Calculator spreadsheet only requests diameter header pipe because it is assumed that the shape of the device is round. As the simulated pipe-lines were square in section, the area of the section was calculated and then multiplied by the value of the horizontal illuminance average daylight in the pipe-line. The average horizontal illuminance is calculated by the referred spreadsheet.

$$\phi_{in} = E_{média} \cdot A \tag{12}$$

Where: φin is the total luminous fluz entering the pipeline; Emédia is the mean horizontal iluminance; A ia the entrance área of the pipeline.

Having obtained the luminous flux input, calculated by "Daylighting Calculator" (φin), the value of the total flux emitted by the product of light at the end of the simulation (φout) Photometric report and calculate the efficiency of the light pipe (in terms of percentage) by the following equation.

$$E = \frac{\phi_{out}}{\phi_{in}} \cdot 100 \tag{13}$$

where: E is thelight-pipe efficiency (LPE); φout is the luminous flux from the light pipe.

MEASUREMENTS

For the empirical research nine light-pipes, made of wood coated by mirror (optimirror plus, reflectance ρ=0,86), with square sections of 10cm, 25cm and 40cm e lengths of 100cm, 150cm and 200cm were considered.

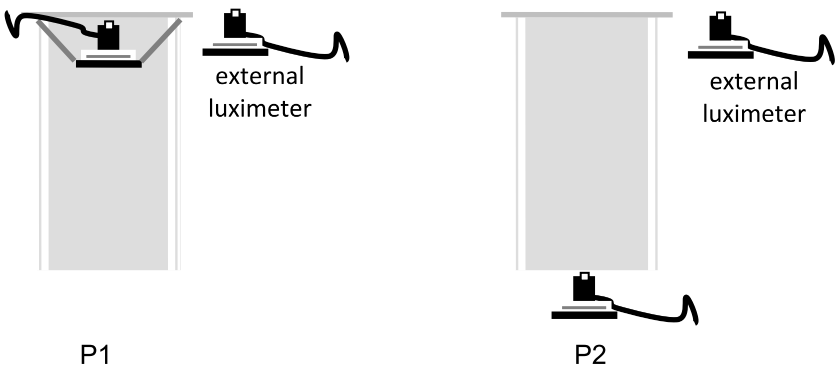
The mathematical model considers a theoretical uniform sky, thus in order to approximate the conditions of a real sky to the considered model, it was considered a real unobstructed overcast sky through the use of acrylic diffusers in the input section of the light-pipes.

The empirical field researches were done during 22/04/2009 and 06/05/2009.

Figure 3. Light-pipes of the empiric field research.

In order to log the data, digital luximeters HOMIS model 824 were used. They were set in the central spot of the input and output section of the light-pipes (respectively P1 and P2 in Figure 4). The data were collected in each point and each light-pipe one at a time, considering, as a reference, an external luximeter, measuring simultaneously the unobstructed horizontal plane.

Figure 4. Schematic illustration of luximeters positioning



COMPARATIVE RESULTS

The results obtained in the simulations with 36 pipelines were compared with a real scale model under real sky condition (LUZ, 2009) and with results calculated using the luminous efficiency of light pipes predictive model (MPELD. These comparisons are presented in the following figures.

Figure 5. Correlation between predicted and measured LPE (light-pipe efficiency).

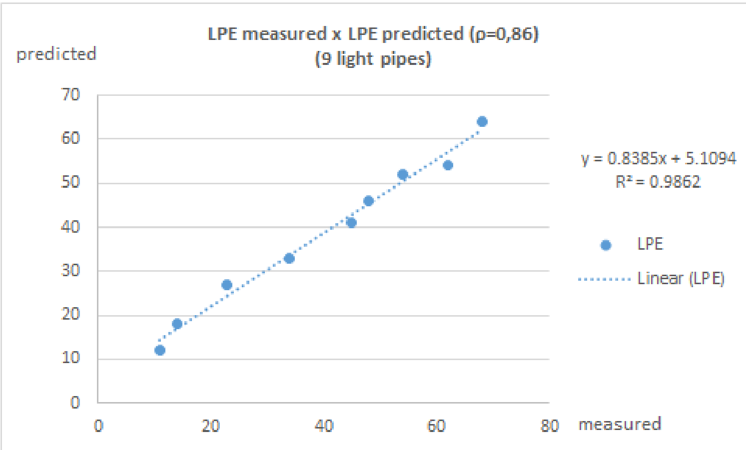


Figure 6. Correlation between predicted and simulated LPE (light-pipe efficiency).

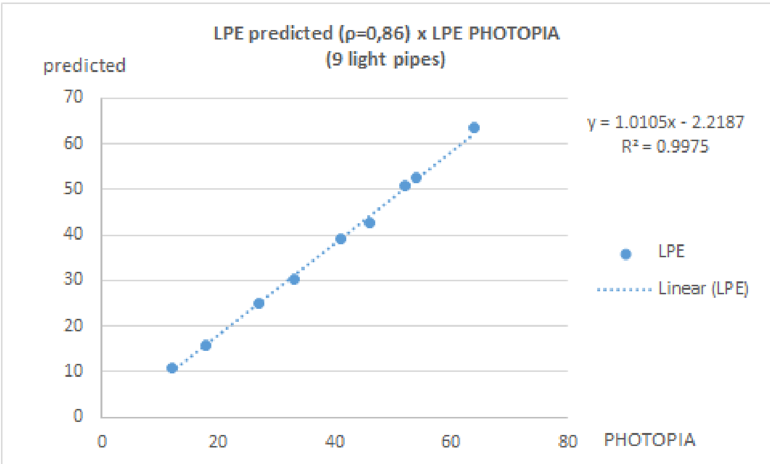

Figure 7. Correlation between predicted and simulated LPE (light-pipe efficiency).

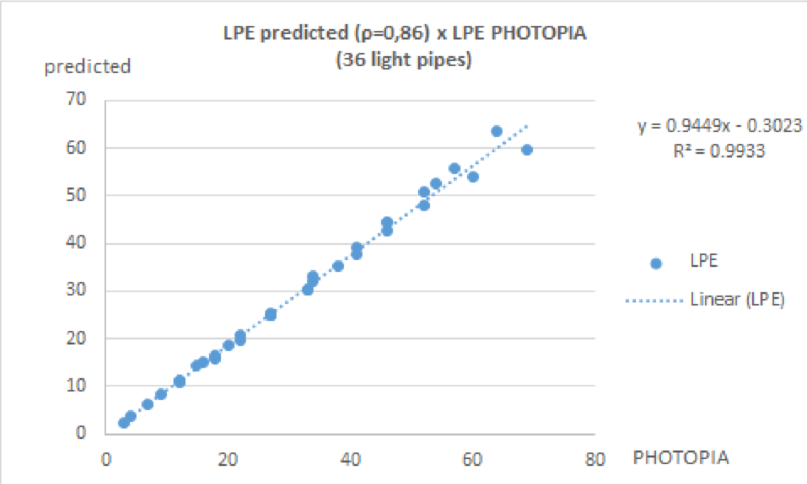

CONCLUSION

The high correlation found between results from the measured data and results from the proposed luminous efficiency predictive model of light-pipes (LEPMLP) with the results obtained from the software Photopia, in terms of estimated values of light-pipes efficiency (LPE), showed that the model is a reliable tool and is easily applicable for dimensioning light-pipes, taking advantage of daylighting in everyday architectural and building design practice, allowing to deliver daylight to rooms without direct contact with the external environment.

ABSTRACT

Facing rapid urbanization, sustainable urban developments become important in urban planning. To tackle urban climate issues in a planning context, a meteorological model with high resolution is useful for evaluating different planning scenarios. This study used the Weather Research and Forecast (WRF) with a single-layer urban canopy model to simulate summer meteorological conditions in Hong Kong, downscaling the spatial resolutions from 4.5 km to 500 m. Hong Kong (HK) was taken as an example due to its high building density in a sub-tropical climate region. The model results were compared against measurements at 25 weather stations. We quantified the urban heat island effect (UHI) in the summer in 2009, and estimated the resultant health impacts based on a temperature-response function. The model results and measurements show a good agreement with an index of agreement of 0.71 and a percentage difference of mean temperature of 1.33%. Our analysis estimated that the hourly temperature in urban areas (29.6℃) is higher comparing to that in rural areas (28.1℃). The Urban Heat Island Intensity (UHII) was estimated to be 1.6℃ on average. The UHI results in different Primary Planning Units show a north-south gradient pattern over Hong Kong: the highest UHII (1.7℃) in northern part of HK, whereas the lowest UHII (0.8℃) in southern part of HK. We found UHII correlates well with urban area size instead of population, highlighting that policy makers of high-density cities should pay attention to urban area size when tackling UHI. In addition, UHI was estimated to cause 75 [95%C.I. 22-158] mortalities in summer. Of which, ~55% of the UHI-related health impact occurs in New Territories, while 39% and 6% of the impact happen in Kowloon and Hong Kong Island, respectively. The results provide critical implications for urban planners to mitigate UHI in cities, especially in less developed countries.

NOMENCLATURE

PPU	Primary Planning Units
TPU	Tertiary Planning Units
UHI	Urban heat island effect
UHII	Urban Heat Island Intensity

WRF the Weather Research and Forecast model

INTRODUCTION

Urban heat island effect (UHI) is one of the major environmental problems in urban areas. Increases in temperature were found to have impacts on energy consumptions, public health and even air quality (Sarrat et al., 2006). According to the United Nations (2012), total urban population is projected to increase to ~67%. Thus, it is of importance to understand the urban heat island effect and the resultant impacts, especially in high-density cities such as Hong Kong (HK) given that the urban infrastructure and building morphology play an important role in the UHI (Rizwan et al., 2008).

Previous studies have shown that UHI was observed in Hong Kong. Memon et al. (2009) examined the reliability of urban heat island intensity (UHII), which was defined as the temperature difference between urban and rural areas. Based on the measurements collected at six weather stations, the study estimated that the mean hourly UHII ranged between 0.8℃ and 2.0℃. Giridharan et al. (2004 and 2005) investigated the UHI in urban high-density residential developments in both daytime and nighttime. Based on the measurements on several selected days in the summer in 2002, Giridharan et al. estimated that the magnitudes of UHI within an estate were 1.5℃ and 1.3℃ in daytime and nighttime, respectively. Although the UHI was estimated in the previous studies, the majority of the studies were based on measurements at sparsely-distributed locations. Thus, the spatial distribution of UHI and the resultant impacts have not yet been fully understood.

Changes in ambient temperature due to UHI may cause heat-related mortality, especially in summer. The health impacts of extreme hot weather events such as heat wave were previously studied (Bai et al., 2014; Zeng et al., 2014; Amengual et al., 2014). For Hong Kong, Chan et al. (2010) employed a statistical approach to investigate the relationship between the heat-related mortality due to changes in ambient temperature. However, the mortality due to UHI was not calculated in the study.

Therefore, this study is aimed at estimating the magnitude of summer UHI in Hong Kong and the resultant heat-related mortality. The results are anticipated to provide critical implications for urban planners and authorities to mitigate UHI in cities, especially for the ones which are being developed in less developed countries such as mainland China.

METHODS

Meteorological Model

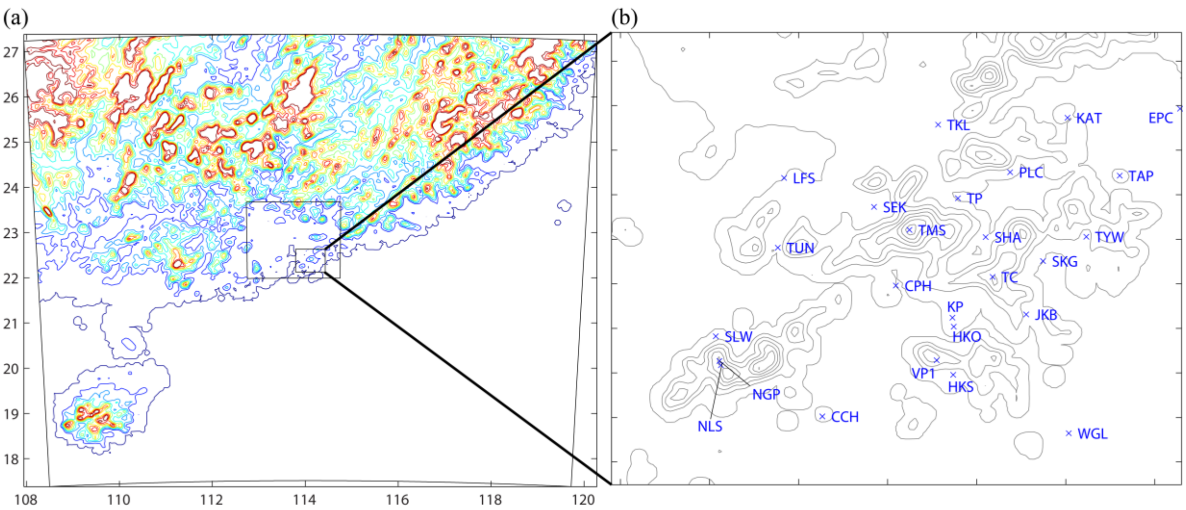

Figure 1 (a) The three WRF simulation domains. (b) The locations of the 25 HKO monitoring stations. The station names are provided in Table 1.

In this study, two months (Jul and Aug, 2009) were selected to investigate the summer UHI in HK. The Weather Research and Forecast model (WRF) (Skamarock et al., 2008) was used to reproduce the spatial distribution of temperature over Hong Kong in the study period. The WRF model has been widely used in urban heat island studies (Chen et al., 2014; Giannaros et al., 2013; Salamanca et al., 2012; Yang et al., 2012). The WRF model was configured to have three one-way domains, using which the meteorology was downscaled from a regional scale to a local scale. Figure 1(a) depicts the WRF domains. The outermost domain (D1) covers most of Guangdong province. D1 has 264×240 grid points with a spatial resolution of 4.5 km. The results of the D1 were then downscaled to the second domain (D2), which encompasses the Pearl River Delta. D2 has 136×124 grid points with a spatial resolution of 1.5 km. The innermost domain (D3) covers Hong Kong. D3 has 130×112 grid points with a spatial resolution of 500 m. A single-layer urban canopy model was adapted to improve the lower boundary conditions and the WRF performance within the urban regions (Masson, 2000). The WRF was configured to have 34 vertical sigma levels from the ground to the model top (50 hPa), with the first 11 layers being concentrated in the first 1 km above the ground level to resolve the structure of meteorology in the planetary boundary layer.

Table 1. The Names and Labels of the 25 Hong Kong Observatory Stations. The Locations of the Stations Are Shown in Figure 1(b).

	Station name	Label		Station name	Label		Station name	Label

8	Lau Fau Shan	LFS	**18**	Ta Kwu Ling	TKL			
9	Ngong Ping	NGP	**19**	Tai Mo Shan	TMS			
10	Nei Lak Shan	NLS	**20**	Tai Po	TP			

Multiple WRF simulations were conducted with a length of each simulation not exceeding a seven-day period. The results of first 24 hours were discarded as a spin-up period. The land use data was provided by the Lands Department of Hong Kong. The initial and boundary conditions were provided by the $1°\times1°$ NCEP FNL (Final) Operational Global Analysis data (NCEP, 2000) at six-hour intervals.

Measurement data to evaluate the WRF model were provided by the Hong Kong Observatory (HKO). The HKO stations are listed in Table 1 and plotted in Figure 1(b). To quantify the model performance, a set of statistical measures was computed similar to Yim et al. (2007; 2012; 2013).

The UHI was quantified by the Urban Heat Island Intensity (UHII), which represents the temperature difference between urban and rural areas. In this study, non-urban areas (except water bodies) were defined as rural areas. Both hourly and two-monthly mean UHII were estimated based on the WRF outputs. Figure 2 depicts urban areas (brown), non-urban areas (green) and water bodies (blue) in Hong Kong.

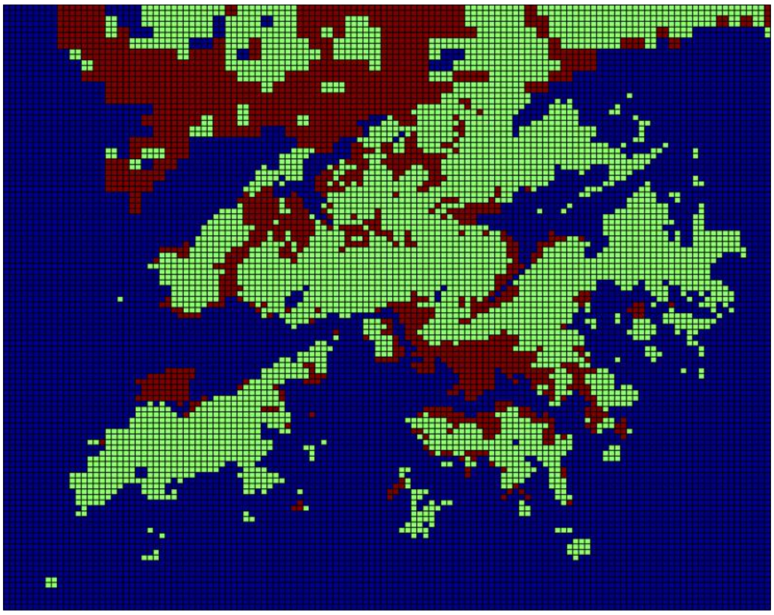

Figure 2 A land use map for urban areas (brown), non-urban areas (green) and water bodies (blue) in Hong Kong.

Health Impact

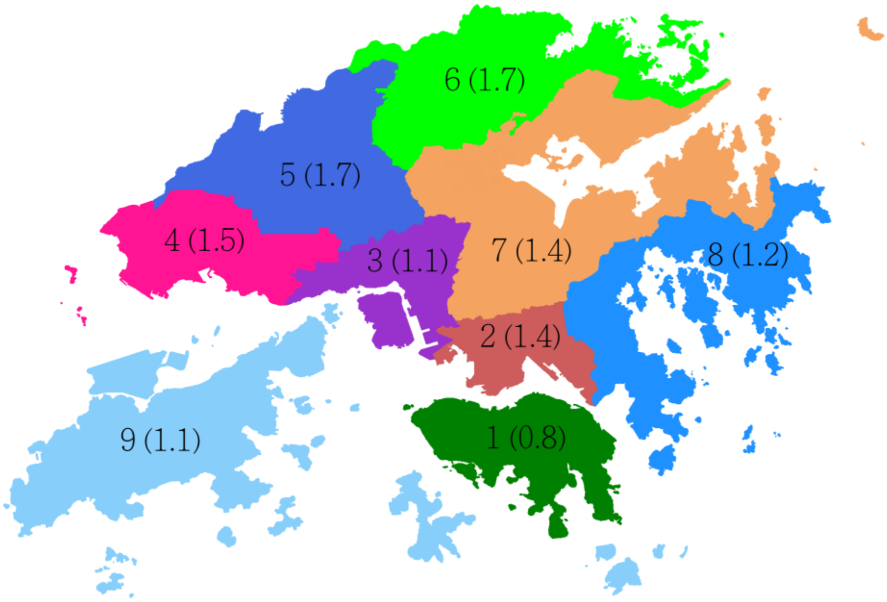

Figure 3 The nine Primary Planning Units (PPU) in Hong Kong. The PPU numbers are marked in the figure. New Territories includes PPUs 3, 4, 5, 6, 7, 8 and 9. Kowloon includes PPU 2, while Hong Kong Island includes PPU 1. The urban heat island intensity (UHII) (°C) values are provided in the brackets.

The health impact due to UHI was estimated based on the Chan et al. (2010). Their study estimated that 1.83% (95% C.I.: 0.73%-3.00%) increase in mortality in Hong Kong is associated with an average of 1°C temperature increase in daily mean temperature above 28.2°C. In their study, the increase of relative risks of heat-related mortality in different areas of residence including Hong Kong Island, Kowloon, New Territories and others were estimated to be 1.43% (95% C.I.: -1.20%-4.30%), 1.36% (95% C.I.: -0.63%-3.47%), 1.40% (95% C.I.: -0.53%-3.43%) and 9.27% (95% C.I.: 1.93%-18.17%), respectively. The areas of residence are depicted in Figure 3.

To estimate the population-exposure to UHI, the daily mean temperature of each day in the study period was overlaid onto the population data in a Tertiary Planning Units (TPU) level provided by the Hong Kong Planning Department. The average daily mortality per 1,000 persons was derived by dividing the annual mortality rate (6.1 deaths per 1,000 persons) provided by the Centre for Health Protection (2012) by 365 days. Thereafter, based on the aforementioned temperature-response function (Chan et al. 2010), the resultant mortality was estimated. We note that the temperature in indoor environments and the influence of population daily mobility were not taken into account in this study due to lack of data that may result in a higher bias in our results.

Uncertainty

For all the input data in the heat-related mortality calculation, an uncertainty distribution was estimated based on a Monte Carlo simulation, in which a triangular distribution of estimates was constructed on the basis of 10,000 samples. Uncertainty bounds were for a 95% confidence interval.

RESULTS

Model Evaluation

Figure 4 depicts time series plots of temperature at 2 m above ground at two HKO stations: HKO (urban) and TKL (rural). The results show that the modelled temperature agrees well with the measurements. As shown in Table 2, the index of agreement of temperature is 0.71 on average. The percentage difference of mean temperature is 1.33%, indicating that the simulation results are promising for our analyses in this study.

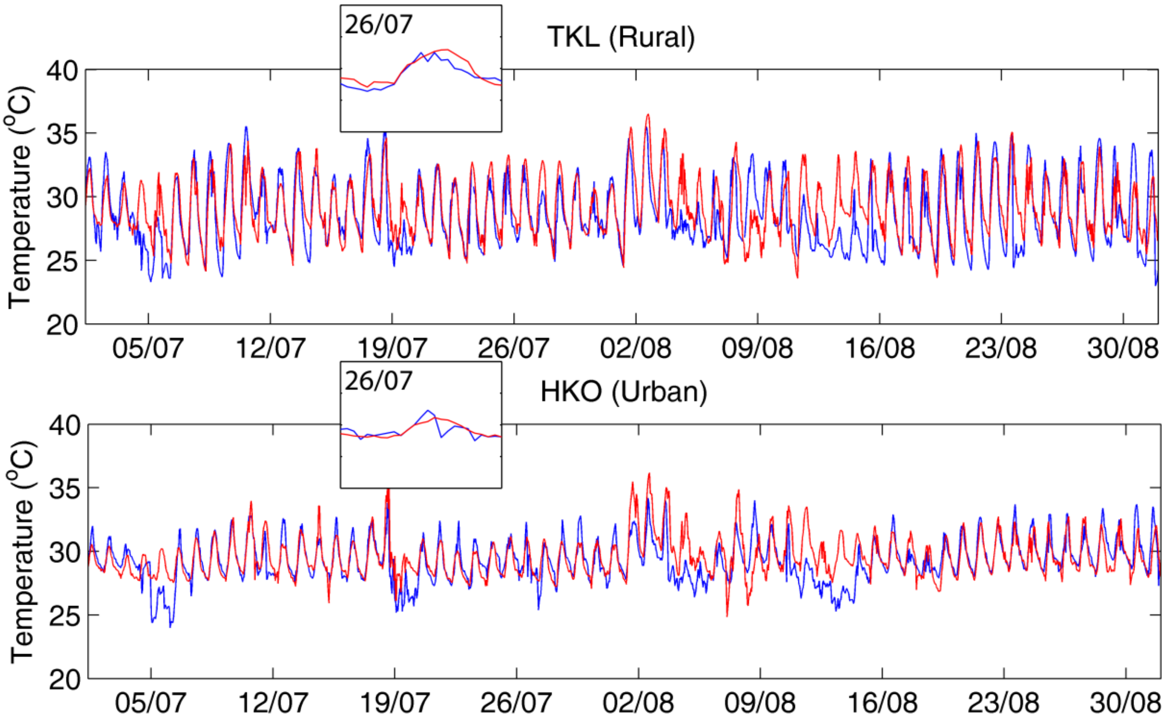

Figure 4 Time series plots of model evaluation of hourly temperature at 2 m above ground at Ta Kwu Ling – TKL (rural) and Hong Kong Observatory – HKO (urban). Blue lines represent observation data, whereas red lines represent model results. The two small figures are zoomed for a randomly-selected day (26/07) for clarity. The locations of the two stations are shown in Figure 1(b).

Temperature Differences between Urban and Rural Areas

Figure 5 depicts the hourly temperature distributions in urban (red) and rural (blue) areas. The results show that the hourly temperature in urban areas (29.6℃) is higher comparing to that in rural areas (28.1℃).

Chan et al. (2010) has found that a unit change in temperature in daily temperature above 28.2℃ is associated with an increase in relative risk of heat-related mortality. Thus, 28.2℃ was defined as a critical temperature in this study. Figure 6(a) depicts the daily temperatures in urban and rural areas. We estimated that the daily temperature in urban areas is always (>98%) higher than the critical temperature. However, only ~35% of the time the daily temperature in rural areas exceeds the critical temperature. The mean daily temperature in rural areas was found to be 28.1℃, which is slightly lower than the critical temperature. As shown in Figure 6(b), the mean UHII was estimated to be 1.6℃ on average.

Figure 3 depicts the UHII in different Primary Planning Units (PPU). In the figure, a north-south UHI gradient pattern is shown. We estimated that the magnitude of UHI (1.7℃) in northern part (PPU 5 and PPU 6) of HK is the highest among the PPUs. The urban population of the both PPUs, when combined, accounts for 12.6% of the total urban population in HK. The lowest UHI (0.8℃) was estimated to occur in PPU 1, which is located at the southern part of HK. The PPU 2, where its population accounts for 29.6% of total urban population in HK, was estimated to have 1.4℃ UHI.

Our estimate shows that the intensity of UHI correlates well with the size of urban areas instead of population. Hong Kong is a high building-density and high-population density city (Ng et al., 2012) due to limited lands for development, and thus its population is not proportional to the size of urban areas. Despite a lower population such as PPU 5 which accounts for only 8.2% of the total HK population, a larger urban area receives more solar radiation and may therefore result in a higher UHII. On the other hand, it should be highlighted that the urban area size pattern is consistent with the UHII pattern as observed in Figure 3. Figure 7 depicts that PPU 5 and 6 have a larger urban area, while PPU 1, 8 and 9 have a smaller urban area. This result indicates that the north-south UHI gradient pattern is associated with the pattern of urban area size.

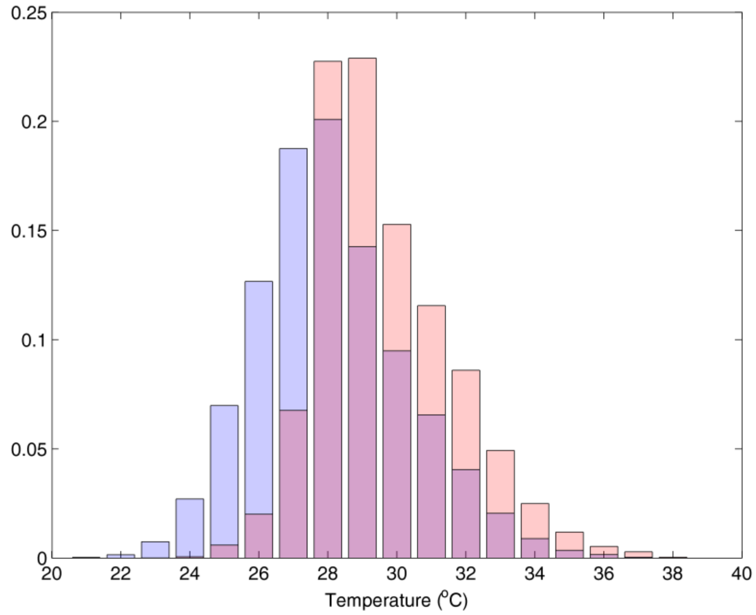

Figure 5 The frequency distribution of hourly temperature in rural (blue) and urban (red) areas in the study period. The x-axis represents temperature (°C), while y-axis represents normalized frequency.

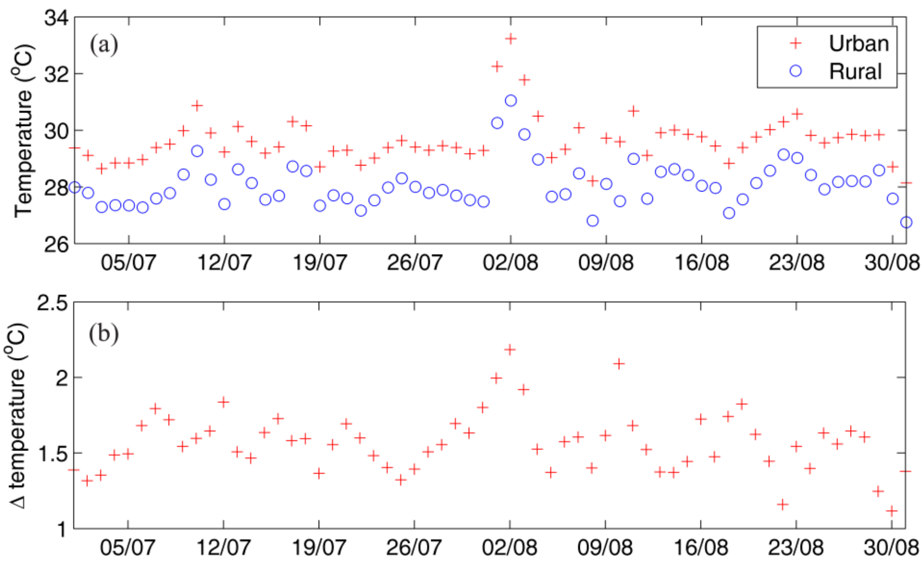

Figure 6 (a) The time series of daily mean temperature (℃) at 2 m above ground in urban (+ in red) and rural (o in blue) areas. (b) The time series of daily urban heat island intensity (UHII) in the study period.

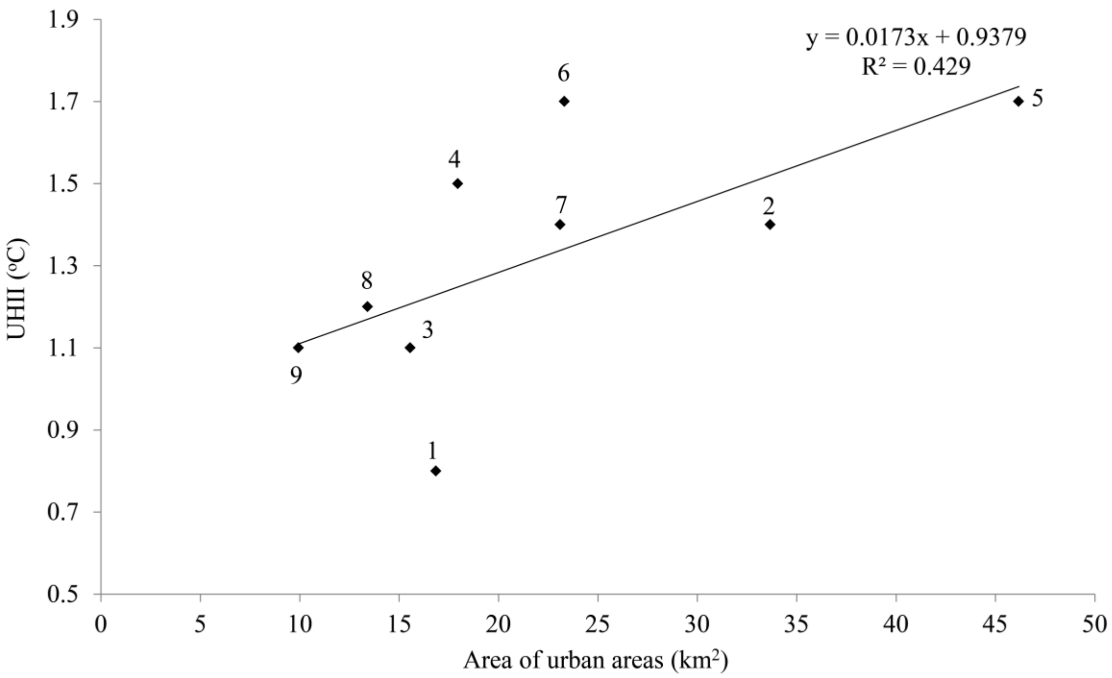

Figure 7 the relationship between area of urban areas (km^2) and urban heat island intensity (UHII) (^oC). The numbers near the data points represent the corresponding Primary Planning Unit number.

Health Impacts

We estimated that UHI causes 75 [95%C.I.: 22-158] mortalities in HK in summer, indicating that ~38 [95%C.I.: 11-79] mortalities are more likely associated with UHI each month in summer. The results show that ~55% of the UHI-related health impact occurs in New Territories, while 39% and 6% of the impact happen in Kowloon and Hong Kong Island, respectively.

DISCUSSIONS

Our results show that HK is affected by UHI in summer, where the mean hourly UHII is 1.6℃. This estimate is consistent with Memon et al. (2009), in which mean hourly UHII was estimated to range between 0.8℃ and 2.0℃. According to Leung et al. (2004), the temperature increase rates at an urban station (HKO) and a rural station (TKL) from 1989 to 2002 were estimated to be 0.61℃ and 0.15℃ per decade. The different increase rate between urban and rural areas indicates that the magnitude of UHI and the resultant health impact may increase in the next decade. Thus, mitigation measures should be implemented to address the UHI. Previous research has studied different mitigation measures such as green roof (Coutts et al., 2013; Zhao et al., 2014), vertical greening (Perini et al., 2011; Tan et al., 2014), and root coating (Bretz et al., 1997). On the other hand, Cheung et al. (2012) showed the importance of air ventilation for enhancing thermal comfort in a city.

Chen et al. (2010) reported that some sensitive groups such as the elderly may be more vulnerable to heat-related mortality. However, age distributions were not taken into account in our estimation due to lack of data. Therefore, more investigations should be done to further estimate the UHI-related mortality among different groups within urban community. In addition, we note that anthropogenic heat emissions, which could play an important role in the formation of UHI, were not taken into account in this study due to lack of the corresponding data. The lack of anthropogenic emisisons may cause a lower bias of our results. Nevertheless, this work identified the UHI and its health impacts due to land use variations (urban vs rural).

Another important impact of UHI is additional energy consumption. Fung et al. (2005) studied the energy consumption due to increase in urban temperature of Hong Kong. Based on the data from 1990 to 2004, the study estimated that the energy cost in summer due to an increase in 1℃ ambient temperature would increase by HK$1.6 billion per year. The study showed an important relationship between the additional energy consumption due to change in ambient temperature. However, the change in energy consumption due to UHI has not been studied in the literature, and thus needs to be quantified in a global change adaption context in the future work.

CONCLUSION

In this study, we quantified the urban heat island effect (UHI) in the summer in 2009 and estimated the resultant health impacts based on a temperature-response function reported in the literature. Our analysis estimated that the hourly temperature in urban areas (29.6℃) is higher comparing to that in rural areas (28.1℃). The Urban Heat Island Intensity (UHII) on average. The UHI results in different Primary Planning Units show a north-south gradient pattern over Hong Kong: the highest UHII (1.7℃) in northern part of HK, whereas the lowest UHII (0.8℃) in southern part of HK. We found that UHII correlates well with urban area size instead of population, indicating that policy makers of high-density cities should pay attention to urban area size when tackling UHI. In addition, UHI was estimated to cause 75 [95%C.I. 22-158] mortalities in summer. Of which, ~55% of the UHI-related health impact occurs in New Territories, while 39% and 6% of the impact happen in Kowloon and Hong Kong Island, respectively. The results provide critical implications for urban planners to mitigate UHI in cities, especially for the ones which are being developed in less developed countries such as mainland China.

ACKNOWLEDGEMENT

The study was supported by the Direct Grant of the Social Science Panel of the Chinese University of Hong Kong [Project ID 4052014]. The authors would like to thank the following government departments for the provided data: the Hong Kong Observatory, the Lands Department of Hong Kong and the Planning Department of Hong Kong.

ABSTRACT

This paper describes the development of a sustainability assessment framework designed to be used in the Gulf Region, which is an area which has experienced large scale building development and also a region in which sustainability assessment is not yet widely used. The complexity and time resources needed to apply existing methods act as a deterrent to active use. Three well-known methods available at the time of the study were investigated in some detail. These were: BREEAM Gulf; Green Building Council LEED; and Estidama Pearl. Cross comparisons of the factors involved in each method were carried out on several levels including: theoretical comparison; practical development and usability; compliance with regulations and standards; and ability to achieve synchronization. A considerable degree of compatibility was found to exist between the methods, particularly if focused on key criteria. As a result a new and specific framework was developed which grouped 24 indicators under five principal headings: site/location, biodiversity and accessibility; energy; water; occupant well-being; and resources and wastes. This new framework was then evaluated by testing with practitioners resulting in confirmation of 20 out of the 24 indicators, and identification of suitable benchmarks.

INTRODUCTION

The Arabian Peninsula is located in a hyper-arid zone, apart from the oil and gas there are minimal natural resources (Galbraith 2008) and the volume of construction work in the region, and Dubai in particular, has been unprecedented. There are impacts on many levels: economic; regional investment; and more specifically on the real estate sector. Dubai in particular has developed some astounding architecture and demonstrates inspiring achievements in form, scale, and budget. However and consequently, the construction industry has laid a heavy burden on natural resources (Al Marashi, 2006).

The Gulf region countries as a group are popularly referred to as the ‘The Gulf Cooperation Council’ (GCC) countries, consisting of: Saudi Arabia, Bahrain, Kuwait, Qatar, the United Arab Emirates, and Oman, with a total population estimated as 46.8 million. At the regional level, the characteristics that are common to the six countries reflect their similar rapid economic expansion, but they also originate from the fact that power generation in the six countries is mainly oil and gas based.

The energy sector, has played a crucial role in the socio-economic development of the GCC countries and also plays a significant role in economic growth and in development of policies towards environmental and sustainability issues in the GCC (Al Zubaidi, 2007).

Meanwhile sustainable buildings construction is still very limited in the region compared to the total building market and as a consequence, their cumulative impact on the reduction of ecological footprint is currently almost negligible. Recognizing the poor ecological situation, a study by Lahn, Stevens and Preston (2012) estimated a 29% potential energy saving in the building sector by 2025 (the

highest among all sectors potential savings) if effective efficiency measures were followed. There is a however reluctance to take up environmental assessment methods in the region; barriers encountered are varied in their type and magnitude. A general lack of understanding, and the level of complexity found in the methods are attitudes reflecting the main issues of concern. There is a need to develop more sophisticated targeted evaluation techniques and to limit the number of prescribed indicators to those of high sensitivity in a more effective basic environmental assessment for buildings in the Gulf region.

An analysis of a previous questionnaire distributed to 120 practitioners in the Gulf region, concluded that 78% had concerns about the difficulty in quantifying the benefits of green buildings and problems with the evaluation documentation process (Salama and Hana, 2010). It was also concluded that the construction industry in the UAE was witnessing a growing awareness of sustainability but the inconsistency of the responses reflected a blurred awareness of the key concepts of green building.

The Emirates Green Building Council (GBC) encourages the use of any recognized green building rating method as a means to creating a more sustainable built environment. There are several methods in the global market place as well as several methods commonly used in the United Arab Emirates (UAE). In the sections below a description of the commonly used methods is given together with a critique followed by the explanation of how an alternative assessment framework was developed, which was devised to be more straightforward to use and addressed the main needs expressed by professionals.

It is important to pursue development and integration of sustainability assessment at this period in history and some argue for intervention from governments to legislate for sustainable buildings and to create design and construction strategies to minimize the environmental impact of new building construction activity. In Kuwait, a survey indicated that 88% of respondents agreed that rules and legislation from government are required to enforce the concept of green buildings (Al Sanad, Gale, and Edwards, 2011). Another survey, concerned with evaluation of new residential building codes in the UAE, showed that using such codes could reduce the CO2 emissions of buildings by 50% (Radhi, 2010).

EXISTING ASSESSMENT METHODS

Assessment tools for environmental analysis of buildings and their surroundings come in many shapes and forms. Some address single issues such as energy use/carbon dioxide production or indoor air quality, whilst others incorporate a wide range of issues under an umbrella tool. The criticism that can be leveled at the latter when it results in a single figure outcome or single rating is that the overall rating compares dissimilar things. This criticism can be partly dealt with by using weighting systems between sub-categories that are agreed across issue boundaries and which can be periodically adjusted. Nevertheless it is the case that most countries have opted to use an overall assessment system as the notion of a single descriptor/evaluation has more public appeal. Over the years a large number of assessment systems have been developed in different countries. Some are prescriptive requiring answers to a large but defined set of questions; some are more flexible. The categorisation can also arise from whether the method is aimed at design features and operation (LEED, BREEAM) or whether dealing with life cycle assessment in great detail such as the German Deutchse Gesellschaft fur Nachhaltiges Bauen (DNGB), the Dutch EcoQuantum, or North American ATHENA. Methods also exist that are wider in scope and more dynamic, such as SBTool (developed by the IISBE organisation from the earlier GBTool). SBTool uses a toolkit approach from which users select relevant issues to suit their building type and location. The Living Building Challenge (LBC) which comprises seven performance categories: place, water, energy, health & happiness, materials, equity, and beauty, takes the approach to a different level by focusing on ‘imperatives’ which can be applied to a wide range of projects and which are undated in response to the market and current state of knowledge.

In this study a wide range of options were considered from which it was decided to focus on three examples of the design-led assessment, two of which have been widely used around the world and have established a place in the market. To these was added a more recently developed local GCC tool. A wide range of assessment methods and tools were examined for use in the study and three well-known options which could be applied were identified.

The reasons for choosing the three methods with their indicators for evaluation were: they are the most common methods in the Gulf region and are recommended by the UAE GBC; they had the ability to offer comparisons and benchmarking; they evaluated whole buildings and not only building parts; they provided a label and third party certification; there was a credible responsible organization behind the label; and they could be applied in different countries or were designed for cross-border application.

BREEAM Gulf 2008

BREEAM (the Building Research Establishment Environmental Assessment Method) was the first assessment system, launched in 1990, to offer an environmental label for buildings. BREEAM Systems are voluntary, consensus-based, and market-driven. Different schemes of BREEAM exist around the world and have been adapted to suit the regions in which they are to be used and to reflect differences in standard practice or cultures (Saunders, 2008). For international projects seeking evaluation under the BREEAM scheme, they should initially use BREEAM Bespoke International. This also allows an opportunity for the client to appoint a local consultant/expert to research the local codes and standards for the particular country/region. The Building Research Establishment uses this information to devise a set of final criteria to be used by the assessor to carry out the assessment on that particular building.

BREEAM Gulf was developed in collaboration with a variety of large organizations based in Qatar, Abu Dhabi and Dubai, with its objective to assist the construction industry in the region to achieve higher levels of sustainability and to recognize local context and issues (BREEAM, 2008).

LEED v.3 2009

LEED (Leadership in Energy and Environmental Design) is owned and administered by the US Green Building Council (USGBC). The method is flexible and can be applied to all building types: commercial, residential and entire neighborhood communities; and works throughout the building lifecycle: design and construction, operations and maintenance. LEED was identified by the Dubai authorities as a ‘tool’ to implement the region’s sustainability ambitions in a systematic manner, with the aim of an end-product that could be officially certified and therefore, internationally recognized. The Green Building Certification Institute (GBCI) was established in 2008 as a separately incorporated entity with the support of the U.S. Green Building Council for project registration and certification. LEED addresses several different project scopes for different building types; the latest version is version 4 which was released in late 2013; the version used in this analysis however was version 3 from 2009.

Pearl 2010

The Pearl Rating System was a key initiative of the Abu Dhabi Urban Planning Council (UPC) under the title Estidama (which means ‘sustainability’ in Arabic) and is a comprehensive rating system. Pearl was released early in April 2010 to provide a sustainability assessment program that aimed to be robust and tailored to the United Arab Emirates in terms of culture and climate. The system covers four pillars of sustainability: environmental, economic, cultural and social. The Pearl system aimed to address the sustainability of a given development throughout its lifecycle from design through construction to operation. The system provides design guidance and detailed requirements for rating a project’s potential performance (Estidama, 2010). It is however, like the others, a complex assessment to implement.

RESEARCH PROCESS

The aim of this research has been to develop a suitable sustainability assessment framework for office building relevant to the local context and priorities of the Gulf region. The research used ‘Mixed Methods Sequential Exploratory Design’ as a research methodology. The purpose of this exploratory sequential design was to develop and test a simple but reliable assessment framework and to generate design parameters. The first stage of the study was a qualitative exploration of theories regarding local context constraints and assessment method practices in the Gulf region. The second, quantitative stage followed-up on the findings from the qualitative stage for the purpose of examining the findings from multiple perspectives. Alternative sources and methods were used to compare, validate, and triangulate results and to examine processes/experiences along with outcomes. Comparative analysis data, case study and self-administered questionnaire were the main elements of the quantitative research.

The main task in the research was to choose and formulate the most appropriate ‘indicator set’, which considered the building's performance in relation to the local environment, culture and economy, as well as business goals. Furthermore, it was the intention to limit the number of indicators in the proposed framework to encourage take-up. Fernández-Sánchez and Rodríguez-López (2010) proposed a methodology used here, based on the identification of sustainability indicators by considering sustainability as opportunities for the project and on the establishment of indicators for measuring and controlling these opportunities. A framework would be essential for linking the vision and goals to the evaluation methodology and the indicators that are to be selected. The initial step was to choose the most appropriate criteria for the indicator set. Alwaer and Clements-Croome (2010) suggested four hierarchical categories of indicators to facilitate the selection process: *Pre-requisite* (Mandatory) indicators which are compliant with standards, regulations and quantified minimum targets; *Desired* indicators: ideal targets for building performance beyond the minimum required by regulations and codes of practice, to include the users vision; *Inspiring indicators*: goals and visions set by client: referring to long term mission and values; *Non-active indicators* or *non- applicable indicators* (the scope of this research project does not require these, and are thus ignored in the analysis). They should also be:

- Representative: Assist in informing choice in design decisions.
- Reasonably simple: Be usable by anyone, including professional designers and lay users with a simple and clear interface.
- Sensitive to change: Be flexible, multipurpose and generic in nature, and useable on many different types of buildings. Therefore enduring and persisting.
- Time resilient: Reflect specific aspects that could have impacts on sustainable buildings for current and future developments.
- Quantitative: Be quantifiable and scientifically valid (quantitative aspects or qualitative converted to quantitative).
- Accurate: Accurately/objectively measure progress towards sustainable development goals.
- Cost-Effective: Be cost effective but give value.
- Accessible: Data accessibility should be made easy and not constrain the process.

A methodology of five design sequential stages was employed: Stage 1 - Critical selection of aspects and indicators; Stage 2 - Structuring of the framework and refinement of selected indicators through comparative review of three existing sustainability assessment methods; Stage 3 - Structuring of the framework and refinement of selected indicators through a case study building study and comparative analysis; Stage 4 - Validation of the framework and indicators through questionnaire survey to local sustainable buildings industry professional; Stage 5 - Results analysis.

Arising from the evaluation, it was clear that all three methods required a high level of professionalism in sustainable design knowledge to be effectively used. The time and cost associated with this specialized knowledge is an important consideration. Moreover, the time required for documentation production is long and even though online submission is possible, the response time from the organisations is relatively lengthy. Typically four to six months is required for complete processing the applications; local experts' opinions suggest that it is usually longer, which also hinders acceptance in the marketplace. Also found as a result of the questionnaire was that the culture of the building industry relied on quick decisions. Credits within the assessment schemes that required substantial effort to be documented and which used external expertise, resulted in extra cost and time for the applicant, and this was one of the major criticisms. The survey also revealed that cost of assessment and documentation was a difficulty as was lack of awareness of the benefits. It was also found that expanding the range of issues in the methods, would also act as a disincentive to use.

The analysis showed that there was a good degree of commonality in approach of the three methods. The compatibility ratio among all the credits of the methods is high when related to the full data set: 65.2% for BREEEAM Gulf and 77.27% for LEED. And in spite of the expanded structure of Pearl in covering more phases of the life cycle, cultural themes of sustainability, natural systems and compliance with the Abu Dhabi plan 2030; the method showed 55.86% compatibility. This gives confidence in being able to define a reduced set of key indicators in a new framework.

DETAILED DEVELOPMENT OF FRAMEWORK

Thirty LEED certified projects in UAE, representing 90% of all LEED certified projects in the Gulf region up to August 2012, were analysed and evaluated and compared to BREEAM and Pearl at the same time. The projects were mostly offices, offices combined with industrial premises, and hotels; ratings achieved fell into the following categories: platinum 10%; gold 46.6%; silver 36.7%; and certified 6.7%. This thirty-project analysis provided a basis for understanding which indicators would be of most value from the wide range to be found if every credit from all three systems were combined.

In order to limit the number of indicators in the proposed new framework to the most relevant and significant, a prioritization process was required. Areas of assessment that were common to all evaluation processes were immediately designated for inclusion in the proposed framework. For the remainder, an analysis was made to determine what priorities would be selected if considered relevant to the following: the most severe local problems; local governmental and stakeholder objectives; mandatory rules and regulations of authorities; Gulf region environmental practices; and regional priorities and synergistic strategies. The sections below indicate in more detail the activities carried out.

Theoretical comparison: To characterize the essence of the three methods, the evaluative framework for environmental management approaches developed by Baumann and Cowell (1999) was adopted to structure the frameworks of the three methods. The purpose of using a framework is to give a better understanding of the context structure with recognized terminology and methodology.

Review of criteria addressed by area-context priorities: To allow review information for each of the three applicable assessment methods, by using the local context priorities drivers for sustainable design, seven criteria were identified: applicability, development, usability, system maturity, technical content, measurability & verification and communicability (Fowler and Rauch, 2006).

Comparison of methods standards and regulations: This aspect investigated and compared each of the three methods to show the level of compliance with standards and regulations on international, regional and local levels.

Comparison of methods impact categories/indicators: To examine the degree of synchronization and the potential for harmonization; since the same elements sometimes appear in different categories in the three methods a direct credit points allocation comparison can be difficult if not impossible (Smith et al, 2006). Accordingly, to allow for more objective comparison and to minimize internal systematic biases associated with the benchmarking of a comparative study, a system of harmonization was employed in which some aspects were reclassified. Figure 1 illustrates the outcomes following the harmonization process by comparing the allocation of weighting from the three methods across ten categories into which the indicators were allocated.

Information and findings from the theoretical and synchronized comparison revealed that the three methods were important in stimulating the market for sustainable building in the Gulf region and that the existence of more than one method could create competitive practices that might enhance the industry. None of methods were fully compatible with regional requirements, particularly in addressing criteria of some environmental issues, or in providing practical applicability to deal with regional contextual issues.

The detailed comparisons were then informed by analysis of their application to a case study building: one for which detailed design information was available and which had already achieved a high classification in LEED. The total number of sustainability certified new buildings up to July 2012 was thirty; two of them having LEED platinum certifications; the case study building was chosen to be one of these: the ESAB Middle East FZE office building. Space does not permit a detailed description of the case study analysis; however it enabled the choice of indicators to be substantiated.

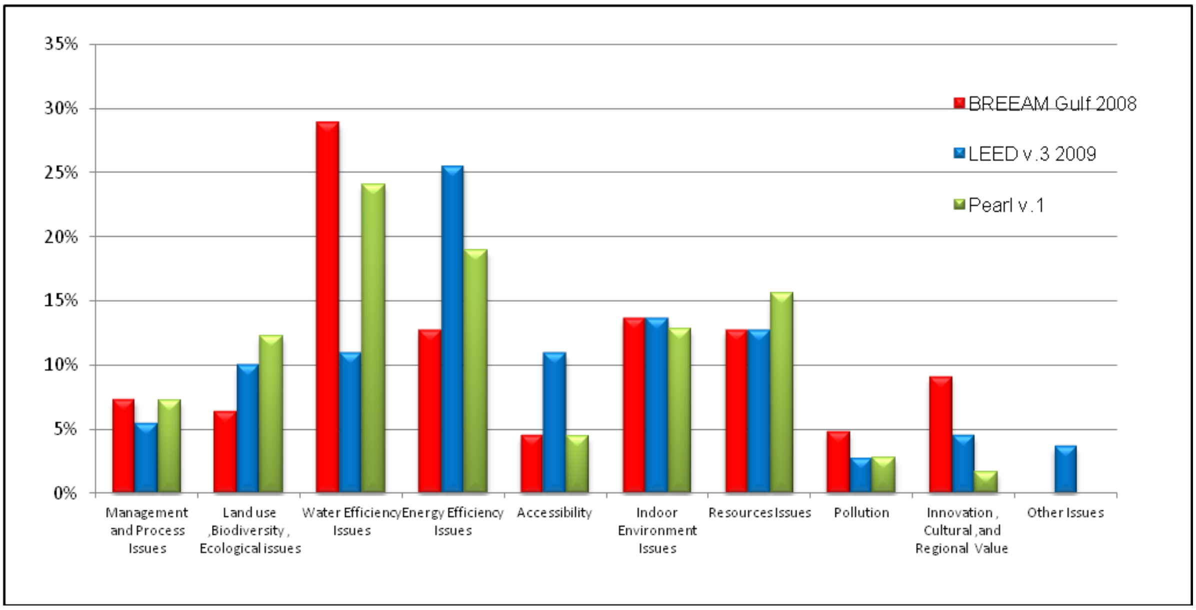

Figure 1 Comparisons of the synchronised and harmonized credit weightings for BREEAM, LEED and Pearl according to credit category.

GULF-REGION OFFICE-BUILDING SUSTAINABILITY ASSESSMENT FRAMEWORK

Arising from the various analyses, 24 indicators were initially chosen grouped under 5 main categories: Site Location Biodiversity & Accessibility; Energy; Water; Occupant Well-being; and Resources and Waste. The allocation of indicators was as follows:

Site location, biodiversity and accessibility (7 indicators): Site ecology; Construction pollution; Public Transport accessibility; Travel planning; Cycle facilities; Electric cars and car-pooling facilities; and Heat island effects on roof and other surfaces

Energy (5 indicators): Primary energy consumption for building operation; Commissioning; Energy monitoring; Ozone depletion/enhanced refrigerant management; and On-site power generation

Water (4 indicators): Interior water consumption; Exterior water consumption; Waste water technologies; Water consumption monitoring

Occupant Well-being (4 indicators): Indoor air quality; Thermal comfort; Smoking; and Emissions from materials.

Resources and Waste (4 indicators): Waste storage/recycling; Recycled construction materials; Locally sourced materials; and Construction site waste management.

SURVEY OF BUILDING PROFESSIONALS AND SELECTION OF INDICATORS

In order to validate the approach being used a survey of building professionals' attitudes was carried out using a questionnaire based on the assessment framework. In total 91 responses were received and 87 of those were deemed to be valid and answered all questions. Responses to key questions are shown in Table 1. The survey also asked participants to rank the importance of the proposed indicators on a scale of 1 to 4. It was also found 87% of industry professionals agreed that the proposed framework would be effective in enhancing performance of office buildings in the Gulf region.

One of the most important aspects of the survey was to confirm or exclude indicators and to check for availability of appropriate benchmarks or indicator-specific analytical tools in order that the value of the indicator could be calculated. A cut-off value of 3.0 was chosen as signifying the professionals' acceptance of the indicator. Table 2 shows the summary results and that four indicators were excluded. The determination of the availability of benchmarking/analysis tools was made easier by the previous comprehensive assessment of available methods for the Gulf Region. In two cases specific additional information to that normally used would be needed to enable the calculation, and in two further cases it was determined that a slightly modified version of the benchmark analysis would be required.

Table 1. Responses from Building Professionals to key questions about sustainability

Response to question	Sustainable Development is a very important concept and principle for the Gulf region countries	Sustainability assessment is an important issue for office building development in the Gulf region	Current design approaches adopted within the building industry in Gulf region countries are creating sustainability problems
Strongly agree	59 (67.9%)	50 (57.5%)	49 (56.4%)
Agree	25 (28.7%)	34 (39.1%)	32 (36.8%)
Disagree	1 (1.1%)	3 (3.4%)	4 (4.6%)
Strongly disagree	2 (2.3%)	0 (0%)	1 (1.1%)
No response	0 (0%)	0 (0%)	1 (1.1%)

Table 2. Gulf-region Office-building Sustainability Assessment Framework: confirmation of indicators to be used from survey and benchmarks (*= further information needed for benchmark use; **=modified benchmark)

Indicator	Rank weighting (out of 4)	Confirmed as included	Benchmark availability
Site ecology	3.91	Confirmed	Confirmed*
Construction pollution	3.67	Confirmed	Confirmed
Public transport access	3.55	Confirmed	Confirmed
Travel planning	3.40	Confirmed	Confirmed
Cycle facilities	2.93	Not confirmed	Excluded
Electric cars	2.84	Not confirmed	Excluded
Heat island effects	2.84	Not confirmed	Excluded
Minimise primary energy	3.83	Confirmed	Confirmed**
Commissioning	3.77	Confirmed	Confirmed
Energy monitoring	3.55	Confirmed	Confirmed
Ozone depl/refrigerants	3.54	Confirmed	Confirmed
On-site power generation	3.37	Confirmed	Confirmed**
Interior water use	3.94	Confirmed	Confirmed
Exterior water use	3.74	Confirmed	Confirmed
Waste water technologies	3.45	Confirmed	Confirmed
Water use monitoring	3.36	Confirmed	Confirmed
Indoor air quality	3.78	Confirmed	Confirmed
Thermal comfort	3.76	Confirmed	Confirmed
Smoking	3.71	Confirmed	Confirmed*
Emissions from materials	3.58	Confirmed	Confirmed
Waste storage/recycling	3.70	Confirmed	Confirmed
Recycled const. materials	3.43	Confirmed	Confirmed
Locally sourced materials	3.46	Confirmed	Confirmed
Const. site management	2.92	Not confirmed	Excluded

A further question concerned the respondents' perceptions regarding impact categories that affect sustainable design of office buildings. Energy and water at 97.7% and 93.4% respectively were the most frequently cited issues. Other categories scored as follows: occupant well-being 73.6%; site location and biodiversity 70.1%; resources and wastes 56.3%; and operation and maintenance 49.4%.

The impact of the survey results was to confirm the approach and scope of the new assessment method described in this paper and to encourage further research and development.

CONCLUSIONS

This paper has presented the key features of a research project designed to generate a new and more easily applied sustainability assessment framework suited to the circumstances of the Gulf Region. The Framework is well-founded being derived from a detailed analysis of available international methods but enhanced by focusing on the key parameters that can be applied efficiently in the Gulf Region. Further analysis and evaluation is required to determine the most effective means to bring the system to the market-place and to assess any potential limitations of the Framework in practice. The data gathered from the professionals and from the study of the previously assessed thirty projects will permit the next stage – that of allocating a more sophisticated and justified weighting to each indicator, to be carried out.

ABSTRACT

India has a rich tradition of passive architectural design practice. There has been, however, little effort to study these design strategies to evaluate their effectiveness. This study analyses the climate responsiveness and thermal performance of domes and vaults in brick masonry.

The study compares the performance of hemispherical domes and segmental vaults in a residence-office building for indoor conditions measured on hourly basis for one year. The study gives the necessary quantifiable performance of domes and vaults constructed using low-cost, local materials as an effective energy efficient design strategy that may be easily adopted as a practice.

INTRODUCTION

Vaults and domes appeared in Auroville in 1982 as an answer to the cement shortage after the oil crisis of 1979. Imported cement from Vietnam and South Korea was being sold in the black market in India at a high price. The labor intensive and high thermal mass construction of domes and vaults in local country fired bricks with lime mortar seemed to be the ideal alternative to RCC roofs.

They can be a good example in today's context of high energy intensive construction techniques. While addressing the increasing demand of housing in India with the use of natural materials, innovative techniques and engagement of local craftsmen as a cost effective, culturally, socially and economically sustainable means; they also provide a continuum of traditional knowledge and employment generation in the region.

An example of a residence-cum-office complex using these techniques was chosen for this study. From the two residences, we have concentrated on the right side of the complex (refer photo – fig 1), which consists of three domes and three vaults, since two of these domes provided us an opportunity to study different ventilation systems – one with an air vent and one with aluminium wind extractor *(Dome 2; Fig 4).*

Figure 1 Mukuduvidu Complex. Southern facade, 1992

CONTEXT AND CLIMATE

Auroville context (warm-humid climatic zone of India):

Latitude:12° N | Longitude: 80° E | Altitude: +60 MSL Winters (Nov – Feb) : 21 °C to 32°C Summers (April – July) : 28°C to 41°C	Daily radiation received: 4 to 7 kWh/m (peak – 1 kW/m² at noon) Annual average rainfall : 1,200 mm North-east monsoon (Oct – Dec) - approx 60% of the annual rainfall South-west monsoon (June – Sept) - approx 20% of the annual rainfall

Alternating land and sea breeze provide reprieve from the hot and humid climate. Relative humidity varies from 60% to 90% throughout the year and wind velocity varies from 0 to 8 m/s with 1.4 m/s annual average (AV weather station data / CBERD project).

Case study. Mukuduvidu Complex. Fact File :

Year:	1990 - 1992
Usable area:	96m^2(ground floor); 48 m^2(first floor); Total: 144 m^2 (this represents the part under study only)
Architects	Poppo Pingel and Mona Doctor-Pingel
Passive Strategies	North-south orientation | thermal mass – 0.22 m load bearing low fired country brick with lime mortar and plaster | 1.2 m overhangs in the south and north | wind exhausts for domes, high ceiling with vault structure to allow for ventilation under the roof | maximum large openings on the south, less large on the north side (rain direction, sun in the summer) with minimum opening of the east and west side | domes are covered with reflective white broken china mosaic | Extensive landscaping with large trees on the west and north, water bodies and Zen sand garden to the south.
Construction methodology:	Up to 4 m spans for vaults and 5 m diameter for domes are economical from structural and functional point of view with this construction method. Vaults were constructed by a wooden sliding shutter of 1 m width. The flat roof achieved by a vaulted roof also allows a terrace for drying and sleeping during the hot summers. Local unskilled labor can be easily trained in the simple masonry required for domes and vaults. A single casuarina pole fixed in the center with a rotating arm acted as a guide to create a hemispherical dome and within a week, the roof was created (Fig. 7.1). All construction work was done manually.
Principles of Baubiologie Employed	Baubiologie (Building Biology) - the study of the impact of built environment on the health of the people and the application of this knowledge to the construction of healthy homes and workplaces – was applied in this building | Concerns of electro-magnetic fields taken care of by a judicious design of electrical layout | Use of natural materials | Bio concrete for the RCC beams, specifically made with hand-cut limestone chips as aggregate | Waterproofing of domes and vaults done without use of chemicals | Natural water-bodies that are self maintaining | All plants are indigenous requiring minimum watering | Waste water is treated and feeds fruit trees | Solar PV with battery, solar water heater, solar cooker for cooking

RESEARCH OBJECTIVES

1. Effectiveness of brick masonry hemispherical domes (internal dia 4.8 m) and segmental vaults (rise 0.55 m and 3 m span) to provide thermal comfort as per adaptive thermal comfort model of ASHRAE 55 across the year as a naturally ventilated building without using any electrical system such as fan to generate air velocity.
2. Identify the time lag in thermal transmission occurring through different walls and roof.
3. Efficiency of the wind extractors installed in a ventilated opening at the top of the dome.
4. Establish the WWR for hemispherical dome space and study it vis-à-vis its adequacy of sufficient air movement.

APPROACH

Within the CBERD (US-India Center for Building Energy Research and Development) project, under the umbrella of Auroville Center for Scientific Research (AV CSR) we are monitoring this building since September 2013 with hourly readings from 10 loggers and 15 sensors placed within the two domes on the first floor and the space on the ground floor formed by exposed brick vaults. The domes have a slightly different construction type: one is with squinches on a square base and another is with precast concrete circular beams also on a square base from where the dome springs. The two domes also have different ventilation system for hot air evacuation (Ref Fig 5 & 6).

Mona Doctor-Pingel has an independent architectural practice, Studio Naqshbandi, and is a team member of CBERD project. Rajan Rawal is Director, Center for Advanced Research in Building Science and Energy, CEPT University. Anna Bakhlina, is an architect, Studio Naqshbandi. Vijai Krishnaraj is an instrumentation engineer, CSR, Philippe Bourdon is a student in construction and energy engineering, ESIROI, Reunion Island

Logic of loggers placement

Surface temperature sensors are placed inside and outside the dome surfaces (at different heights) within the dome. Each of the sensors is covered with a white thermocol strip (25 mm x 50 mm x 5mm, Figure 7.5) to protect the sensor and to enable easy adhesion to the surface. One free hanging logger is placed inside each dome and the vault to measure air temperature and RH in the rooms (approximately 1.50 m above the ground, on the height relative to occupants use). There is a logger installed in a thermocol box (adaptation of the Stevenson screen) outside the residence for ambient temperature measurements. (For the type of loggers used and location refer the table and illustration – Fig. 2, 3, 4).

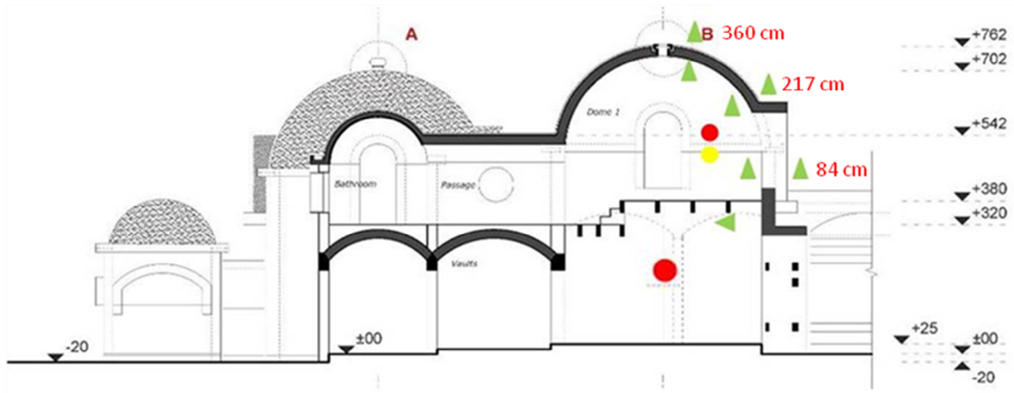

Figure 2 Section A-A' through **Dome 1** with placed data loggers and surf temp sensors placement (color code Figure 4)

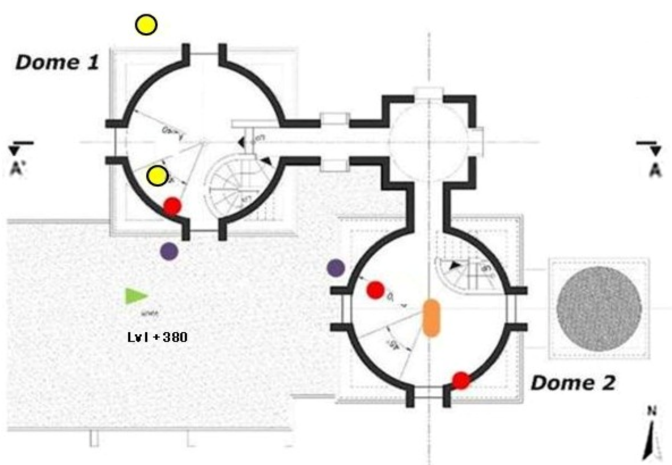

Figure 3 First floor plan with loggers placement.

	ONSET loggers			
	logger type	measurments	№ of loggers	accuracy :
	U12-012	temp, RH,Lux	2	T : ±0.35º C From (0 to 50 º C) RH: ± 2.5% (from 10 to 90 %)
	U12-013	temp, RH,	4	T : ±0.35º C From (0 to 50 º C) RH : ± 2.5% (from 10 to 90 %) External Input Channels : ± 2 mV ± 2.5% of absolute reading
	U12-006	-	2	± 2 mV ± 2.5% of absolute reading ± 2 mV ± 1% of reading for logger-powered sensors
	UX100-011	temp, RH,	2	T : ±0.21°C from 0° to 50°C RH : ±2.5% from 10% to 90% typical to a maximum of ±3.5% including hysteresis
	ONSET sensors

	T-DCI-F900-L-O	air-velocity (single drection,hotwire)	1	+/-0.05 m/s or 1% full-scale

Figure 4 List of loggers and sensors.

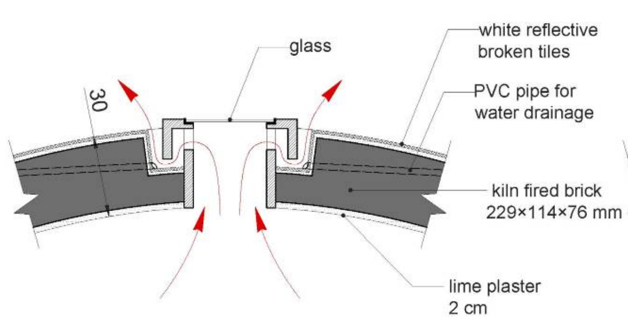

Figure 5 Detail B. Dome 1. Air vent.

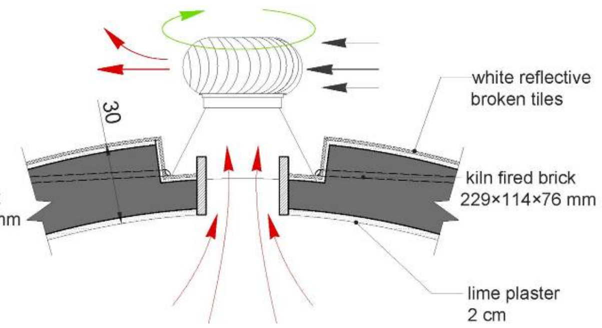

Figure 6 Detail A. Dome 2. Air vent with wind extractor.

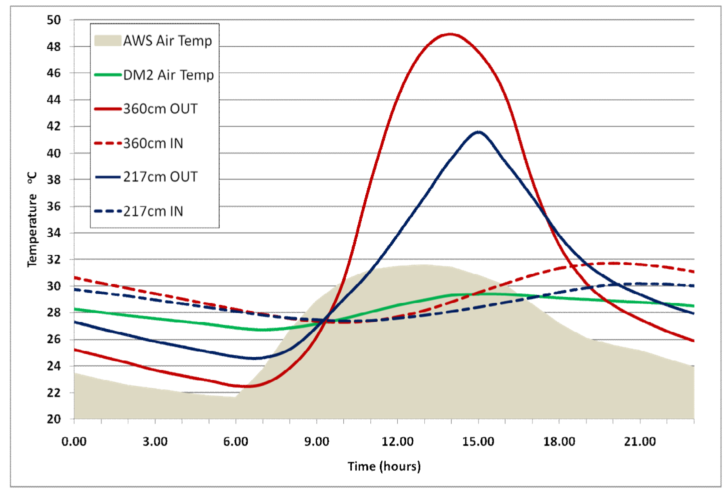
Additionally hand held readings are taken every three weeks, measuring air, globe and surface temperatures, air-velocity and humidity in every room under study as well as checking for any specifics that could not be taken by continual data logging. Any changes or abnormalities are recorded meticulously.

Surface temperature sensors are placed on ceiling and rooftop both for the vault and the domes. Weather data is obtained from an Automatic Weather Station (AWS) set up by the Indian space research organization at Auroville.

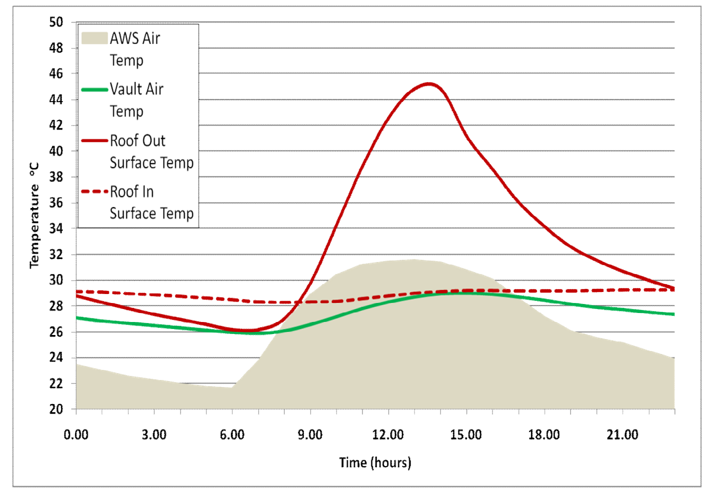
Figure 7 From the left: **1 -** Dome with rotating arm under construction; **2** – Air vent opening detail on the top of the dome; **3** – Dome 2: Air vent with wind extractor; **4-** Air-velocity sensor fixed in the Dome 2; **5 –** Fixed surface temp sensor on the vault covered with white thermocol strip

OUTCOMES

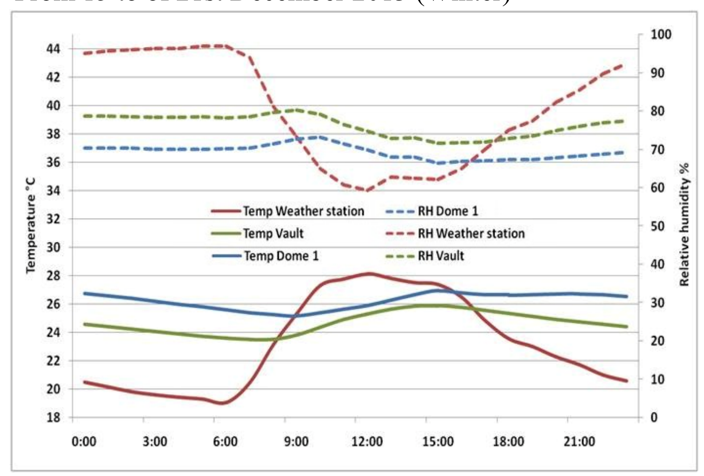
Graph 1. Hourly values of mean surface temperature for Dome 2 - IN vs. OUT March 2014



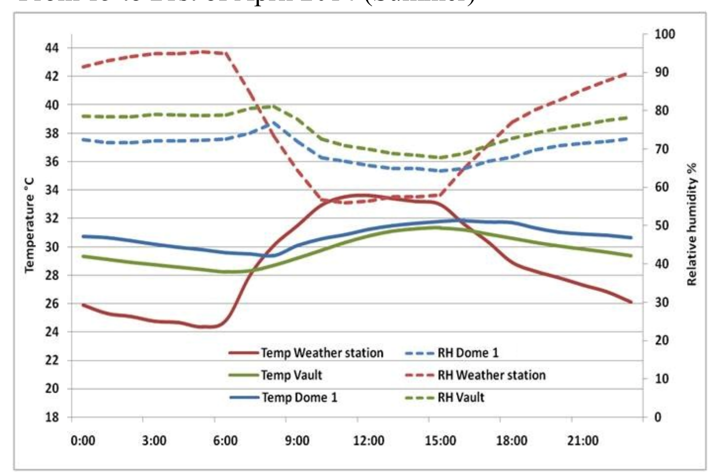
Graph 2. Hourly values of mean surface Temperature for Vault - IN vs. OUT March 2014



Graph 3. Hourly values of mean Relative Humidity and Ambient Temperature of Dome 1 vs. Vault From 15 to of 21st December 2013 (Winter)



Graph 4. Hourly values of mean Relative Humidity and Ambient Temperature of Dome 1 vs. Vault From 15 to 21st of April 2014 (Summer)

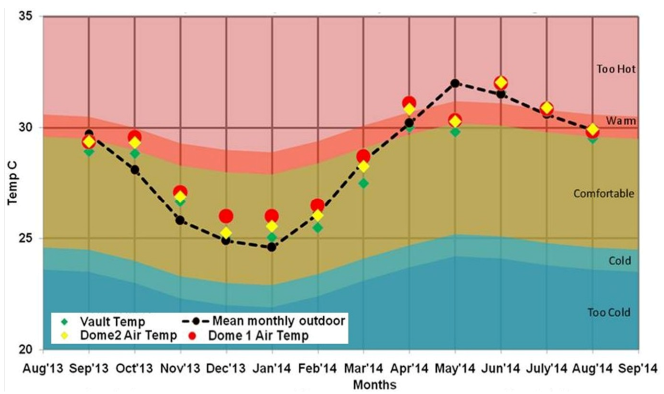


Graph 1 indicates that the outside surface temperatures are increasing towards the top of the dome, due to the increasing sun exposure, the same trend is reported for the inner surface with a 6 hours thermal lag (from outer to inner surface).

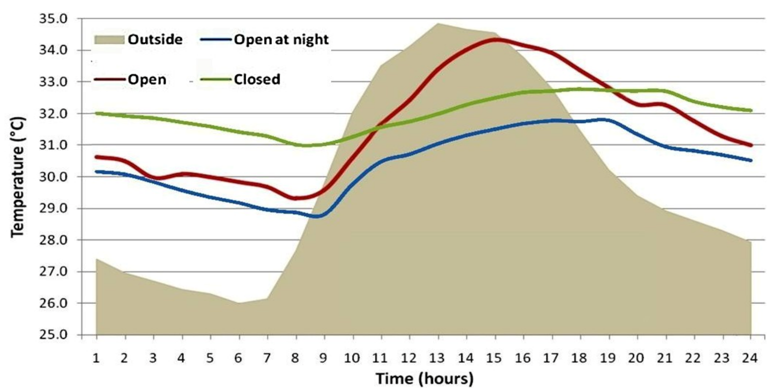
Graph 2 shows the performance of the vault in the same condition and through the same period of time as Graph 1. The time lag is more significant than the dome. The ceiling thermal lag is 8 hours from outer to inner surface. Ceiling surface temperature remains relatively stable thanks to high thermal mass and cross ventilation occurring in the vault.

Graph 3 and Graph 4 shows the comparison of the indoor air between the dome and vault looking at one week data in December (winter) and April (summer). In summer, the air temperature time lag is 3 hours for the vault and 4 hours for the dome. In winter, time lags dropped to 2 and 3 hours. Winter sees lower time lags but the same trend remains, the vault has the shortest air time lag which is synonymous to a more efficient cross ventilation.

Graph 5. Values of mean temperature in Dome 1, Dome 2 and Vault from Sep 2013 till Aug 2014 with Adaptive comfort zones (CARBSE), for Naturally Ventilated Buildings, *(13 ^{0}N, Chennai)*



Graph 6. Dome 1 air temperature with 3 different opening scenarios (weekly mean in April-May 2014): Windows closed throughout day & night; Windows open throughout day & night; Windows open at night and closed during the day



Graph 5: Overlapping the mean monthly temperatures of the building with the adaptive thermal comfort zones elaborated by CARBSE for Chennai, we can observe that the vault remains within the comfort range from September to May, whereas domes are within the comfort range from September to April (without any electrical ventilation system). Dome 2 is slightly cooler than the Dome 1, the major difference coming from the wind extractor proving that wind extractor helps to reduce the indoor temperature by increasing hot air extraction even when windows are closed. We can conclude that vaulted space shows better thermal performance.

Graph 6 compares the air temperature for three windows opening scenarios in Dome 1 and clearly indicates that the strategy to close the windows during the day to keep the fresh air and opening at night to cool down shows the best results. Detailed analysis of our data shows that windows open at day (09-18hrs) increases the indoor air temperature by 2°C more than when they are closed. Also windows open at night (18-09 hrs) allows an extra cooling of 1.2 °C than when they are closed.

Air Velocity measurement in Dome 2: The maximum and minimum air velocity recorded at the wind extractor is 1.54 m/s and 0.11 m/s respectively. The average is 0.57 m/s. The hourly mean values show that the air velocity increases at night time when land breeze prevails. More data and studies need to be undertaken with sophisticated instruments on the air movement in the room especially for the cross ventilation.

Surface to Volume Ratio and WWR study.

The vault has large overhangs on the south and north (1.2 m) and walls that are shaded / shared on the east and west. The domes have smaller overhangs on openings only (0.6 m) and the dome surface gets heated by direct sun radiation throughout the day, while the vault get alternately heated on the East then on the West side, not both at the same time. This difference has a repercussion on heat transmission and storage in the walls.

Table 1. Surface, volume and WWR calculation of the room with spherical dome and comparison with an equivalent vault-flat roof room interims of area & volume.

	Existing Dome	Equivalent Vault
Floor surface area	23 m²	23 m²
Internal volume	60.2 m²	60.2 m²
Internal height	3.6 m	2.61 m
Exterior surface area	79.5 m²	88.8 m²
Exterior wall surface area *	69.56 m²	60.71 m²
Surface area of openings	6.71 m²	32 m²
Window to Wall Ratio	**9.6%**	**36%**

* Exterior semi-spherical dome surface is counted as a wall surface

Comparing the WWR for vault and dome shows that the total area of opening is much less in the dome, mainly due to structural constraints. For the warm humid zone this leads to less possibility for ventilation and air movement.

CONCLUSIONS

- Thermal comfort can be achieved in a naturally ventilated building under a warm and humid climate using passive strategies. The overall performance of vault is more satisfactory than the dome in this case study due to its larger openings enhancing cross ventilation and lesser solar heat transmission.
- The thermal mass of the domes and vaults ensures a time lag of 2 - 4 hours for the air temperature. Domes' being less than the vault.
- Temperature on the surface of the dome increases towards the top.
- Ventilation at the center of the dome is important. The installation of the aluminum wind extractor on the top of the dome fares better than the air vent design as it increase hot air dissipation.
- The dome and vault are more comfortable in the winter than in summer months in warm humid climate. Other factors such as lifestyle habits and indoor air velocity would need to be considered.
- Air-velocity data for all the areas under study was not available. This would be important to take into account for naturally ventilated areas, especially without electrical ventilation systems.
- A comparison with modern RCC dwellings in the same climate can be undertaken in the next phase of research.
- Occupied buildings that are naturally ventilated are difficult to monitor, since behavior patterns and use of the building change with the outdoor conditions.

Temperature Regulation and Thermal Energy Storage Potential of Phase Change Materials Layer Contained at the Back of a Building Integrated Photovoltaic Panel

Ahmed Hassan[1], Hamza Nouman[1], Ali Assi[2] & Brian Norton[3]

ABSTRACT

Photovoltaics (PV) deployed in high solar radiation high ambient temperature climate suffer huge loss in efficiency and degrade faster due to higher panel temperature. In order to overcome the temperature induced loss of power and life, s paraffin wax based solid-liquid phase change material (PCM) integrated at the back of PV is investigated in high temperature climate of UAE. The temperature drop on the PV panels due to inclusion of the PCM is recorded and compared to a reference panels without PCM. The associated voltage gain caused by temperature drop of PV due to PCM also recorded to evaluate the effectiveness of PCM in temperature regulation and electrical performance enhancement of PV. A temperature drop of 12 °C and and associated voltage gain of is observed which shows such systems are effective in even mild weather condition of a hot climate

INTRODUCTION

Silicon photovoltaics (PV) show a power drop above 25 °C with a temperature coefficient of up to -0.65 %-K-1 depending on type of the PV cell and the manufacturing technology [1]. The operating temperature reached by PV panels and associated power drop largely depends on the climate of the site. In Germany 50 % of the solar radiation incident on a PV panel is above 600 W/m2 while in Sudan this value reaches 80 % resulting different operating temperatures and associated power drop [2] urging a strong need for PV temperature regulation to maximize both panel lifetime and power output. Different passive and active heat removal techniques have been used to maintain PV at lower temperatures. Passive heat removal in free standing PV relies on the buoyancy driven air flow in a duct behind the PV [3]. Heat removal depends on ratio of length to internal diameter (L/D) of the duct [4] with the maximum heat removal obtainable at an L/D of 20 [5]. Passive heat removal in building integrated photovoltaics (BIPV) relies on buoyant circulation of air in an opening or air channel, instead of a duct, behind the PV [6] Active cooling of PV relies mostly on air or water flow on the front or back of the PV surface. Effect of air flow at different inlet velocities and air gaps on front side and back side of PV temperature was modelled and a maximum 34.2 °C temperature decrease was predicted at air inlet velocity of 1 ms-1 and front and back air gap of 20 mm [7] .Water flow on the front surface of a free standing PV has a decreased cell temperature of up to 22 °C along with decreasing reflection losses from PV surface yielding an 8-9 % increase in electrical power output [8]. Water flow on the back of a façade integrated PV has theoretically shown optimum electrical and thermal performance at a water flow rate of 0.05 kgs-1 for a particular system in the weather conditions of Hefei, China at insolations of 405 W-m-2 and 432 Wm-2 [9] .

Passive cooling of BIPV with solid-liquid PCMs were experimentally and numerically evaluated using a paraffin wax as PCM and an a rectangular aluminum container with internal dimension of (300

[1]United Arab Emirates University, United Arab Emirates, [2] Lebanese International University, Lebnese Republic,.& [3]Dublin Institute of Technology, Republic of Ireland, ,

mm x 132 mm x 40 mm) having selectively coated front surface to mimic a PV cell [10]. Temperature distributions on the front surface and inside the PCM were measured experimentally and predicted numerically with 2D and 3D finite volume heat transfer models which showed good agreement between experimental and numerical results [11,12]. Building on this work, Hasan et al., fabricated and characterised 4 different cell size PV-PCM systems to investigate performance of 5 different types of PCM to find out the optimum PCM and the PV-PCM system for this application. Two PCM, a eutectic mixture of capric-acid-palmitic acid, PCM1 and a salt hydrate CaCl2.6H2O, PCM2 were found promising in an aluminum based PV-PCM system [13]. In current work larger PV panels are integrated with in an aluminum based PV-PCM system containing PCM fitted internally with back to back vertical aluminum fins. The devised system is deployed outdoors in UAE climate during a mild season to observe the effectiveness of such PV-PCM systems.

METHODOLOGY

EXPERIMENTAL SETUP

Two 30W polycrystalline EVA encapsulated PV panels with dimensions of 500 mm x 400mm (PTL-Solar) were used in the experiments where one served as a reference and the other contained PCM. The calibrated t-type copper-constantan thermocouples with a measurement error of ±0.2 °C were installed on all and a National Instruments Compact- Rio data acquisition system was used to record the weather data on site for solar radiation intensity, wind speed and ambient temperature shown in figure 1. Rectangular PCM containers of internal dimensions 480 mm x 380 mm x 50 mm were fabricated from a 5 mm thickness aluminum alloy (1050A) and fitted with straight vertical back to back fins of the same alloy with 60 mm horizontal spacing. A 1 mm thin layer of silicon based glue was applied at the interface of the PV panel and the PCM container and kept under pressure for two days until the glue settled and a strong bond was realized between the aluminum container and the PV panel. The reference PV and PV-PCM were installed at the latitude angle in Al Ain, UAE between 23/03/2014 and 02/04/2014. The data acquisition measured temperatures on front and back surface for the reference PV and on front and back surface and in the middle of the PCM slab contained at PV back for the PV-PCM system. The open circuit voltage and short circuit currents were also measured for both the reference PV and PV-PCM system.

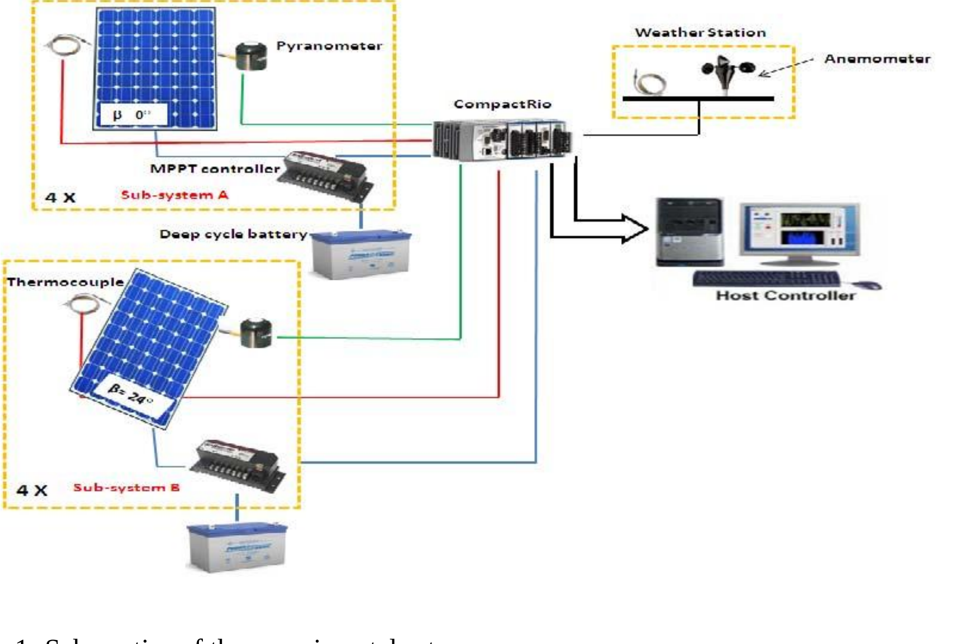

Figure 1- Schematics of the experimental setup

DATA ACQUISITION

Data acquisition system was built to record readings of the panel's voltage, current, temperature, and solar insolation. Besides, the site ambient temperature and wind speed were included in the data-logging architecture. CompactRIO 9073 was used as a real time data-logging device, while the data can be remotely monitored on a LabVIEW interface program. The developed LabVIEW program stores the PV panels' electrical and environmental variables during the daily sun hours. The data acquisition setup consists of the following components:

-CompactRIO 9073 : a reconfigurable real time controller and data acquisition chassis. The used model comprises 8 slots for I/O modules, 2 M gate embedded FPGA core, and a 266 MHz real time controller.

-NI 9227 : 4 channel differential analog current input module with nominal current rating of 5 A and maximum rating of 14 A. Two NI 9227 modules were used in this project, since 8 current measurements are required to be stored from the 8 PV panels.

-NI 9229: 4 channel differential analog voltage input module with maximum voltage range of -60 to 60 V. Two NI 9229 modules were used in this project to carry out 8 voltage measurements for the 8 PV panels.

-NI 9205: 32 single-ended channels or 16 differential channels analog voltage input module with maximum voltage range of -10 to 10 V. One NI 9205 module was used in this project, where 9 input ports were deployed to read measurements from weather sensors (8 pyranometers & 1 anemometer).

-NI 9213: 16 channel thermocouple input module. Only one module was used in this project, since only 9 channels were required, 8 to measure the 8 PV panels temperature and 1 was dedicated to measure the ambient temperature.

-Ethernet cable: Category 5 cable to establish the network between the host computer and the real time target (CompactRIO).

-NI LabVIEW development software: this includes the standard LabVIEW modules, the LabVIEW FPGA Module, the LabVIEW Real-Time Module, and the NI-RIO driver.

First, the NI CompactRIO system was assembled by installing the NI analog input modules, connecting the system to the host PC via an Ethernet cable, and powering up the device with its corresponding DC power supply. Then the network setting was configured to establish a communication between the CompactRIO and the host computer. Finally, an FPGA program was built on the LabVIEW development software and then stored in the real-time target. A host VI was built along with the FPGA VI to monitor the captured signals and represent them in plots and indicators.

RESULTS AND DISCUSSION

Figure 2, 3 and 4 shows the solar radiation intensity, ambient temperature and wind speed for the duration of experiment. Figure 2 shows that the day time peak ambient temperature varied between 29 °C to 37 °C which is a mild temperature for UAE weather conditions offers a peak day time summer temperature of upto 50 °C. Figure 3 shows that the peak time wind speed varied between 7km/h to 23 km/h. Figure 4 shows that peak time solar radiation intensity varied between 480W/m$_2$ on a cloudy day to 1240 W/m$_2$ on a very clear day. This weather caused the PV panel to heat resulting peak time reference PV temperature between 45 °C to 58 °C owing to the cloudy and sky respectively shown in Figure 5. The inclusion of PCM into PV resulted in a drop in PV temperature which reduced peak time PV temperature down to between 44 °C and 47°C shown on cloudy and sunny day respectively shown in Figure 5. The cooling effect produced by the PCM contained at the back of PV resulted in a peak time temperature drop of 5 °C to 11 °C on cloudy and clear sky conditions respectively shown in Figure 6. The temperature drop shown in Figure 6 reduced PV temperature resulted a higher open circuit voltage on PV containing PCM compared to PV without PCM shown in Figure 6 and yielded a voltage improvement peaked at 1.3 volts to 1.7 volts. The results shown in figure 6 explain that the PCM demonstrated a temperature regulation effect which was lower early in the morning for every day and increased as the PV reference temperature increased. Temperature results plotted over several days (Figure 5) also show that the PV with PCM showed a consistently lower temperature than PV without PCM which explains that the PCM regenerated every night to produce cooling for the next day. It is important to note that the PCM showed lower temperature regulation earlier in the morning while the reference PV panel temperature is below 40 °C, above this temperature during noon time, PCM showed higher temperature regulation. Figure 5 shows that the PCM achieved temperature regulation ranging from 8 °C in the modest temperature day compared to 11 °C on the hot day. It also points out that the PCM is expected to achieve higher temperature regulation in the higher temperature peak summer days which will be tested in coming months. From Figure 5 and Figure 6 it can be observed that the decreased temperature on the PV panel yielded an increase in PV voltage to enhance electrical power output from the PV.

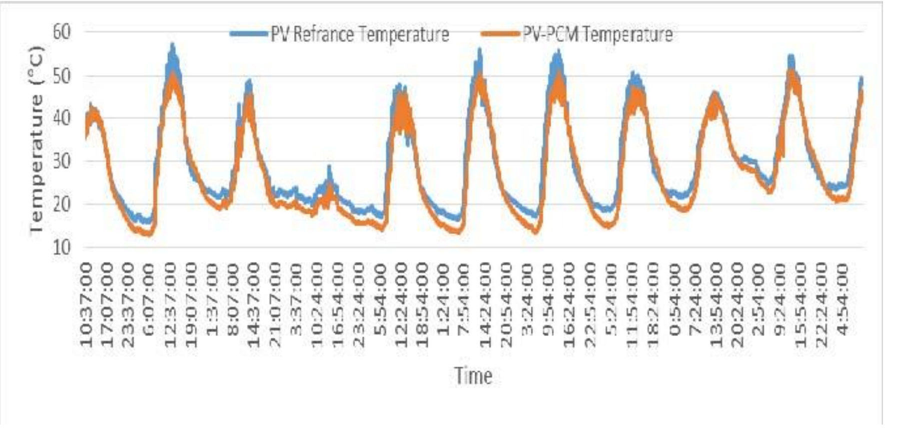

Figure 5: Reference PV and PV-PCM temperatures measured in Al Ain UAE, between 23/03/2014 till 02/04/2014

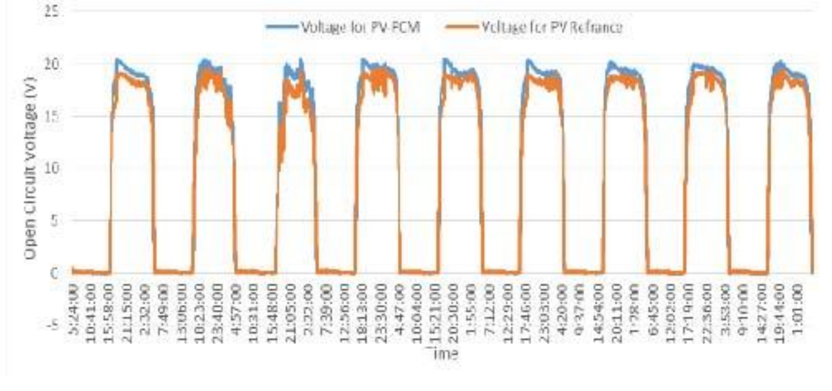

Figure 6: Reference PV and PV-PCM open circuit voltage measured in Al Ain UAE, between 23/03/2014 till 02/04/2014.

ECONOMIC EFFECTIVENESS

Authors have evaluated the use of PCM for lowering of PV temperature and extra power produced for Vehari, Pakistan which has very similar climate to the current site on experiments, Al Ain UAE. In the previous research, the PCM have been found cost effective with a return on investment about two years considering mass produced PV-PCM systems. Similiar results are expected for the current research which will be a subject of future publication for a year around testing of such systems [14]. The stored heat can be used for space or water heating. In case of UAE, the space heating demand is rare therefore Authors are currently conducting experiments for the extraction of stored heat for water heating applications in UAE and will soon publish the results. The hot water produced have larger demand in hospital buildings in UAE compared to residential developments.

CONCLUSION

The results obtained for testing PCM in higher temperature climate shows a promise for PV temperature regulation and power enhancement in the mild season of February where it always get back to solid. It needs still to be tested in the peak summer whether the PCM regenerates and gets back to solid at night by natural convection or it needs forced coolant flow to remove the heat contained in PCM.

The Role of Thermal Mass in Humid Subtropical Climate: Thermal Performance and Energy Demand of CSET Building, Ningbo

Nishita Baderia, M.Arch Environmental Design
The University of Nottingham, UK
nishitabaderia@gmail.com

ABSTRACT

The role of thermal mass in humid subtropical climate has always been intriguing. Located on the eastern coast of China, in humid subtropical climate zone, the Centre for Sustainable Energy Technology (CSET) building, Ningbo, is the first of its kind in the country. It is developed as an exemplar building which displays various energy efficient techniques to increase user comfort and reduce energy demand. Although, the use of heavyweight construction has always been controversial in such climates due to small diurnal range (10°C) and high humidity (65%-95%), the building possesses high thermal mass in the form of 300mm thick concrete walls and 400mm thick concrete slab. The objective of this study was to analyse the thermal performance of CSET building, Ningbo in terms of thermal comfort and energy demand, with respect to the high thermal mass. Through this study, it was also aimed to establish the role of thermal mass in humid subtropical climate zone. Parametric analysis was performed on the building using computer simulations, carried out on TAS Thermal Analysis Simulation Software, to obtain comparative results with and without night ventilation, for four cases: (i) As-designed case, (ii) Reduced building mass, (iii) Heavyweight building materials substituted with lightweight materials and (iv) Omission of the building's glass envelope. Results indicated that the as-designed case i.e high thermal mass coupled with night ventilation performs the best in terms of thermal comfort and energy demand and hence plays a vital role in the thermal performance of CSET building. It was further established that in humid subtropical climates, night ventilation, proper shading, controlled daytime ventilation and moderate internal gains could improve the performance of heavyweight buildings, such that they perform better than the traditionally accepted lightweight buildings.

Keywords: *humid subtropical climate, thermal mass, night ventilation, thermal comfort, energy demand*

INTRODUCTION

Thermal mass is said to function as a climate moderator as massive building envelopes can attenuate the temperature fluctuation and reduce the indoor peak temperature. Thermal mass has been defined by Yannas (1994) as the capacity of a building to store and release heat at different times of the day. Thermal capacity is expressed as "the energy required to raise the temperature of a layer of material". Usually, "higher the density of a material, higher is the resulting thermal capacity" (ibid).

Nishita Baderia is an architect working as a sustainable building design professional in India

Therefore, buildings with high thermal capacity are termed as heavyweight and include all masonry construction, while buildings with low thermal capacity are thermally lightweight and include timber or steel frame construction (ibid). It is often believed that using thermal mass is a universally ‘good thing’ (Baker & Steemers, 2000). However, the benefits of the effect of thermal mass depend on several parameters such as climate conditions, building thermal properties, ventilation, thermal insulation, occupancy and internal heat gains.

Traditionally, it was believed that the use of thermal mass did not have any benefits in humid subtropical or warm-humid climates. According to Szokolay (2000), up to the mid 1980s it was considered preferable to have elevated, lightweight, cross-ventilated buildings in such climates. However, these traditional design principles were being questioned by researchers like Szokolay (2000) and Soebarto (1999) who have investigated the role played by thermal mass in warm-humid climates. Their studies suggested that the debate between the performance of heavyweight and lightweight buildings in such climates was futile as both constructions performed equally well, with heavyweight performing slightly better than lightweight buildings (see Figure 1).

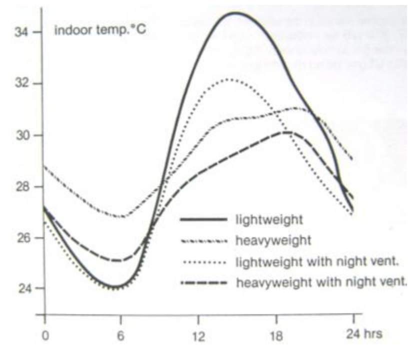

Figure 1 *Performance of lightweight and heavyweight buildings in warm-humid climate, Source: Szokolay, 1985 cited by Baker & Steemers, 2000*

Although much work has been done till date, more studies need to be conducted to ascertain the effects of the much debated use of thermal mass in humid subtropical climate. For the purpose of this study, an exapmlar building (using high thermal mass), located in humid sub-tropical climate was selected.

The Centre for Sustainable Energy Technology (CSET) building is situated in Ningbo (28˚51'-30˚33'N and 120˚55'-122˚16'E) which is located on the eastern coast of China, to the South of the Yangtze River Delta (see Figure 2.1) (Lau et. al. 2006). According to the most widely used world climate classification done by Köppen-Geiger (Kottek et. al. 2006), Ningbo lies in the humid subtropical zone. The building is developed as an exemplar building which displays various energy efficient techniques to increase user comfort and reduce energy demand. The building incorporates high thermal mass i.e. it is thermally heavyweight.

The climatic analysis of Ningbo revealed a diurnal range of about 10°C and a relative humidity of 65-95%. Due to the small diurnal swing and high humidity in summer, it was felt that the thermal mass may not perform as expected. Lau et al. (2006) also suggested that night ventilation may not be very effective in providing pre-cooling in summer. Due to these reasons, it was considered essential to analyse the role of thermal mass in CSET building. Through this analysis, it was aimed to re-establish the role of thermal mass in humid subtropical climate zone so that this study can be referred to by designers designing in similar climate all over the world.

CSET BUILDING, NINGBO

The CSET building, developed as a climate integrated design, promotes energy efficiency, generates its own energy from renewable sources, uses locally available materials with low embodied energy and harvests rainwater (Lau et al.,2006). Along with other climate responsive strategies, the building has internally exposed 300mm thick concrete walls and 400mm thick concrete slab. This implies that the building uses internally exposed thermal mass to minimize temperature fluctuations in summer & winter. The architectural drawings of the building are presented in Figure 2 (a), 2 (b) and 3.

The section shown in Figue 3 depicts the building functions. The laboratory, a workshop and an exhibition space are located in the semi-basement floor. While the research and teaching areas for post graduate students are situated on the second and third floor. The offices, a meeting room with staff kitchenette are all distributed on the fourth and fifth floor (see Figure 3).

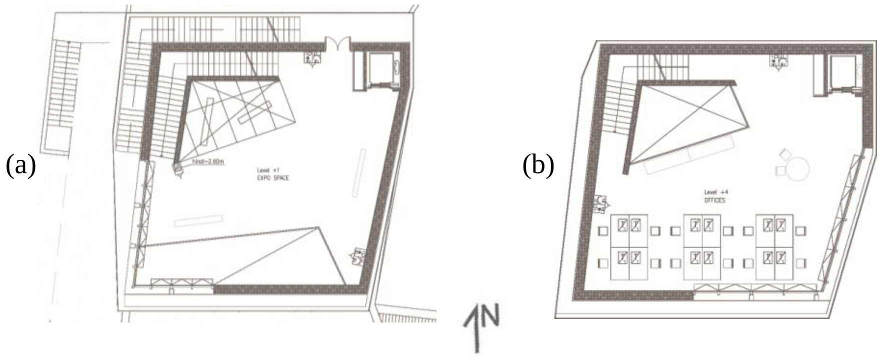

Figure 2 *(a) Ground floor plan (b) Third floor plan, Source: MCA*

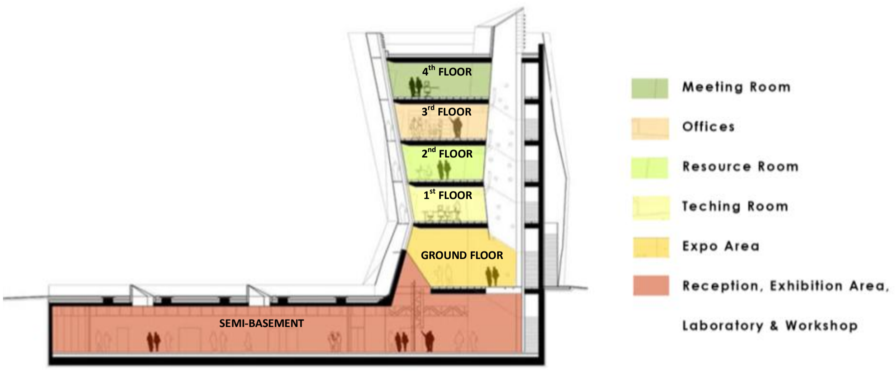

Figure 3 *Building function, Source: MCA*

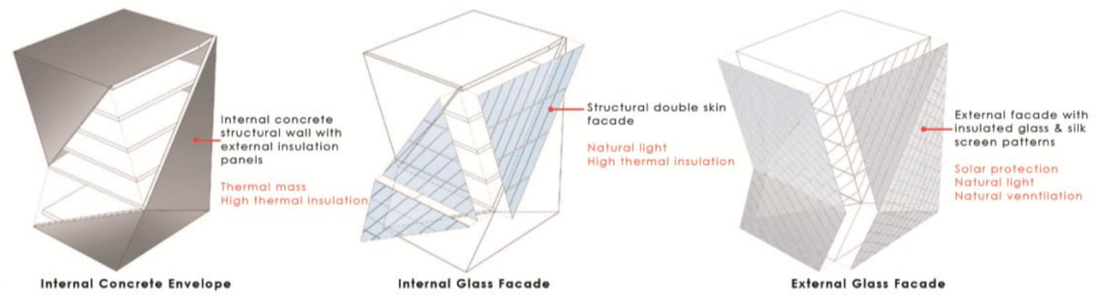

Figure 4 *The building envelope, Source: (MCA, SBE, 2006)*

The opaque parts of the building are made of externally insulated concrete and have openings for natural ventilation. The transparent parts of the building are made of high performance glass which in combination with the external façade provides thermal insulation while optimising daylight penetration into the internal spaces. The second skin makes an external envelope around the building. This external envelope is made of silk screen laminated glass in order to avoid direct solar penetration into the internal spaces (refer Figure 4). The double skin on the south side is sealed providing a thermal buffer, passive pre-heating in winter and exhausting unwanted warm air in summer. The skin on east and west walls is open and provides solar protection and vents excess solar gains.

METHODOLOGY

This research was based on thermal performance analysis of parametric variations in the building envelope which could be tested by performing computer simulations. The parametric analysis was performed for the following cases:

Case I: Base Case

I - a: Base Case without Night Ventilation

I - b: Base Case with Night Ventilation

Case II: Reduction in Mass

II - a: Reduced Mass without Night Ventilation

II - b: Reduced Mass with Night Ventilation

Case III: Lightweight Construction

III - a: Lightweight Walls without Night Ventilation

III - b: Lightweight Walls with Night Ventilation

III - c: Lightweight Walls and Suspended Ceiling without Night Ventilation

III - d: Lightweight Walls and Suspended Ceiling with Night Ventilation

Case IV: Omitting the Glass Envelope

IV - a: Omitting the Glass Envelope without Night Ventilation

IV - b: Omitting the Glass Envelope with Night Ventilation

The comparative analysis of the above mentioned cases helped in answering the much debated question about the difference in the performance of heavyweight and lightweight buildings in humid subtropical climate. The following considerations / assumptions were made for performing the dynamic thermal simulations on the software.

Comfort Range / Energy Demand. As per the climate analysis of Ningbo as well as review of available literature regarding comfort range, 19°C to 27°C was classified as the thermal comfort range for CSET building. Similarly, based on Pasivhaus and Keller Technology's standards, the benchmarking for heating and cooling demand for Ningbo is taken in the range of 30 KWh/m² to 40 KWh/m².

Building Analysis Software. The Building Thermal Analysis Program used for performing the analysis, the New Generation TAS v. 9.1.3a developed by Environmental Design Solutions Ltd. (EDSL). TAS, is a dynamic thermal simulation tool. It allows the user to model, zone and subsequently simulate the building to predict its energy consumption, CO2 emissions, operating costs and occupant comfort.

Model Geometry. The geometry of the model was created in accordance with the information provided on the architectural drawings. Due to the limitations of the software, the façades were modelled based on the assumption that they are vertical i.e. they were modelled without the inclination indicated in the drawings (See Figure 5 (a) and (b)).

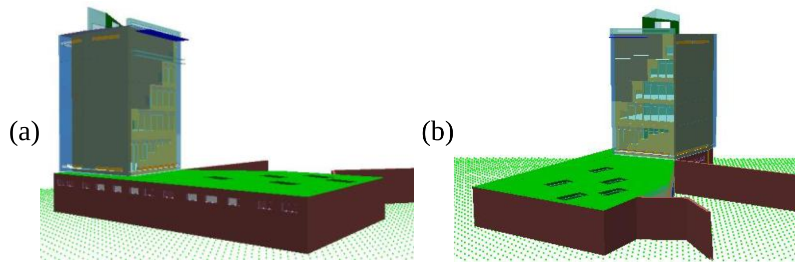

Figure 5 (a) South-west view of model (b) South-east view of model (the tilt on the south is not considered), Source: Created by author using TAS

Weather Data. The weather file used for the analysis was sourced from Energyplus and the nearest available location to Ningbo was Shanghai. After reviewing the two weather files, the difference between their temperature profiles were considered negligible. Therefore, the weather file of Shanghai was used for all simulations (refer Lau et all, 2006).

Building Elements. Information regarding construction materials to be applied to the various building elements like external wall, internal walls, floor, roof, glass etc. was obtained from Lau et al. (2006). Some of the specified materials were not available in TAS construction database; hence the closest to the specified were selected. For this reason, a slight variation occurred in the U-values of some of the building elements. The details of the building elements are as given in Table 1.

Table 1. Building Elements

S.No.	Building Element	Building Material	U-Value (W/m^2°C)
1	Externally insulated wall	300mm concrete with 120mm insulation	0.24
2	Internal wall	200mm concrete	1.9
3	Floor	400mm concrete	1.4
4	Basement floor	Concrete Slab with cavity insulation	0.4
5	Roof	Concrete	0.24
6	Openings in external wall	High performance clear glass	1.5
7	External glass envelope	Silk screen laminated glass	5.6

Internal Conditions. Based on the use of the space, assumptions were made regarding occupancy, equipments and lighting gains in the building and the same are presented in Table 2. These assumptions were kept constant throughout the study.

Table 2. Internal Conditions

Floor	Space	Occupancy (@ 80W/ person)	Equipment	Lighting
Semi-basement	Reception, exhibition, lab, workshop	15 persons	No equipment No equipment	None in summer, 6W/m2 in winter
Ground Floor	Expo area	3 persons	No equipment	None in summer, 6W/m2 in winter
First Floor	Teaching room	30 persons	30 laptops @ 80W per laptop	None in summer, 6W/m2 in winter
Second Floor	Resource room	15 persons	No laptops	None in summer, 6W/m2 in winter
Third Floor	Offices	10 persons	10 PCs @ 100W per PC	None in summer, 6W/m2 in winter
Fourth Floor	Meeting room	10 persons	No equipment	None in summer, 6W/m2 in winter

As mentioned earlier, the comfort range was classified as 19°C to 27°C. Simple natural ventilation was simulated for all cases. The aperture settings were such that the apertures began to open if the dry bulb temperature in the adjacent zone exceeded 23°C, and were fully open if the dry bulb temperature reached 26°C. The apertures began to close when the internal temperature exceeded the external temperature. The building is occupied from 8:00am to 6:00pm and for incorporating night ventilation, all windows were opened from 7:00pm to 8:00am, for all seasons except winter. The maximum wind speed was assumed to be 10m/s, beyond which the apertures began to close regardless of the temperature. An infiltration rate of 0.2 ach was considered.

No heating or cooling was modeled, as the intent of the study was to test the performance of the building with or without thermal mass, isolated from all heating and cooling strategies. For the purpose of calculating heating and cooling demand, another set of simulations were run for which the heating set point was taken at 19°C and the cooling set point was taken at 27°C.

Data Selection. For evaluating thermal comfort, firstly the dry bulb temperature was observed over a period of a week in summer (17th – 23rd July, warmest week), mid-season (15th – 21st October) and winter (18th – 24th December, coldest week). Secondly, the total number of occupied hours from the whole year, when the temperature exceeded 27°C was extracted for every zone for each case. As the occupied time for this building is 8:00am to 6:00pm, the total annual occupied hours is 3650. Finally, the energy demand was observed in terms of the total annual heating and cooling demand of the building. The internal gains due to equipments, lighting and occupancy were expressed in KWh/m² and remained constant throughout the study. The solar gains varied according to the building fabric.

COMPARATIVE ANALYSIS

The parametric analysis conducted for the specified cases revealed that the performance of the building deteriorates upon reduction in building mass. It was identified that the main benefit of a heavyweight building was that the variation in internal temperature was smaller and closer to the average external temperature than a lightweight building. In the lightweight substitute of the building, the fluctuations in internal temperature were larger and presented higher peeks than the heavyweight building as well as the ambient temperature (refer Figure 6). From the comparison of the building with and without the glass envelope, it was found that the thermal mass became more effective when it received lower solar gain since the low transmittance glass acted as a shading device for the building.

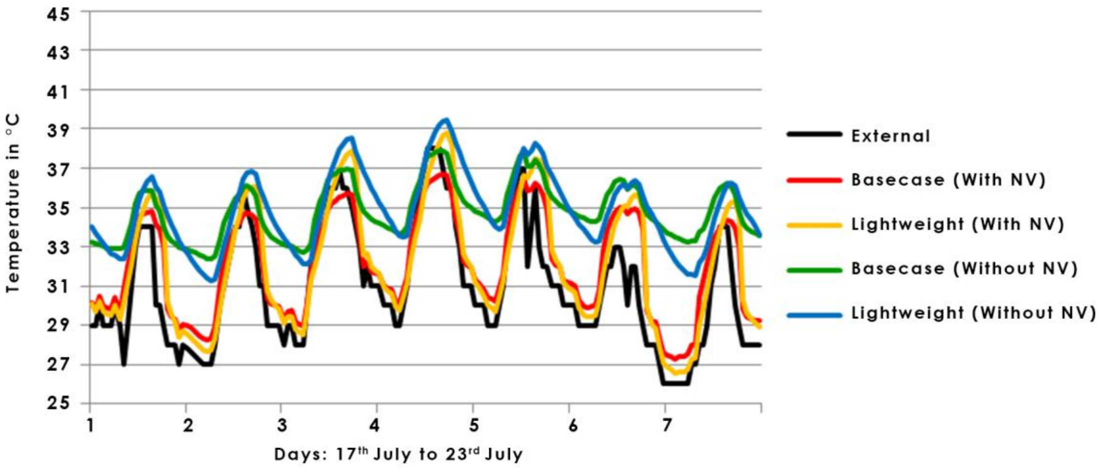

Figure 6 Indoor summer temperature profile: Basecase v/s Lightweight Construction, Source: Author

In general, for all cases, night ventilation (NV) enhanced the performance of the building. In summer, during the warmest week, the condition “with night ventilation” was found to perform better than “without night ventilation” for the Ground Floor, while the upper floor temperatures for the two conditions, were almost coinciding with “with night ventilation” performing better. Even though night ventilation assists in lowering the temperatures, they were still found to be above 27°C during the occupied hours implying that extreme summer conditions would result in overheating unless cooling is provided. During mid-season, all the temperatures lay in the comfort zone i.e. 19°C to 27°C. Although both lower as well as upper floors benefited from the effect of night ventilation, the benefits were more visible in in the lower floors. In extreme winter conditions, the internal temperatures lay out of the comfort range i.e. they were below 19°C.

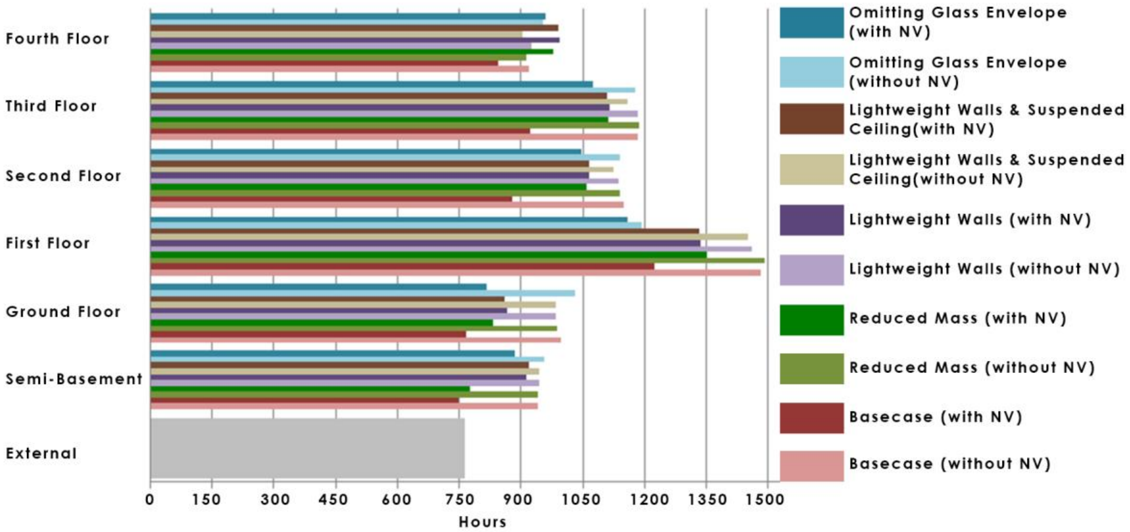

Figure 7 *Hours exceeding 27°C during occupied hours: Comparison between all cases, Source: Author*

During the 3650 occupied hours, the building was found to experience comfortable temperatures in mid-seasons. The number of hours when the ambient temperature exceeded 27°C, the upper limit of the specified comfort range, is 760. Even during the warmest summer days the building exhibited stable indoor temperatures, though at temperatures above the thermal comfort range i.e. 27°C. The graph shown in Figure 7 reveals that for all the cases, without night ventilation, the number of hours exceeding 27°C during occupied hours is similar in each zone. Night ventilation enhances the building performance and there is variation in the results for this condition among the various cases. For every zone, the Base-case, a combination of thermal mass and night ventilation works best. Floor wise analysis revealed that the first floor was the worst performing floor, probably due to very high gains from occupancy and equipments. The performance became better with night ventilation. The semi-basement floors performed the best as they had low occupancy and high thermal mass. The ground floor performed better than the upper floors in all cases. The ground floor experienced about 770 hours exceeding 27°C, i.e. similar to ambient, while for the upper floors the number was about 1010(refer Figure 7).

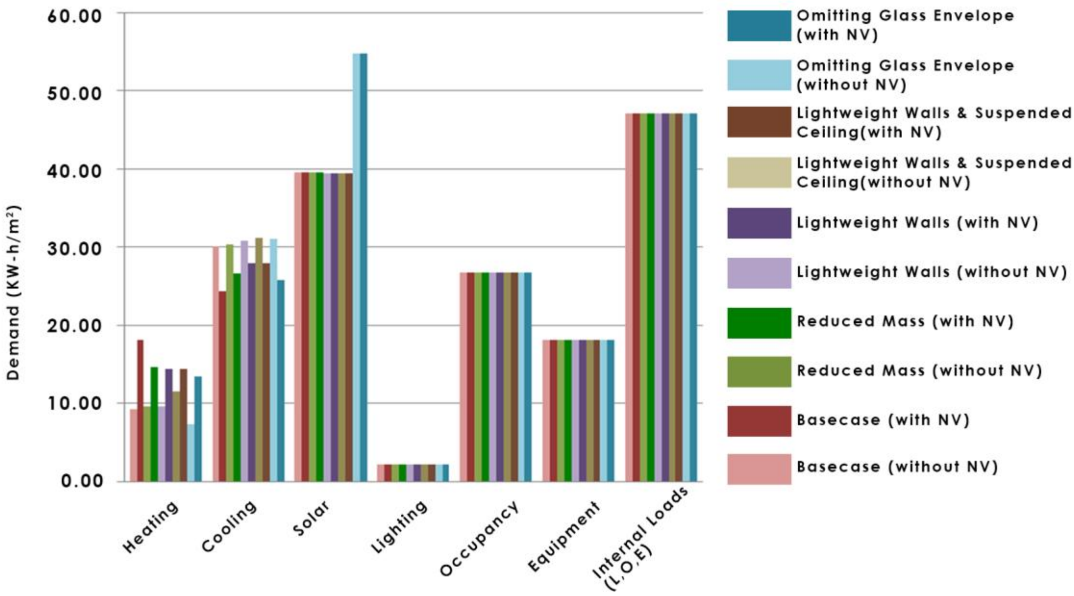

Figure 8 *Annual loads: Comparison between all cases, Source: Author*

In terms of energy demand, although the annual cooling load reduced with the incorporation of night ventilation, the annual heating load increased (refer Figure 8). Due to the limitation of the software, for some days in spring and autumn when the ambient temperature was very low, although night ventilation was not required, the apertures were still open. This might have resulted in an over-estimate of the heating loads. The total annual heating and cooling load for the building was found to be 39 KWh/m² and 42 KWh/m² for Base-case without night ventilation and with night ventilation respectively. These values are higher than the Passivhaus standard of 30 KWh/m²; however the values lie in or slightly above the specified range of 30 KWh/m² to 40 KWh/m² for heating and cooling. This implies that there is scope for improvement in the thermal performance of CSET building.

The lower floors (semi-basement and ground) in the building perform well due to low occupancy and equipment gain, while the upper floors (1st to 4th) suffer due to higher gains and lesser openings. Therefore it is strongly believed that reducing the gains and provision of more openings in the upper floors would improve the performance of the building.

CONCLUSION

From the above analysis, a broader conclusion can be drawn that a heavyweight building i.e. a building with high thermal mass, when coupled with night ventilation, appropriate shading and moderate internal gains from occupancy, lighting and equipments, performs better than a lightweight building in a humid subtropical climate even though this climate has small diurnal range and high humidity. This conclusion is in conjunction with the results of the studies conducted by Szokolay (2000) and (Soebarto, 1999) on the role of thermal mass in warm- humid climate.

Although, this research was contextually bound to one building in Ningbo, China, the inferences made would be helpful in establishing the general performance of thermal mass in humid subtropical climate which would assist building designers designing in this climate anywhere in the world. However, as the design and microclimate of each building plays a very important role in its performance, there are limits to the generalisability of the results. For this reason, it will not be advisable to prepare design guidelines based on the analysis of only one building. Based on a similar methodology as followed in this research, further research may look at thermal performance analysis of more intitutional buildings in this climate zone. Due to high relative humidity associated with humid sub-tropical climate, there is risk of condensation occurring due to contact of moist air with cold internal surfaces in buildings. As an extention to this study, further research may test the risk of condensation associated with lightweight and heavyweight construction in humid sub-tropical climate zone.

ACKNOWLEDGMENTS

This research has been carried out by the author, for the final term dissertation, while pursuing M.Arch Environmental Design at The University of Nottingham. The author would like to thank Mr. Benson Lau , Prof. Brian Ford and Ms. Lucielia Taranto Rodrigues for their support and guidance.

ABSTRACT

Any building essentially contains walls and roof which are directly exposed to external environment. Undoubtedly the most critical part of the whole building surface is the roof as it receives the maximum solar radiation particularly in summer months thereby increasing the heat load in buildings. Many studies have been conducted over the years to consider the potential building energy benefits of Extensive Green Roofs. There is a sharp increase in the number of countries that conduct green roof research in the last two decades realizing its importance globally. A green roof offers a building and its surrounding environment many benefits, which include: storm water management, improved water run-off quality, improved urban air quality, extension of roof life and a reduction of the urban heat island effect; other benefits also include enhanced architectural interest and biodiversity.

Green roofs cool through latent heat loss and improved reflectivity of incident solar radiation. This suggests that green roofs are predominately seen as a passive cooling technique. Intensive literature review shows that barely any research is done in Indian context for usage of green roof. Green roofs are hardly visible in Indian context; probable reasons are lack of awareness, socio-cultural backgrounds and cost factors. Also it has not been given importance in local building bylaws. Moreover, an in-depth research is needed on green roof in Indian climatic conditions as we have longer sunny days with higher solar intensity (thereby increasing load on air conditioning). It may prove to be important 'investment' in longer terms considering the huge energy requirements in the future.

The paper also highlights study in composite climate of central India with high global horizontal irradiation. It highlights thermal simulation modelling using Autodesk Simulation CFD (Computational Fluid Dynamics) software, used as a tool to validate the summer cooling potential of extensive green roofs.

Key words: Extensive Green Roofs, Passive and Low Energy Architecure, Energy consumption in Buildings, Simulation Modelling

INTRODUCTION

Walls only receive about two-thirds of the maximum solar radiation that falls on the roof, and considerably less than this on the wall which faces away from the equator. The period of reception of direct solar radiation on walls is shorter than on roofs: east and west walls will only receive direct sunlight for half of the day. Undoubtedly the most critical part of the whole building surface is the roof.

In any location near the equator this receives the greatest amount of solar radiation, thus the highest heat load. The horizontal roof receives maximum solar radiation during the summer and generally is the main path of heat flux entering the living space.

City surfaces are prone to absorb and release large quantities of heat thereby creating urban heat-island effect. Urban heat-island (UHI) is a common phenomenon where urban temperatures are significantly higher than those of its surrounding suburban and rural areas in summertime. UHIs can affect communities by increasing summertime surface temperature of building envelopes and infrastructures; intensifying thermal discomfort; elevating cooling energy use and peak energy demand; adding air pollution; and raising risks in heat-related illness or mortality. A higher air temperature tends to increase cooling needs and reduce working efficiency of cooling systems for built environments, resulting in higher power demand and energy use.

The roof of a building can be fully or part covered with a layer of vegetation known as a Green Roof. A green roof is a layered system comprising of a waterproofing membrane, growing medium and the vegetation layer itself. There are two main classifications of green roofs; extensive and intensive. Extensive green roofs have a thin substrate layer with low level planting, typically sedum or lawn, and can be very lightweight in structure. Intensive green roofs have a deeper substrate layer to allow deeper rooting plants such as shrubs and trees to survive. Extensive systems offer the most cost effective solution over intensive types. Extensive roofs are the preferred option for retrofitting onto existing buildings as the structural capacity of the roof will often not have to be increased. Green roofs greatly reduce the proportion of solar radiation that reaches the roof structure beneath as well as offering additional insulation value.

India is experiencing an unprecedented construction boom. The country doubled its floorspace between 2001 and 2005 and is expected to add 35 billion m^2 of new buildings by 2050. Buildings account for 35% of total final energy consumption in India today, and building energy use is growing at 8% annually. Studies have shown that carbon policies will have little effect on reducing building energy demand. Various researchers have predicted that, if there are no specific sectoral policies to curb building energy use, final energy demand of the Indian building sector will grow over five times by the end of this century, driven by rapid income and population growth. The growing energy demand in buildings is accompanied particularly by an increase in electricity use. This also leads to a rapid increase in carbon emissions and aggravates power shortages in India. Growth in building energy use poses a challenge for the Indian government.

It becomes very important for architects, designers, builders and owners to focus on building designed with Passive measures, design tools and methods thereby reducing/kerbing energy consumption in buildings thereby moving in the direction of sustainability.

This paper addresses the potential building energy reduction benefits arising from the enhanced thermal properties of a Green Roof making it essential part of passive design and low energy architecture.

THE STUDY CASE

Variation of the solar thermal gain in a typical room with green roof using Autodesk Simulation CFD (Computational Fluid Dynamics) software as an analysis tool is investigated in this study as compared to that of a conventional bare roof situated in the state capital of Chhattisgarh state, Raipur having composite climate. Simulation is performed for one typical solar day corresponding to the peak summer season and generally peak temperature of the day in a given time so as to understand the difference between conventional and green roof outcomes. Because this scenario simulates a design day, the simulation of air movement is done with natural convection only.

Geometry

The room admeasuring 6.0 M X 3.5 M consisted of two windows on the southern side and a door on the northern side, east-west being the longer axis of the room, which is naturally ventilated had been taken as a case for the study. The construction of the room is of RCC framed structure having conventional RCC beams, columns, floor and roof along with brick work (0.23 M thick) covered with cement plaster as infill. Total height of the room taken including parapet is 4.05 M and interior room height is 3.0 M.

The green roof consists of a water proofing membrane (thickness taken as: 0.01 M), growing media: soil (thickness taken as: 0.15 M) and green cover: grass (thickness taken as: 0.10 M)

Material Properties

Table 1. Material Properties for Simulation Modeling

Material	Thermal Conductivity (W/m-K)	Resistivity (K-m/W)	DENSITY (kg/m3)	SPECIFIC HEAT (J/kg-K)	EMISSIVITY
Air (variable) (void)	0.02563	-	Equation of state	1004	1
Brick with plaster: walls	1.44	0.69	2100	875	0.94
Glass (window)	0.78	1.28	2700	840	0.92
Hardwood (door)	0.16	6.25	720	1255	0.8
Steel concrete cement (floor, roof slab, columns & beams)	1.75	0.57	2400	840	0.92
Water proofing membrane	1	1	950	837	0.8
Growing media: Soil	1	1	766	1000	0.92
Grass	0.115	8.69	500	1380	0.3

Simulations

The simulations are performed for peak summer hours of **2:30 PM on 30th of May (Figure 1 to Figure 5).** Considering the fact that because of time lag, temperatures in late hours than afternoon peak temperatures may give varied results; simulations are also done with the same parameters on the same day changing the time only to **6:00 PM in the evening (Figure 6 to Figure 10).**

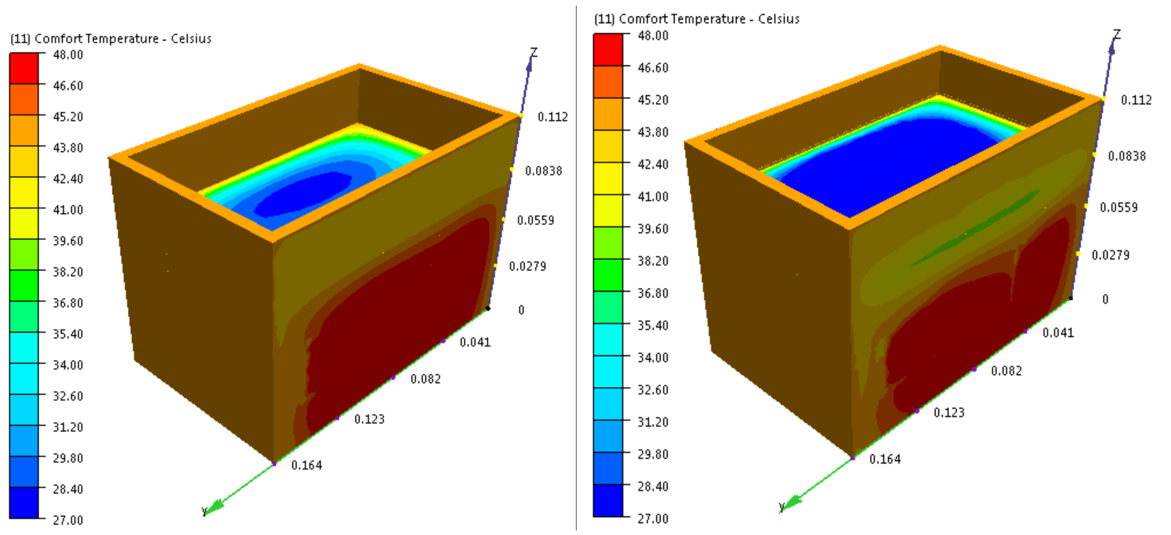

Figure 1 *(a) Temperature distribution without green roof and (b) Temperature distribution with green roof (both simulations at 2:30 PM, outside temperature: 44°C, humidity-13%, highlighting external surface temperatures around the room and roof)*

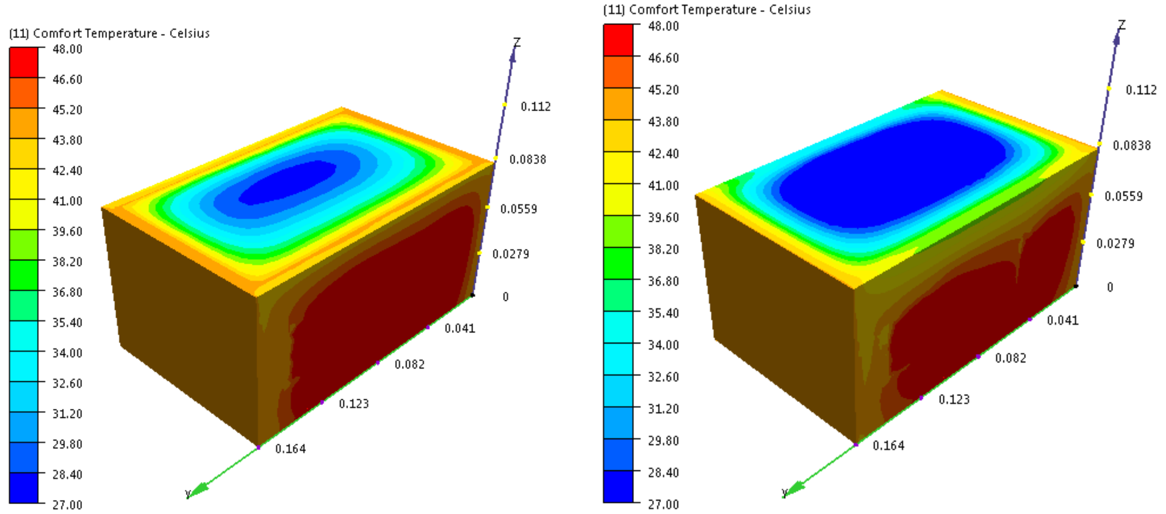

Figure 2 *(a) Temperature distribution without green roof and (b) Temperature distribution with green roof (both simulations at 2:30 PM, outside temperature: 44°C, humidity-13%, highlighting external surface temperatures around the room and roof)*

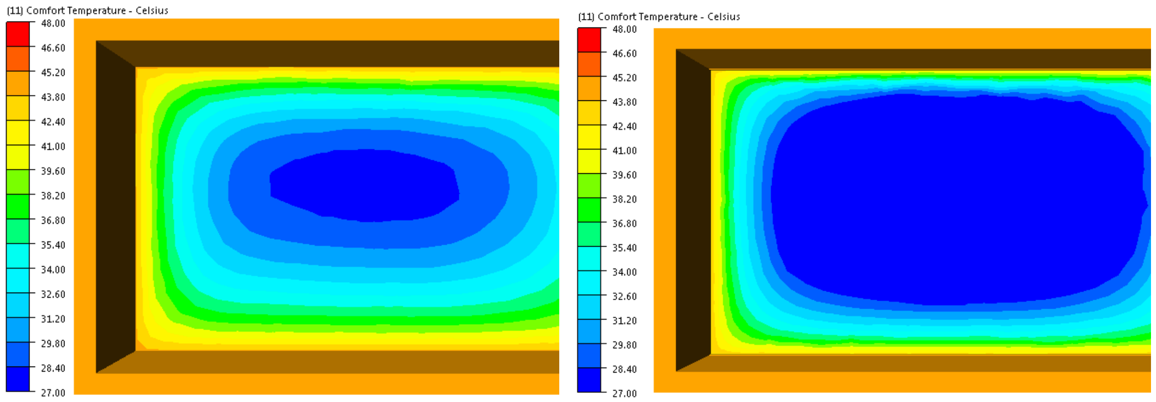

Figure 3 *(a) Temperature distribution without green roof and (b) Temperature distribution with green roof (both simulations at 2:30 PM, outside temperature: 44°C, humidity-13%, highlighting external surface temperatures around the roof)*

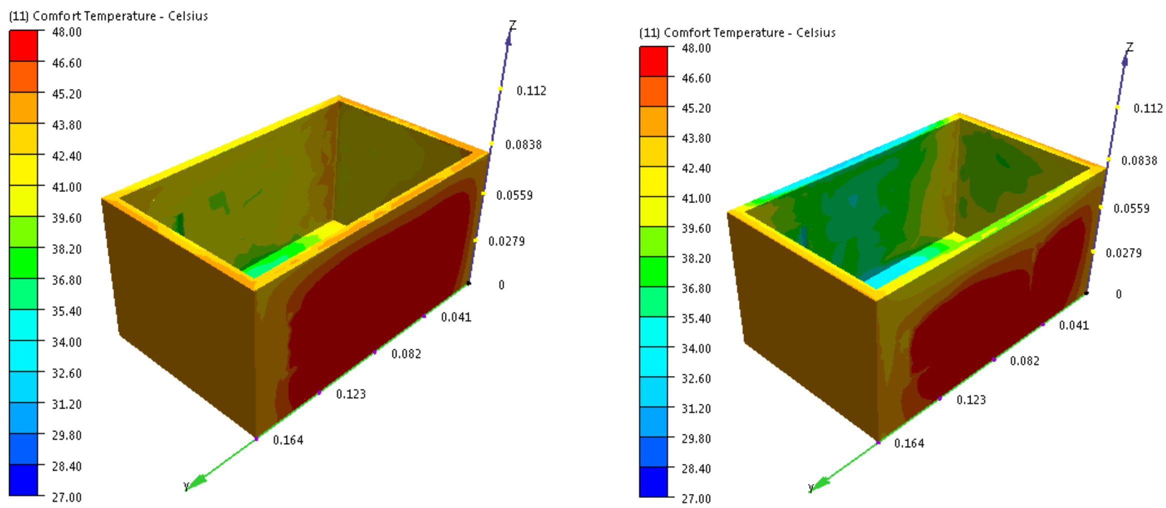

Figure 4 *(a) Temperature distribution without green roof and (b) Temperature distribution with green roof (both simulations at 2:30 PM, outside temperature: 44°C, humidity-13%, highlighting internal and external surface temperatures)*

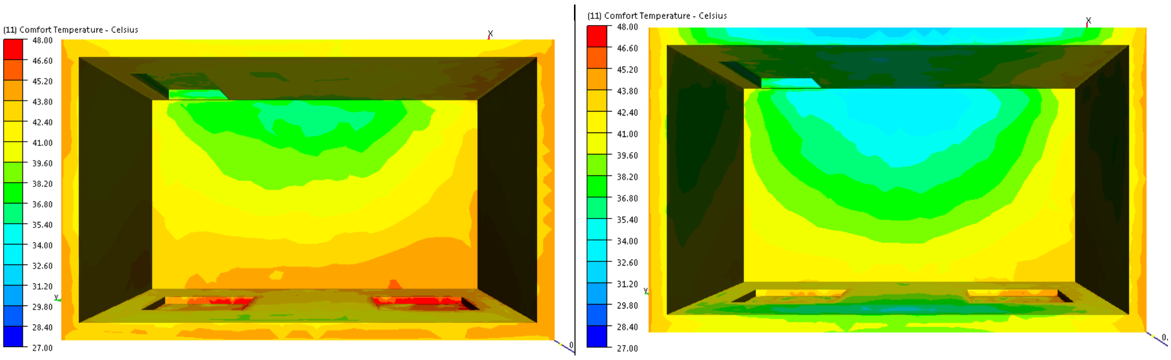

Figure 5 *(a) Temperature distribution without green roof and (b) Temperature distribution with green roof (both simulations at 2:30 PM, outside temperature: 44°C, humidity-13%, highlighting internal surface temperatures)*

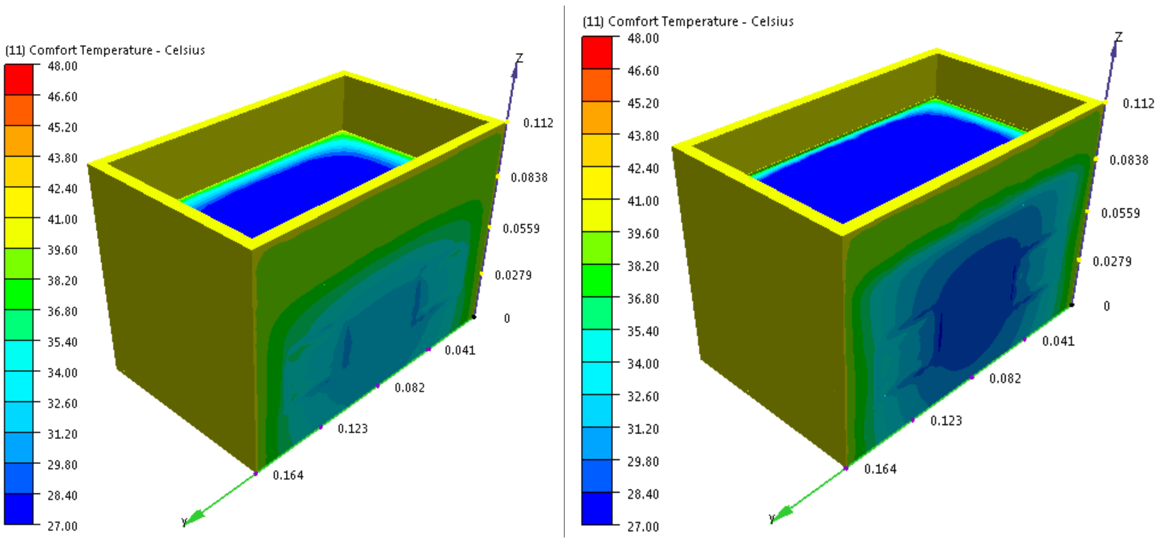

Figure 6 *(a) Temperature distribution without green roof and (b) Temperature distribution with green roof (both simulations at 6:00 PM, outside temperature: 40°C, humidity-12%, highlighting external surface temperatures around the room and roof)*

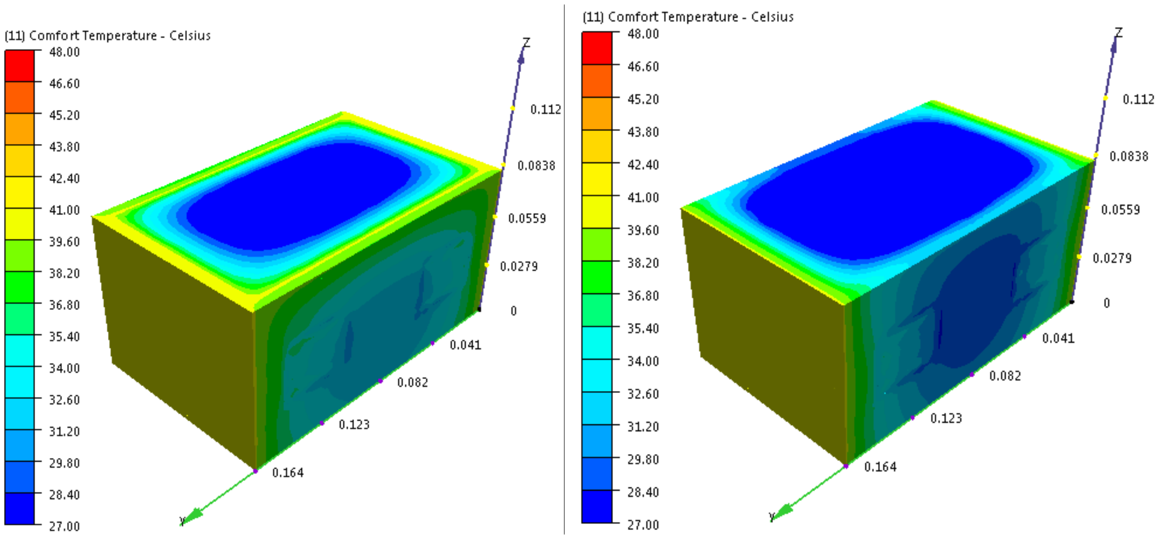

Figure 7 *(a) Temperature distribution without green roof and (b) Temperature distribution with green roof (both simulations at 6:00 PM, outside temperature: 40°C, humidity-12%, highlighting external surface temperatures around the room and roof)*

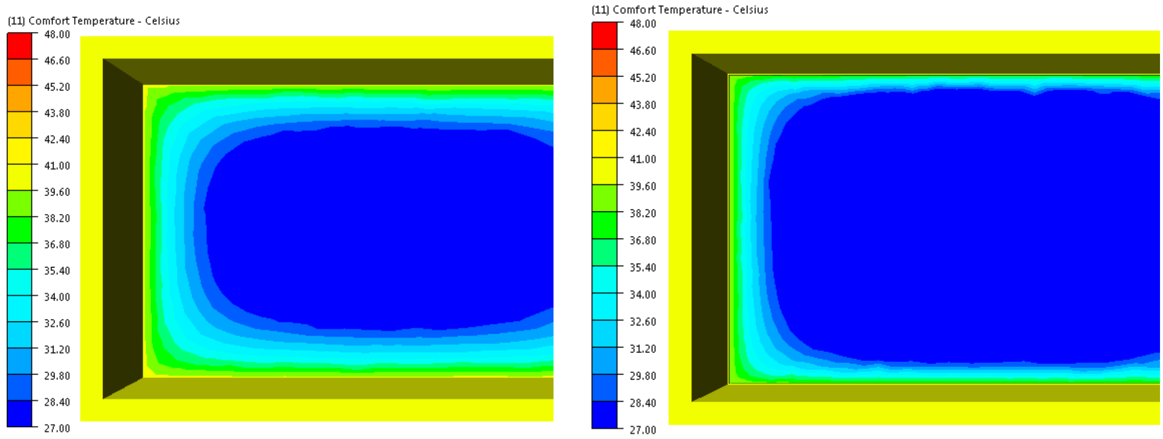

Figure 8 *(a) Temperature distribution without green roof and (b) Temperature distribution with green roof (both simulations at 6:00 PM, outside temperature: 40°C, humidity-12%, highlighting external surface temperatures around the roof)*

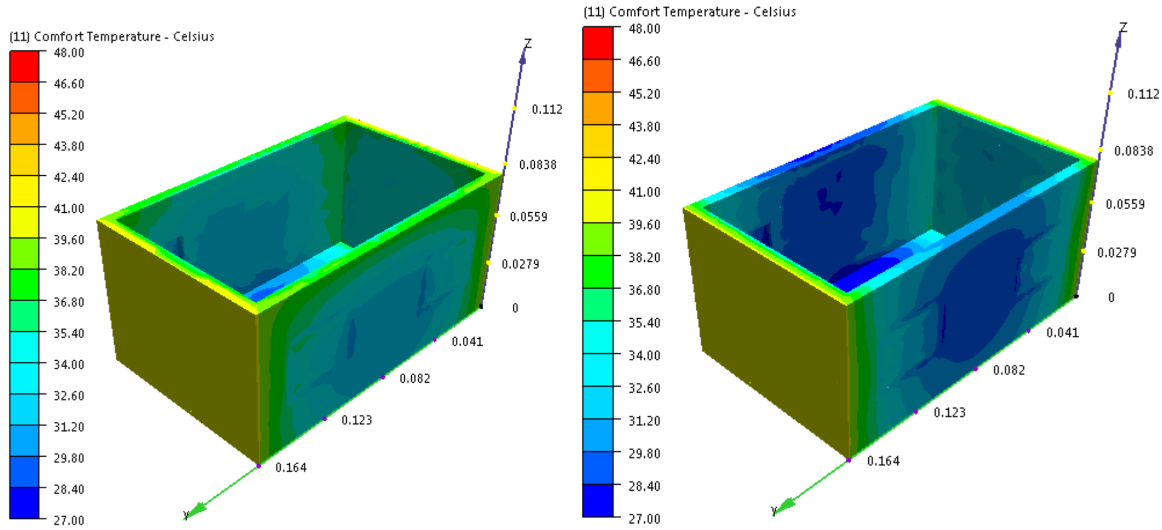

Figure 9 *(a) Temperature distribution without green roof and (b) Temperature distribution with green roof (both simulations at 6:00 PM, outside temperature: 40°C, humidity-12%, highlighting internal and external surface temperatures)*

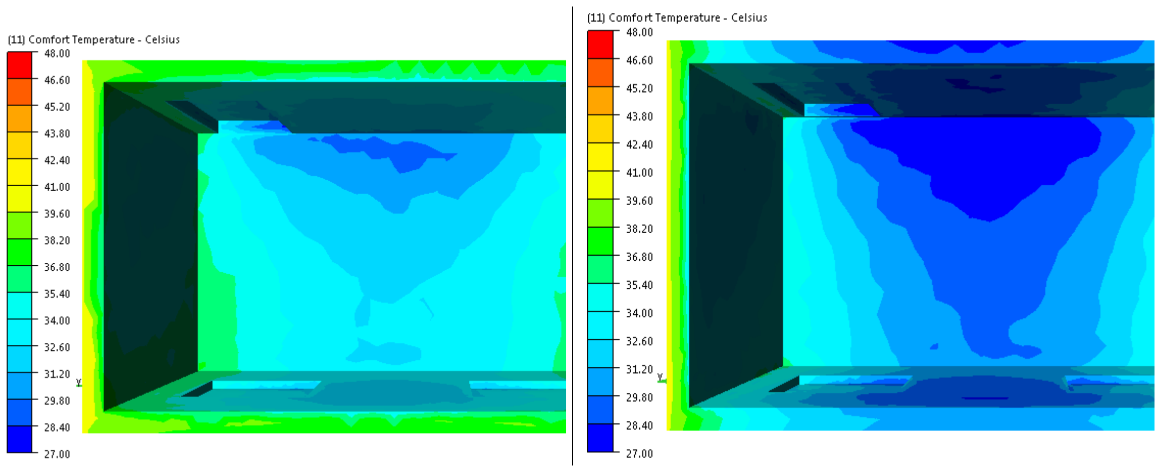

Figure 10 *(a) Temperature distribution without green roof and (b) Temperature distribution with green roof (both simulations at 6:00 PM, outside temperature: 40°C, humidity-12%, highlighting internal surface temperatures)*

RESULTS

As shown **in Figure 1 to Figure 5**, upto 4°C reduction in temperature difference is visible in simulation modeling above the green roof as well as inside the room in given location and environmental conditions as compared to that of bare conventional roof.

And in the same model changing timings of the simulation to 6:00 PM (shown **in Figure 6 to Figure 10**), shows difference more than 4°C temperature i.e interior of the room will be more than 4°C cooler because of the presence of a green roof and similarly temperatures above the green roof also show similar differences.

CONCLUSION

Review of various scientific research works shows the importance and potential of green roof in numerous ways. Energy required for conditioning of spaces is aggravated in urban areas through the exhaustion of natural resources spent for electricity production (electricity production in the state of Chhattisgarh, India is by coal fired thermal power plants). Harnessing conventional fossil fuels and heat emissions by AC systems further add to the temperature increment in the environment. Planting a green roof will reduce *a.* exterior temperatures: therby controlling micro climate because of plant's presence and will reduce the urban heat island effect and *b.* inside temperatures: thereby reducing cooling loads inside the buildings.

The analysis of the simulations done with the help of computational fluid dynamics (CFD), clearly highlight the importance of a green roof as a passive design measure to be incorporated in buildings which would decrease the cooling requirements or the burden on the Air Conditioning systems for Raipur city in geographical location of the state of Chhattisgarh in central India.

An extensive review of the computational fluid dynamics (CFD) simulation results have exposed the following key factors when assessing their energy saving potential in the context of building use:

1. Observations of simulations providing green roofs in the buildings in the city of Raipur showed that green roofs are effective in reducing heat flow through the roof, thus lowering the energy demand for space conditioning in the building.
2. The green roof was effective in reducing high temperature and temperature fluctuations experienced by the roof membrane in conventional roofing system in the summer.
3. Since the average mean temperature was greater then comfort level temperature therefore, thermal comfort cannot be achieved only by providing green roof but it can reduce the load on air conditioning systems to considerable levels.
4. Results proved highly satisfactory and provided enough confidence for the study to be extended further for a larger solution space in real life measurements.

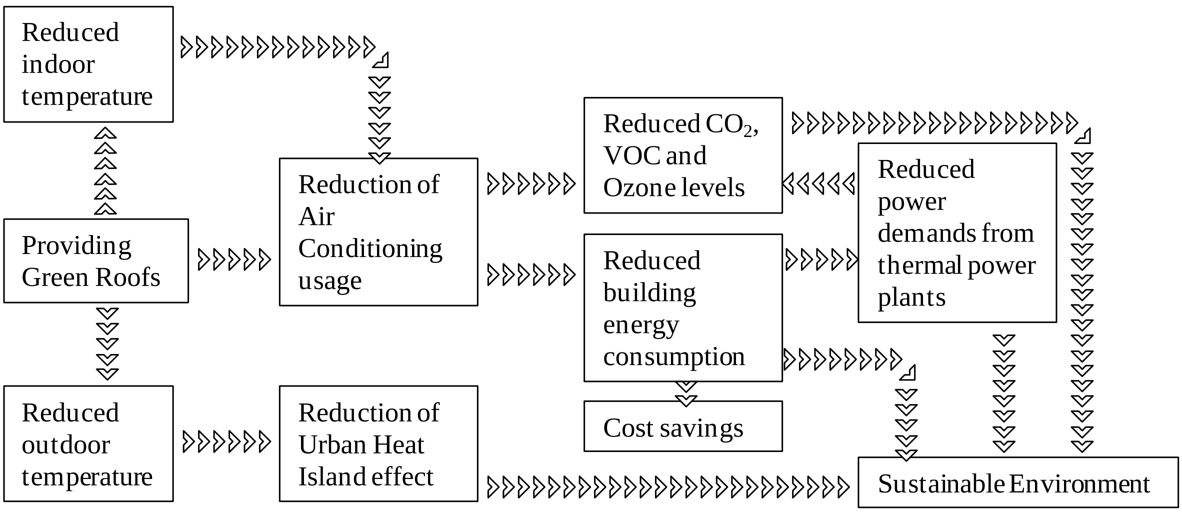

***Figure 11** Benefits of Providing Green Roofs*

Enormous use of ground for various purposes has lead to disappearance of green planted surfaces. In order to prevent dangerous and uncomfortable urban heat island effects the indispensable need of planted surfaces is quiet inevitable as is confirmed by many researchers. For example, a study estimated that an increase of 1°C in air temperature would require the addition of about 500 megawatts (MW) for air-conditioning of buildings in the Los Angeles Basin. Similar air temperature increases in urban areas are taxing the ability of developing countries to meet urban electricity demand while raising global greenhouse gas (GHG) emissions associated with energy use and power generation. Space constraints have further reduced the applicability of green surfaces in various areas surrounding the building envelope. Consequently, planting green roofs become very promising and stabilizing choice in the present scenario.

ACKNOWLEDGMENTS

ABSTRACT

To help architects and designers make early design decisions, an online tool (WinOpt) has been developed. WinOpt optimizes various components associated with the design of windows, such as Building orientation/Azimuth Angle (angle with respect to North), Aspect Ratio, WWR (Window Wall Ratio), SHGC (Solar Heat Gain Coefficient) of glass used for windows, and various local shading strategies such as overhang and side fins. WinOpt performs annual energy simulations for a given location using EnergyPlus. It uses an optimization tool in the back end (GenOpt) to reduce the few million simulations to a few hundred, thus helping in making rapid design decisions. WinOpt optimizes the design to minimize the operational energy for conditioned buildings and could maximize thermal comfort for unconditioned buildings. It also has a parametric option where parametric simulations are performed for selected values for various input parameters. This can help the user understand the spectrum of design solutions. Since EnergyPlus can evaluate both thermal comfort conditions and energy consumption in a building, WinOpt could help in design decisions for low energy/ net zero energy buildings.

INTRODUCTION

Among the various end use energy consuming sectors, buildings form a significant portion. There have been various efforts to reduce building energy consumption during design as well as operational phases. Most of the solutions could be used in a cost effective manner when incorporated during the building design phase. To evaluate the performance of various energy conservation measures, there are various simulation tools available. A list of these tools is provided at the US Energy Efficiency and Renewable Energy website (Building Technologies Program: Building Energy Software Tools Directory, 2013). A comparison of available tools can be found at Crawley B. D. et al. (2008).

There are various tools available that can help in early design. Autodesk Vasari (2013) focuses on conceptual building design using both geometric and parametric modeling. It supports performance-based design via integrated energy modeling and analysis features. EnergyPlus (Building Technologies Program: EnergyPlus Energy Simulation Software, 2012) is one such tool which was developed by the U.S Department of Energy. During the design phase of a building, EnergyPlus allows the user to pre-compute the energy usage and thus optimize the building design. EnergyPlus performs a whole building energy simulation.

COMFEN (2013) is a tool designed to support the systematic evaluation of alternative fenestration systems for project-specific commercial building applications. It dynamically simulates the effects of these key fenestration variables on energy consumption, peak energy demand, and thermal and visual comfort. The results presented in graphical and tabular format within the simplified user interface for comparative fenestration design cases help users move toward optimal fenestration design choices for their project. COMFEN uses EnergyPlus as its computational engine.

Many times, architects and designers face the situation where the combinations of Energy Conservation Measures (ECMs) available to them can run in to few millions. Further, larger simulation run time for building simulation model could be exhaustive in terms of cost and time. Also, for large models, higher simulation run time could lead to a delay in the optimization process.

Various building energy optimization tools are currently available to the users. GenOpt (2013), a tool developed by Lawrence Berkeley National Laboratory, can optimize problems where the cost function is computationally expensive and its derivatives are not available or may not even exist. Another tool, BEopt (2013), provides capabilities to evaluate residential building designs and identify cost-optimal efficiency packages at various levels of whole-house energy savings. DesignBuilder (2013) has a parametric analysis facility that is useful for searching 'optimal' designs.

To find out optimization solution for their buildings, user needs to have expertise in both optimization tools and simulation tools. There is a need for tools where users can address the problem directly, without learning simulation and optimization tools. During the early design stage, architects are the main performers of energy simulation (Bambardekar et al., 2009). The designs are more conceptual, not specifying the complete details of the buildings. Further, there are large numbers of ECMs to be considered for the building. A few quick simulations need to be performed and optimal choices need to be identified for a sustainable design. In producing the WinOpt tool described here, we have considered some of the key factors involved in the design of a façade and developed a tool that can minimize the operational energy for conditioned buildings and maximize thermal comfort for unconditioned buildings.

To reduce the direct solar heat gain into the building, one needs to optimize the design elements of a window. A few of these factors are:

1. Building orientation of the building with respect to true North
2. Aspect Ratio of the building (Length/Breadth ratio of the building)
3. Window-Wall Ratio (WWR)
4. The type of glass in the windows
5. Details of shading devices such as depth of the overhangs and side-fins

To compute the energy consumption of a building, one needs details such as type of building, operational schedules, internal loads, and Heating Ventilation and Air Conditioning (HVAC) systems. Most of these variables are provided as default values in the simulation model so that a user can directly select their optimization variable, provide an acceptable range of values, and view solutions.

DESCRIPTION OF THE TOOL

WinOpt is a tool that performs a multi-parameter optimization for reducing the energy consumption of a building. WinOpt achieves this by using EnergyPlus to compute the energy consumed by the building and using GenOpt for optimizing the user-selected design parameters. The algorithm chosen for optimization by GenOpt is a hybrid of the Generalized Pattern Search (GPS) algorithm and the Particle Swarm Optimization (PSO) algorithm, which is used to initialize the search. These algorithms can perform optimization for both continuous and discrete independent variables. The continuous independent variables are Azimuth angle, WWR, Overhang depth, and Aspect ratio, and the discrete independent variable is the glass type of the window.

WinOpt is being developed as a web-based application. The tool is developed on Apache/2.2.16 (UNIX) and Web pages are developed in PHP and use JavaScript/jQuery Technologies. At the back end, socket programming has been implemented, the code for which is written in the C language. The inputs submitted from the User Interface (UI) are pre-processed by a PHP script that generates the corresponding EnergyPlus Input Data File (IDF) for the simulation. The IDF name and the weather file name are then sent to a bash script that manages the simulations while the front end shows the progress of the simulations. Once the simulations are done, the UI is redirected to the results page, which shows the results. The architecture of the tool is shown in Figure 1.

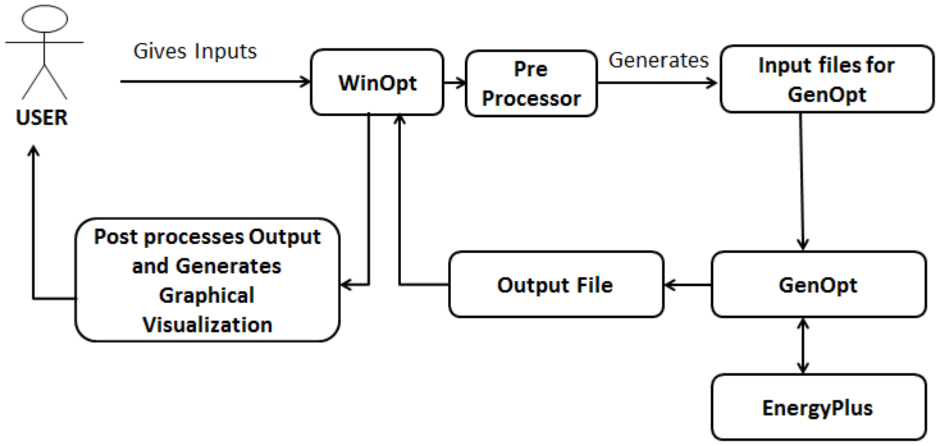

Figure 1 Work flow diagram of WinOpt

First, the tool takes the static parameters, which are the location of the building and HVAC type to be used in the building, as input. After the static parameters, it takes the ranges of the various variable parameters for which the building design is to be optimized. It then uses EnergyPlus and GenOpt to perform simulations in order to get an optimal output. There is also an option to perform parametric simulations on user specified values without any optimization, to give the user a complete spectrum of possible outputs for analysis.

In the tool, four different types of HVAC systems are available for selection – Packaged Terminal Heat Pump (PTHP), Packaged Single Zone (PSZ)-HP, Central Air Conditioning with a water cooled chiller, and Central Air Conditioning with an air cooled chiller. Each building type can be selected with any one of the available HVAC options listed in Table 1.

Table 1: Input parameters for different HVAC systems

S. No.	Parameter	PTHP	PSZ-HP	Central AC Water cooled	Central AC Air cooled
1.	Cooling Type	Direct Expansion coil	Direct Expansion coil	Water cooled screw chiller	Air cooled chiller
2.	Heating Type	Electric Heat Pumps	Electric Heat Pumps	Electric Resistance	Electric Resistance
3.	Fan Control	Constant Volume	Constant Volume	Variable Air Volume	Variable Air Volume
4.	Coefficient of Performance (COP)	2.8	3.0	5.5	3.1
5.	Heating Seasonal Performance Factor (HSPF)	1.91	1.91	Not Applicable	Not Applicable
6.	Air-side economizer	None	None	None	None

S. No.	Parameter	PTHP	PSZ-HP	Central AC Water cooled	Central AC Air cooled
7.	Heat Recovery	None	None	None	None
8.	Zone air set point	Cooling 24°C Heating 20°C	Cooling 24°C Heating 20°C	Cooling 24°C Heating 20°C	Cooling 24°C Heating 20°C

When GenOpt is used in the optimization mode, a series of random variable combinations are generated and simulations are performed to identify the low energy combinations. The optimization algorithm narrows down its search to the least energy consuming combinations from the above step. This leads to a clustering of variable combinations that produce low energy use. This could mislead a user about the range of solutions that are available. In order to make the user be more aware and cautious about the solution sets that are available, the option of performing a parametric simulation is also provided. Parametric simulation is a brute force method for performing simulations for all the possible combinations. This is time consuming but provides a full spectrum of results. Therefore, it would be useful for the user to be able to choose a limited set of variables for use in the parametric simulation based on the results from the optimization mode. Both these methods are compared in Table 2.

Table 2: Comparison of optimization and parametric mode

	Optimization mode	Parametric mode
Number of simulations	Low	High
Time	Low	High
Knowledge about ECMs applicable for the given design	No	Yes

A case study that illustrates the operation of GenOpt and the difference between parametric and optimization results is presented in the following section.

CASE STUDY

Location – Hyderabad, India
Building Type – Office
Building Footprint – 100 sq.m
Operation schedules – Mon – Fri (09:00 AM – 06:00 PM)
HVAC system – PTHP

Table 3 Input variables for optimization

S.No.	Parameter	Minimum	Maximum	Step Value
1	Building Orientation (°)	0	90	10
2	Window Wall Ratio (%)	20	80	10
3	Overhang Depth (m)	0.2	1	0.1
4	Aspect Ratio	1	2	0.1

Input parameters and ranges used in the optimization mode are listed in Table 3 and the four different values of glass types used are listed in Table 4.

Table 4 Glass types for optimization

S.No.	Glass type	U- value (W/sq.m-K)	Solar Heat Gain Coefficient (SHGC)	Visible Light Transmittance (VLT) (%)
1	Type-1	1.5	0.25	50
2	Type-2	3.72	0.28	27
3	Type-3	1.5	0.20	35
4	Type-4	5.7	0.67	67

Input parameters and ranges used in the parametric mode are listed in Table 5 and different values of glass types used for performing the simulations for parametric mode are listed in Table 6.

Table 5 Input variables for the parametric simulations

Parameter	Value 1	Value 2	Value 3	Value 4	Value 5
Building Orientation (°)	0	45	90	135	180
Window Wall Ratio (%)	20	40	50	60	80
Overhang Depth (m)	0.3	0.5	0.8	1.2	1.5
Aspect Ratio	0.6	1.0	1.3	1.5	1.8

Table 6 Glass parameters used for the parametric simulation

S.No.	Glass type	U- value (W/sq.m-K)	SHGC	VLT(%)
1	Type-1	3.3	0.15	15
2	Type-2	3.3	0.25	25
3	Type-3	3.3	0.40	40
4	Type-4	3.3	0.60	60
5	Type-5	3.3	0.85	85

The results can be broadly categorized in two formats:

1. An 'N' dimensional interactive graph as shown in Figure 2 and 3. Using this graph, the user can get insights such as which combination of variable parameters produces the best performance in terms of energy use. The user can also study the impact of various parameters on the performance of the building.
2. A 'Bitmap' visualization of the data as shown in Figure 4. This visualization is available only for parametric simulations. This visualization is useful for finding and understanding clustering (if it exists) in the energy consumption of the building. Therefore, using this visualization, the user can study the parameters that have a major impact on the energy consumed by the building.

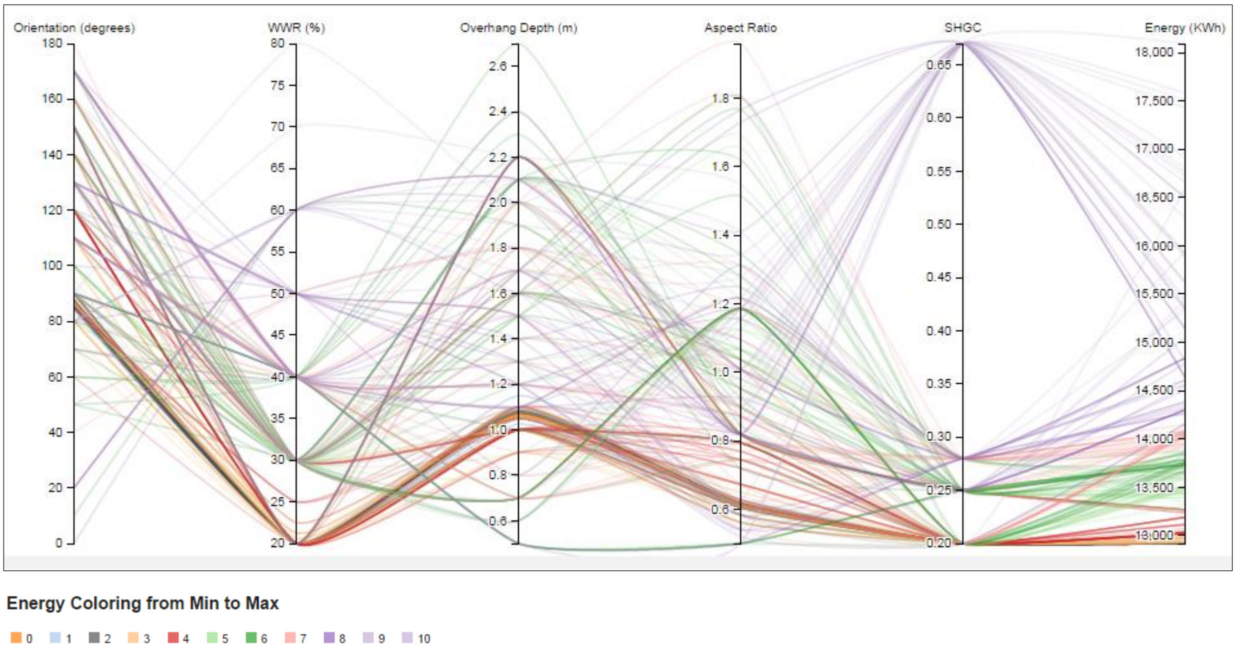

Figure 2 Near-optimal solutions obtained using GenOpt, which are used to inform the selection of parameters for use in the parametric study

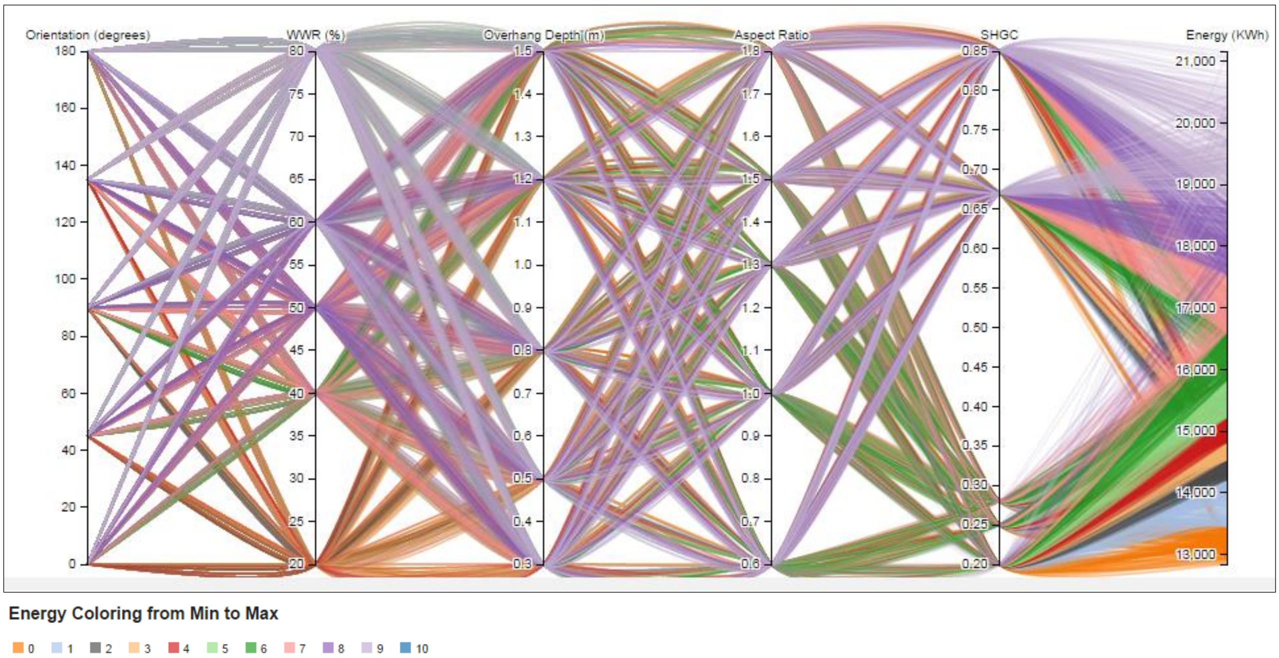

Figure 3 Results obtained by performing parametric simulations

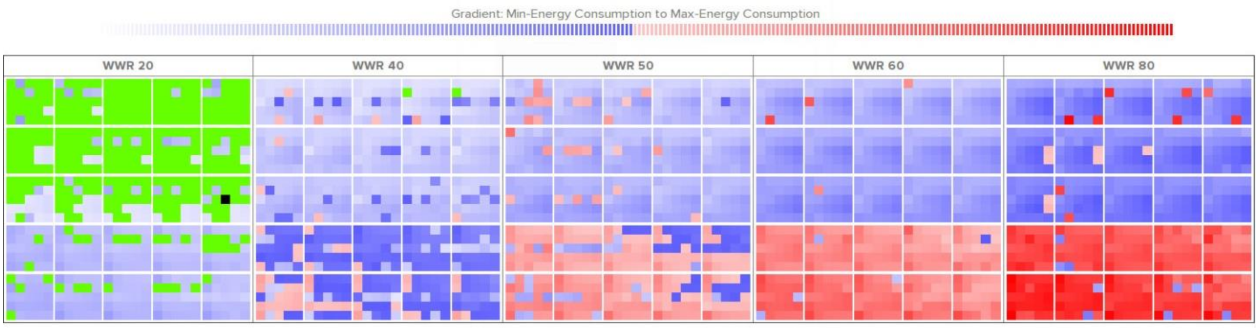

Figure 4 Bitmap visualization of the data

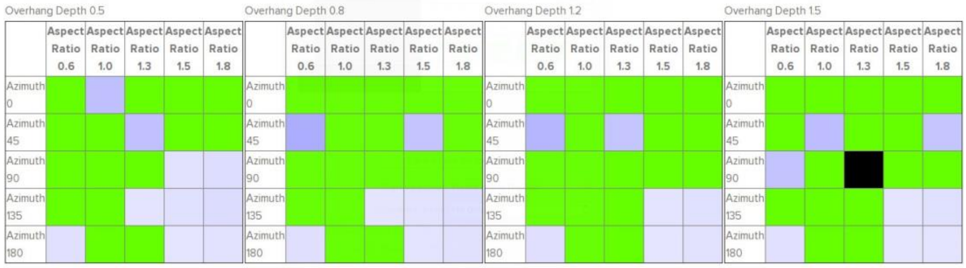

Figure 5 Bitmap visualization of the data with Zoom option

The following observations can be made from the Bitmap Visualization from Figure 4 & 5:

1. The **Green Region** in the graph shows the areas that are close to the minimum energy as given by parametric simulations (within 5%). As can be seen, this could be achieved by diverse combinations.
2. The **Black Point** in Figure 5 shows the minimum energy value obtained by parametric simulations.
3. The **Red Region** shows the area of maximum energy consumption which appears to be highly clustered in regions of high WWR and high SHGC.
4. The color gradient in graph goes from Green to Blue to Red, where green represents the minimum energy consumption, with blue color depicting medium energy consumption and red depicting high energy consumption.

Also, from the visualizations, we can see that GenOpt performs only an optimal number of simulations to find the most energy efficient configuration and the solutions begin to cluster around the local minima. The energy ranges from 12,841 kWh to 21,044 kWh in the graph showing the results of parametric simulations, performed only on specific values of variable parameters as shown in Figure 3. Hence, this gives a broader spectrum of energy consumed by the building, as compared to performing optimized simulations, in which energy ranges from 12,920 kWh to 18,093 kWh. We can also see that the minimum energy found by performing an optimized number of simulations using GenOpt is very close to the minimum energy obtained by performing parametric simulations on specified inputs.

Also, from Figure 4, it is seen that, as the WWR increases, the clustering in the lower right corner increases. This shows that with increasing WWR, the energy consumption of the building also increases. This observation is in accordance with what one would expect of energy consumption in hot areas. Therefore, using the visualization presented in Figure 4, we can analyze the clustering in the energy consumption statistics of the building.

CONCLUSION

WinOpt optimizes the design parameters of the windows for minimal operational energy consumption of a conditioned building. It helps in reducing the total number of simulations to be performed and also has visualization tools embedded within it for easier and faster analysis. This tool can therefore be useful in reducing the time and cost for the early stage design.

From the case study, it was found that the total number of simulations performed by WinOpt was 311. However, if each and every possibility has been simulated individually, the simulation count would have been 246,848 (19 x 7 x 29 x 16 x 4). Here 19 different values of azimuth, 7 different values of WWR, 29 different values of Overhang Depth, 16 different values of Aspect Ratio, and 4 different values of Glass Type are considered. The 311 simulations are then only 0.12% of the total possible simulations.

The parametric option in WinOpt is helpful for the users to understand the spectrum of design solutions. With the help of different visualizations that the tool provides, the users can get useful insights about the energy consumed by the building, which can help them in making rapid design decisions for their buildings.

Since the backend of WinOpt uses EnergyPlus as an engine for simulations, the tool could be modified to support simulation for free running / naturally ventilated buildings by evaluating thermal comfort conditions instead of the energy consumption of the building; WinOpt could then also help in design decisions for low energy/ net zero energy buildings.

ACKNOWLEDGEMENT

The work reported here was an activity of the Center for Building Energy Research and Development (CBERD), which is supported by the Joint Clean Energy Research and Development Center (JCERDC) funded by the Indian Ministry of Science & Technology and the U.S. Department of Energy and administered by Indo-US Science and Technology Forum in India. Work on energy efficiency in buildings at Lawrence Berkeley National Laboratory is supported by the Assistant Secretary for Energy Efficiency and Renewable Energy, Office of Building Technology, State and Community Programs of the U.S. Department of Energy under Contract No. DE-AC02-05CH11231.

The Four Sustainable Design Perspectives

Mark DeKay, R. A.
University of Tennessee, Knoxville
mdekay@utk.edu

ABSTRACT

This paper, illustrated with built examples, uses Integral Theory to map four distinct yet ever-present perspectives on Sustainable Design, each with fundamentally different methods, criteria for value, and definitions of good form. The perspectives are articulated by intersecting two primary distinctions: 1) subjective (interior) vs. objective (exterior) ways of knowing and 2) perspectives of individuals (parts, persons, members) vs. collective systems (wholes, networks, societies). This yields four different viewpoints: Behaviours (singular-objective) [the "IT" prospects], Systems (collective/inter-objective) [the "ITS" prospects], Experiences (singular-subjective) [the "I" prospects], and Cultures (collective/inter-subjective) [the "We" prospects]. From each of these varied perspectives on design, the nature of Sustainable Design and that of Nature itself show up quite differently. Yet many Sustainable Design approaches are primarily grounded in the singular-objective Behaviours Perspective. The expanded multi-perspectival view presented here can enable designers to more comprehensively address the complexity of today's ecological challenges by including the individual, cultural and social dimensions that contribute to the creation of a sustainable world.

Keywords: integral theory, performance, systems, cultures, experiences, sustainability

1 INTRODUCTION

Perhaps because of the dominance of empirically-based sustainability perspectives, and the culturally predisposed listening that many of us have for it, designers commonly equate sustainability with technology and sustainable technology with quantifiable energy efficiency or its visible hardware, such as photovoltaic collectors. While Sustainable Design is increasingly associated with performance measures, the wider profession is, on the other hand, increasingly ideologically pluralistic. Despite this pluralism, the design fields, and Sustainable Design in particular, seem to have *no collective framework* for navigating and transcending the fragmentation that entrenches both academia and practice.

Subjective perspectives are missing from most Sustainable Design thinking. As an example, in the US, there are no LEED credits for creating experiences of beauty, none for creating or fitting to ecological order and none for placing people into rich symbolic relationships with Nature. Quality and subjectivity do not appear on this horizon. This is not to argue for devaluing this approach: the technological view of Sustainable Design has done great things for our awareness of the limits of resources and environmental sinks—and the relationships of building design to these.

Similarly, environmentalism based on scientific rationalism has not been very effective. The message goes something like this: 'Look, we have the facts … the sky is falling, we're running out of everything you need, the climate is going crazy and Nobel laureate Al Gore (former US Vice-President) has pictures of the polar caps that should scare the pants off of all of us.' Well, if that does not work to get our collective profession in action, statistics about the contribution of buildings to landfill waste, water consumption and CO_2 production probably will not work too well with a broad audience either—that is, when that's the *only* argument we are making. To address these issues, this paper expands on the

The author is a Professor in the School of Architecture, University of Tennessee, Knoxville, Tennessee.

theoretical views introduced in *Integral Sustainable Design* [1, 2] which was the first work to apply Integral Theory [3, 4] to design, and in particular to the field of Sustainable Design.

2 INTEGRAL THEORY'S FOUR PERSPECTIVES

Integral Theory is an emerging theory base that the author has found to be helpful in teaching and thinking about the complexity of Sustainable Design. An integral theory begins with the assumption that everyone is right—at least partially—and seeks to fashion an intellectual framework that both transcends and includes differences. An integrally-informed approach to Sustainable Design (or anything else) challenges us to hold *multiple simultaneous perspectives* and to address different levels of awareness across the spectrum of human development. Integral Theory is a model that could help design educators and practitioners reconsider the scope, breadth, and multifaceted aspects of sustainability. Integral Theory, as developed by the philosopher Ken Wilber, is based on a cross-cultural comparison of human knowledge, experience, and inquiry [3, 4].

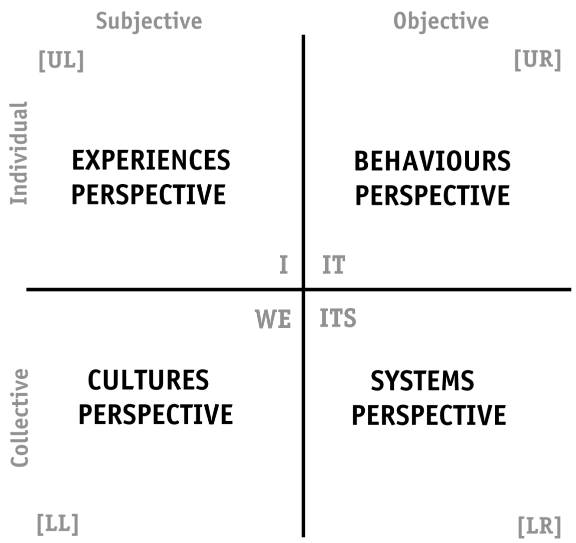

Figure 1 *The four quadrants of Integral Theory*

This paper is limited to the study of one of the most fundamental aspects of the integral model: *quadrants.* At its most essential level, Integral Theory organizes variables for any problem into a matrix of *quadrants* that intersect individual and collective phenomena with objective and subjective knowledge. These combined variables reveal the following considerations (See Fig. 1): 1) *Experiences:* self and consciousness; 2) *Behaviors:* science, mechanics and performance, 3) *Cultures:* meaning, worldviews, and symbolism, and 4) *Systems:* social and natural ecologies and contexts.

The four quadrants are not separate phenomena, but rather four simultaneous perspectives on any event. For this reason, this paper uses the term *perspectives* in place of *quadrants.* Each quadrant or dimension of reality is ever-present and co-arises with the others. The philosopher Michael Zimmerman notes that "The quadrant perspectives correspond generally to the four ways in which universities divide research methodologies (that is, truth-claim generating practices or paradigms): fine arts (UL), humanities (LL), natural sciences (UR), and social and systemic natural sciences (LR)" [5].

Often the two right-hand quadrants, both objective, are considered together, yielding *three value spheres,* associated with *Self* (UL), *Culture* (LL) and *Nature* (UR/LR), or alternatively, *Art, Morals,* and *Science*. Wilber refers to these as "The Big Three," noting that each domain can be associated with the fundamental language distinctions of I, WE, and IT/ITS, or first, second and third person perspectives. This indicates that the perspectives are not opinions or speculative theory, but rather, are so fundamental as to be embedded in all natural languages. The Big Three are the classic value domains of *Beauty, Goodness* and *Truth*. The point is that every event in the manifest world has all three (or four) of those dimensions. You can look at any event from the point of view of the 'I' (how I personally see and feel about the event); from the point of view of the 'we' (how not just I but others see and understand the event); and as an 'it' (the objective facts of the event) [6]. The four fundamental perspectives on any occasion (or the four basic ways of looking at anything), turn out to be fairly simple: they are the *inside* and the *outside* of the *individual* and the *collective* [6].

3 THE FOUR INTEGRAL SUSTAINABLE DESIGN PERSPECTIVES

Figure 2 shows 'The four Sustainable Design perspectives.' The proposition is that each type of perspective is ever-present in all languages and cultures; each both discloses and occludes certain phenomena. *An Integral approach to design is one that unites the beautiful, the art of design, and the good, the ethics of design, with the true, the science of design.* We can also think of design as having four primary dimensions (the four perspectives of the quadrants), each requiring different perspectives on the practice and products of design:

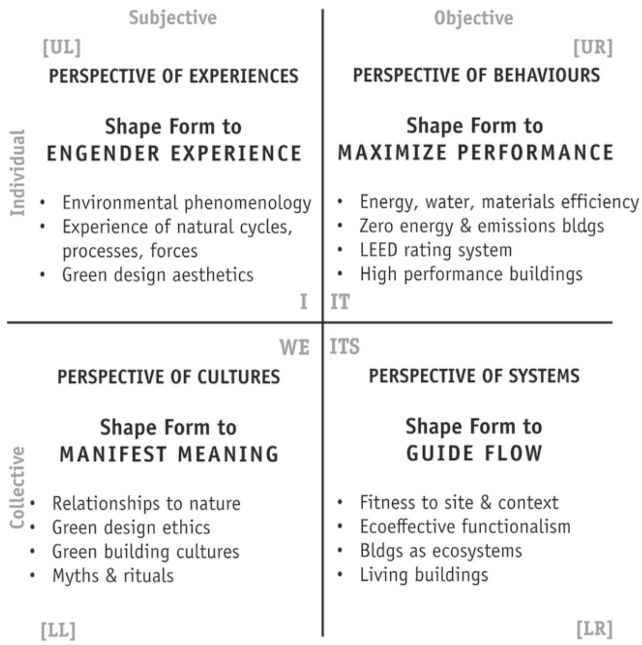

Figure 2: *The four Sustainable Design Perspectives*

Behaviours Perspective: individual parts or members with their performance characteristics, activities, and functions;

Systems Perspective: patterns of forms and flows of energy, information, people, and materials that order ecological and social relationships;

Experiences Perspective: systemic members (human and non-human) with various forms of perception, sentience, and awareness;

Cultures Perspective: shared meaning and understanding at various levels of complexity arising from individual members interacting with each other.

Applied to the consideration of Sustainable Design, the framework reveals that much of the current dialogue takes the Perspective of Behaviours [UR] and is concerned primarily with performance that can be 'measured and weighed,' an important, yet partial view. The Perspective of Systems [LR] reveals that eco-efficiency is not enough by itself to create healthy ecological pattern, and that a logic of 'systems and relationships' can be used to organize the UR logic of 'parts and performance,' either of which *can* constitute a reduction to 'flatland' (Fig. 3). High-performance design collapses everything to the upper right quadrant. Green, ecological approaches collapse reality to the lower right quadrant, or to the right side of the four-quadrant matrix (the web-of-life). Wilber calls this *subtle reductionism* as contrasted with the *gross reductionism* of the upper right. It may be that paying more attention to the perspectives of Experiences [UL] and Cultures [LL] has the potential to vastly expand the effectiveness of the objective arguments for 'design with nature.' Objective, mental arguments often fall on deaf ears for people oriented primarily with values from the subjective (what it feels like to me) and the inter-subjective (what is means to us) perspectives.

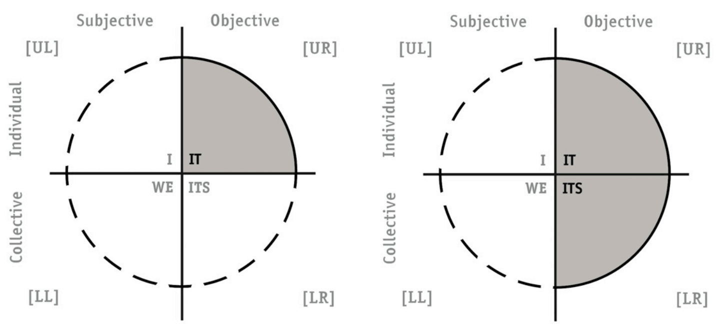

Figure 3 *Gross (left) and subtle (right) reductionism*

4 INTENTIONS AND CRITERIA FOR GOOD FORM FROM THE FOUR PERSPECTIVES

Architectural design is a discipline that requires the shaping of form; in the end, something is built or it is not a building. We can then ask the following questions: 1) *Thinking as designers, how shall we shape* *form for sustainability from each perspective?* and, 2) *From each quadratic perspective, what is the designer's intention and what are the criteria for good form relative to sustainability?*

From the Behaviours Perspective [UR] the design question is: *How shall we shape form to maximize (eco)performance?* Good form minimizes resource consumption and pollution while maximizing preservation and recycling.

From the Systems Perspective [LR] the design question is: *How shall we shape form to guide ecological flows?* Good form solves for ecological pattern by creating structure in the built environment that best accommodates ecological processes through mimicry of and fitness to the context of natural ecosystems.

From the Cultures Perspective [LL] the design question is: *How shall we shape form to manifest the meanings of ecological systems and our relationships to them?* Good form reveals and expresses 'the patterns that connect' in ways that celebrate the beauty of natural order, place inhabitants into relationships with living systems (or their idea of Nature) and situate human habitation in bioregional place.

From the Experiences Perspective [UL] the design question is: *How shall we shape form to engender experiences of Nature and process?* Good form orchestrates rich human experiences of Nature and its phenomena and creates centring places conducive to self-aware transformation to higher levels of (ecological) consciousness.

5 NEW PRINCIPLES FOR INTEGRAL SUSTAINABLE DESIGN

Given the heterogeneous ideas of Sustainable Design, the following illustrative principles have been defined in Figure 4 for each perspective. A *principle* is a statement of the fundamental basis of something, a truth or proposition, as an injunction, that makes ideas portable. Principles serve as the basis of a system of belief or reasoning, and they can be applied across a range of situations. There could be more or less than those given. The principles below follow as articulations of what can be called "an Overarching Principle of Integral Sustainable Design": *Design for sustainability by considering multiple levels of developing complexity in the intersecting domains of self, culture and Nature.*

Experiences perspective [UL]	• *Design profound aesthetic experiences* of natural processes and a living world, accessing multiple senses. • *Design to access human psychological connections to place,* at multiple levels from archetypes to the Transpersonal. • *Design centring places conducive to self-aware transformation* to higher levels of Nature consciousness.
Behaviours perspective [UR]	• *Design high-performance buildings* that maximize efficient use of water, energy and material resources while minimizing waste and pollution. • *Design with on-site renewable resources* of sun, wind and light. • *Design to create safe, healthy places with long-term value*, eliminating toxicity to present or future generations.
Systems perspective [LR]	• *Design at three levels of holarchy*: to build a larger whole, to create a whole and to organize smaller wholes. • *Design living systems using ecology as the model*. Fit flows to local renewable systems while also supporting techno-industrial ecosystems. • *Design solutions fit to particular places,* considered as local site, larger neighbourhood and region.
Cultures perspective [LL]	• *Design based on a high and conscious environmental ethic* in which humanity and Nature both thrive in regenerative human ecosystems. • *Design to place people into significant relationships with Nature* by making visible how culture is interconnected with living systems. • *Design for cultural communication by using the symbolic languages of design* to make evident the meaning of ecological systems.

Figure 4 *Design principles from the four perspectives*

6 THINKING AND BUILDING FROM THE FOUR PERSPECTIVES

Each of the four foundational perspectives require a different way of thinking. These distinctions in thinking yield different concerns for Sustainable Design and a different sustainable architecture. They can also be combined. At an Integral level of complexity, a design might consciously employ all four.

6.1 Thinking and Building from the Behaviours Perspective

The Behaviours Perspective employs an analytic logic of parts and performance that allows designers to dissect projects, measure performance and assess results. It assures efficiency of the constituent building parts. We understand the order of the whole in terms of our *knowledge of individual elements.* It is the most clear and certain way of design thinking. Behaviours Perspective methods depend on observation and on what can be derived from observation. They require us to look scientifically and objectively at observable phenomena, the behaviours of things and people and at the relationships that are seen and quantifiable. Out of this measuring of things one arrives at high-performance buildings as a goal. Its logical extension is plus-energy buildings, zero-emissions buildings, and so on. This perspective reveals that we are running out of many resources and polluting at rates faster than Nature can absorb. It implies a shift from finite to renewable resources. It’s also the perception that takes our vital signs and the planet’s and researches what is healthful and what is not. Thus, in addition to net-zero resource use, infinite recycling and the transition to design with renewables, it promotes a non-toxic environment. Who can argue with that?

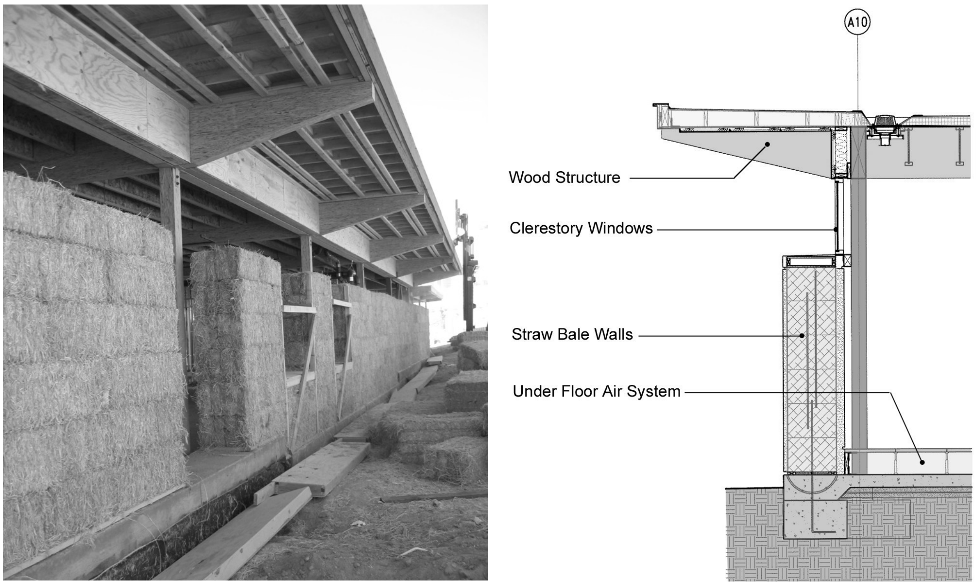

Figure 5 *Santa Clarita transit maintenance facility, Santa Clarita, California, 2008; © HOK*

The first LEED Gold certified straw bale building (Fig. 5), this super-insulated building utilizes photovoltaics to provide half of the operational energy needed and reacts automatically to changing climatic conditions of its desert climate. It uses under-floor air distribution and high-performance glazing. The combination of high- and low-tech solutions helps this building to exceed stringent California energy efficiency standards by 40 per cent.

6.2 Thinking and Building from the Systems Perspective

The Systems Perspective uses a logic of systems and relationships. It is concerned with finding patterns as a basis for making effective design decisions. It is an associative logic that allows designers to see relationships between facts, forces, processes and form. Whereas the Behaviours Perspective tends toward thinking about the ‘application of technology’ and uses quantity as the criteria for success, this perspective embeds technology in architectural patterns, fitting design to its contexts. The Systems Perspective is inter-objective, a third person perspective on social and natural systems. Integration is its most prized value.

In buildings, energy-efficient elements can be combined in intelligent ways to make buildings as energy systems. An example is a passive solar-heated building that can be combined with efficient envelopes and with spatial organizations, orientations and materials to collect, store and redistribute solar energy in complex diurnal and seasonal patterns. The systems of the passive solar-heated building can be combined with those of the naturally ventilated and daylighted building systems. These can be integrated with active mechanical systems, on-site green power systems, and so on. These energy systems can be further integrated with spatial systems, with patterns of use and social order, the order of structural, material and construction systems, with hydrologic systems in the building and site, natural habitat on site, larger contextual urban systems, and so on.

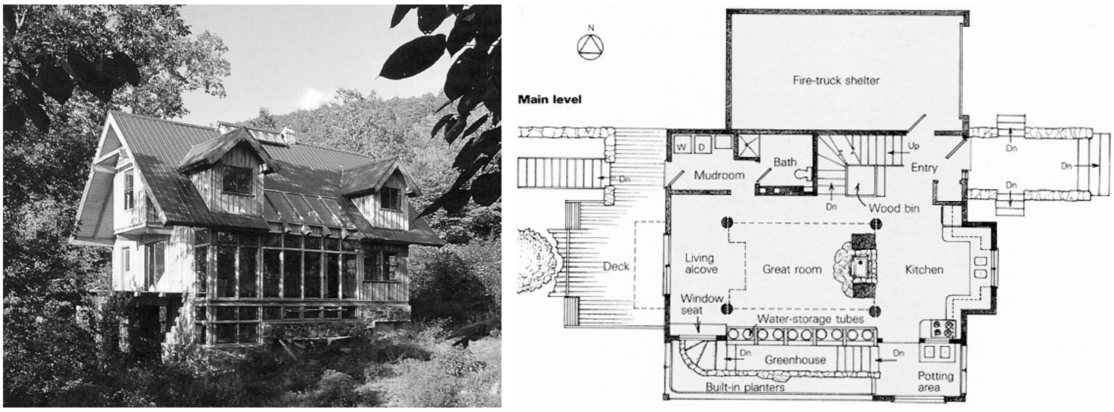

Figure 6 *Solar Farmhouse, Fox, Arkansas, © Gary Coates, with Kansas State architecture students*

In the Solar Farmhouse (Fig. 6), the vernacular dogtrot type meets an atrium and solar greenhouse in a traditional Ozark mountain farmhouse language. The building is organized a series of interrelated design patterns, both social and climatic [7]. The "Dog-Trot Atrium" pattern as a transformation of Alexander's pattern, "Common Areas at the Heart," functions also as a stack-ventilation room and a toplight room. The house is heated by direct gain rooms with solar collection from individual windows and a ridge-top skylight, combined with a substantial two-storey sunspace. Translucent, cylindrical water-filled fiberglass tubes located between the sunspace and the great room serve as thermal mass (and as a food-producing greenhouse), with additional mass in an under-floor rock bed and in the stone walls of the greenhouse stair. The open plan and section allow warm air to rise and enter upper rooms via interior windows, while stratified air is recovered from the top of the atrium and returned to ground level.

6.3 Thinking and Building from the Experiences Perspective

In thinking about the Experiences Perspective, we are concerned with the interior experiences and intentions of designers and with the experiences of the occupants of a sustainable design. For Sustainable Design to be more effective, designers can address the fundamental reality and richness of our human interior experiences. Essentially, if people are to love sustainably designed environments, by necessity designers will have to create loveable places! This means we may choose to design rich full-person experiences, including a range of aesthetic experiences, because responsible action flows most freely from affection, which of itself requires an engaged relationship. A mature Integral Sustainable Design fully engages the human experience of Nature and the subtleties and richness of human feeling in space and place. It is also time for the cultivation of a highly developed theory and practice of Integral Sustainable Design aesthetics that is developmental and multi-perspectival.

To have meaningful discourse about ecological relationships in designed things, individuals must be able to perceive and experience these relationships. Sustainable Design can then ask the design question: *How can important ecological relationships—and the ways design creates relationships to these—be made into significant human-felt experiences?*

Figure 7 *Marie Short House, Kempsey, New South Wales, Australia, 1975, Glenn Murcutt* [8]

Through extensive design for natural ventilation, the Marie Short House (Fig. 7) creates the experience of the process of ventilative cooling. Adjustable steel louvers in the walls control the flow of wind-driven cross-ventilation, while fixed wood louvers allow airflow beneath gables and above open porches. Wide eaves protect from the sun; open plans align space and moving air. And the building communicates the relationship of form to these processes. In its passivity is the occupant's experience of connection to process and place.

> Think of the building as an instrument that's picking up all these sounds..... It's addressing the topography, the wind patterns, light patterns, altitude, latitude, the environment around you, the sun movements. It's addressing the summer, the winter and the seasons in between. It's addressing where the trees are, and where the trees are will tell you about the water table, the soil depth, climatic conditions.' —Glenn Murcutt [9]

6.4 Thinking and Building from the Cultures Perspective

Designers understand that both the *relationships of the natural world* (gravity, climate, energy, ecology, etc.) and *human relationships* (social interactions and human interactions in culture) must be solved for. Seeing Sustainable Design from the Cultures Perspective asks designers to look at how any design places us into relationship with Nature in ways that embody meaning. Anything we design creates or modifies a system of ecological relationships and places humans into an inhabited system in which our relationships to natural forces and processes are tightly bound.

Looking at design from this perspective, designers can ask, *How can Sustainable Design be appropriately ordered to fit its cultural context?* and *How can the patterns of ecological relationships in which the building participates be made culturally significant and appropriate?*

Figure 8 *Shangri La Botanical Gardens and Nature Center, Orange, Texas, 2004, Lake/Flato* [10]

Serving as a place to educate visitors on native ecosystems, the Shangri La Botanical Gardens (Fig. 8) use the surrounding site as part of its regionalist architecture. This LEED Platinum project serves primarily as an interpretive centre for the site's native ecosystems (cypress and tupelo swamp, wooded uplands, and prairie lowlands) as well as a facility for study and research. Nature centres are some of the clearest American expressions of a postmodern Cultures Perspective on Sustainable Design, because they take a clear attitude on what Nature is and tell the story of the human relationship to Nature. While it may perform well, this performance is in service to a cultural ethic.

7 CONCLUSION

A premise of Integral Sustainable Design is that more expansive perspectives on the world are necessary to meet the diverse ecological, social, cultural, ethical, and technological challenges of the twenty-first century. Species interdependence and humans' role in shaping a sustainable future require new approaches that include, yet expand the current emphasis of Sustainable Design on scientific-objective measures. The implication for design is not that each building should address all four perspectives all the time, but rather, that one can be integrally-informed by this expanded view and thus consider, using the tools and methods of that view, each of the four perspectives to question whether or not the issues embedded in the each are relevant for the project at hand.

In addition to designing high-performance buildings and sites, a more Integral view of Sustainable Design incorporates understandings of problems and their solutions that also address the other three important classes of issues.

The highest levels of performance require a systemic approach using method and concepts revealed only from the Systems perspective. Performance in an ecosystem is about dynamically balanced exchanges of energy, information and materials that bring systemic health. Ecological health trumps green efficiency.

The inclusion of a focus on the Experiential Perspective on Sustainable Design fosters the possibility of direct personal knowledge of Nature. Knowledge always precedes care. Care often gives rise to spontaneous action that benefits the object of care. We humans tend to care more about those we know than those we don't know. Having groups of people have experiences of 'Nature-via-design' gives rise to dialogue and interpretation, the key to cultural transformation. Culture in a sense is the effect of all of our conversations. So as designers, can we give people something to talk about?

When Sustainable Design manifests, reflects and expresses ecological processes (from the Cultures Perspective), such as the water cycle for example, it gives people the opportunity to become more aware of living processes and their relationships to them. The stories of our relationships to Nature as told though ecologically expressive built works are powerful. Such expression could allow Sustainable Design to become as transformative of the settled landscape as was post-war suburbia.

ABSTRACT

How can the summer behaviour of timber buildings be improved without worsening its seismic performance? The research developed by Fraunhofer Italia, Free University of Bozen-Bolzano and supported by Trees and Timber Institute CNR – IVALSA, focuses on passive features of the building envelope. Combining the classifications of the Italian territory based on climate (equivalent Cooling Degrees Days) and structural indicators (horizontal elastic response spectrum), possible improving strategies with thermal mass for different climatic zones are identified. The research considers both building physics and structure implications and matches two structural typologies (Platform Frame and Cross-Laminated Timber) with different building features. The building physics analysis determines some effective building components whose improved cooling energy performances are evaluated by dynamic simulations under the critical period. The structural analysis is aimed at calculating seismic behaviour and limits of a timber structure with applied additional mass loads. The following paper describes the TIMBEEST research methodology by providing work-in-progress results.

INTRODUCTION

The development of architecture features is significantly influenced by the geographical situation. Timber buildings are mostly widespread in cold climates, because of a good thermal performance and the availability of raw material. In fact, the use of timber constructions, especially lightweight walls, is not common in the Italian building stock. The low thermal inertia of timber buildings is identified as one of the main reasons for the worsening of summer thermal behaviour in comparison with clay block or concrete. Hence, it is a limit during the cooling season in hot climates. Passive design of building envelop considers environmental circumstances such as local climate and site conditions, and adopts suitable passive cooling techniques as thermal mass in order to reduce indoor temperature without the use of HVAC systems. Since 1970s, researchers have studied the effect of thermal mass on energy demand and cooling/heating peak loads. Furthermore, the distribution optimization of thermal mass layer and the effective thickness have been investigated. Baverstock demonstrated that the thermal mass effect

in a commercial building, located in Perth (Australia), decreased the cooling peak loads of 27 %. On the basis of a specific time-dependent method, Shaviv evaluated that the optimum thickness of a concrete thermal mass should be 10 cm for internal partition and 15 cm for external walls. Brown proved that thermal mass applied to walls and floors made possible to achieve cooling demand decrement of 18-20 %. Robertson provided recommendation regarding the best use of thermal mass in residential and small commercial buildings: a 5-10 cm mass wall is usable for daily heat absorption, storage and release, and it is possible to obtain an annual reduction of sensible heating and cooling as high as 40 % for the mild climates. Kosny and Kossecka determined that the distribution of thermal mass on internal side of walls is the best solution for U.S. climates in order to decrease the energy demand. Al-Sanea and Zedan demonstrated that for the arid climate of Riyadh (South Arabia) the thermal mass distribution is optimal when split in two parts by insulation layers, placed at inside, middle, and outside. A previous Fraunhofer research project (Paradisi et al., 2012) regarding the improvement of summer thermal behaviour of timber building investigated and prototyped the technology, which integrates aluminium tubes filled with sand and water on internal side of wall. It has been used in the “Med in Italy House” during the Solar Decathlon Europe 2012 competition, held in Madrid. The thermal assessments, carried out by both dynamic simulation and monitoring campaign, confirm that thermal mass in direct contact with the indoor environmental notably influence thermal comfort and cooling peak loads. TIMBEEST research project aims at understanding the possibility of improving the summer behaviour of timber buildings across the Italian territory by using thermal mass without worsening its seismic performance. This because Italy is a country characterized by an intense and widely spread seismic activity (Civil Protection Department) and high temperature during summer (Pinna, 1978), especially in southern areas. Timber technology presents an excellent structural behaviour in seismic zones, but its low thermal inertia (compared to clay block or concrete buildings) is one of the reasons for worsening the energy performance in cooling period. Since timber technology is rare or even absent in Central and Southern Italy, it is an opportunity to investigate the technological feasibility and effectiveness of timber buildings, considering both thermal performance and structural implications. Three research entities – Fraunhofer Italia for technological development and thermal assessments, Free University of Bozen-Bolzano for dynamic simulation, and Trees and Timber Institute CNR – IVALSA for structural aspects – are trying to answer this question thank to the Autonomous Province of Bolzano-Bozen which supports the research project.

METHODOLOGY

In order to achieve the mentioned goal, the research is structured in three phases as follows:

1. Maps of the Italian territory visualize physical features regarding external restraints such as climate and seismic indicators (equivalent Cooling Degree Days CDD and horizontal elastic response spectrum Se, respectively). The combination of these indicators allows creating a Synthesis Map, which pinpoints the critical areas for timber buildings in terms of summer thermal and seismic behaviour.
2. In order to evaluate energy and structural performances, the most common sample of standard buildings components (walls, roofs, slab/floors) in Platform Frame (PF) and Cross-Laminated-Timber Panels (CLT) with different types of insulation materials is identified. These building components are applied to a reference model, used for dynamic simulations.
3. Based on scientific literature review on thermal mass, on dynamic simulation output data and on linear static analysis, the standard building components are improved. A multi-criteria analysis is developed in order to find out the solution of thermal mass integration in the building envelope which is optimized for 110 capital cities of Italian Provinces. The output data of this phase will be applied to further dynamic and seismic dynamic simulations in order to define the percentage of improvement and its geographical extent, comparing both standard and improved building components.

First phase: Analysis

The first analysis is focused on external restraints regarding energy aspects. In order to achieve a better evaluation of building energy performance, dynamic simulation tools require more complex and detailed inputs such as hourly weather data (Pernigotto et al., 2013). The Test Reference Year TRY as defined by the European technical standard EN ISO 15927-4:2005 is considered as weather data. The TRYs are those provided by CTI – Italian Technical Committee at May 2013. In order to qualify the Italian territory by the high temperatures during summer which can affect the cooling energy demand of buildings, the research team of the Free University of Bolzano-Bozen calculates the equivalent Cooling Degree Days (CDD, [K d]) referred to TRY according to Gasparella et al. (2011). The equivalent CDD, also called Climate Indicator (CI), is calculated for the period from May to September considering: 1) monthly average sol-air temperature ($\theta_{sol\text{-}air,\ \alpha,}$ [°C]) referred to three different horizontal surfaces with absorption coefficient value (α, [-]) respectively 0,3, 0,6 and 0,9; 2) setpoint of cooling temperature (θ_{in}, [°C]) equal to 26 °C. CI indicates the climate characteristic given by temperature and solar radiation of the typical year referred to all Italian capital cities. It is classified in quartiles, as shown in **Table 1** and visualized using QUANTUM GIS software, as shown in **Figure 1a**. The second analysis aims at classifying the Italian territory according to seismic action. Italy is a country characterized by a high seismic activity including areas with low energy earthquakes (e.g. Vesuvius area, Etna area), and areas with seldom earthquakes with higher energy (e.g. Eastern Sicily, Calabria Apennines), as states by the Civil Protection Department. In order to provide a Seismic Indicator (SI), which describes the seismic action on buildings, throughout the Italian territory, the horizontal seismic action on buildings is calculated by the research team from the CNR – IVALSA. To define it, the elastic horizontal ground acceleration response spectrum ($S_e(T)$, [-]) is calculated for 110 capital cities of Italian Provinces according to NTC 2008 and Eurocode 8, assuming the type D of ground classification. **Figure 1b** represents an example of elastic response spectra: x-axis shows the structural period of the building. It is also possible affirm that the fundamental period of timber buildings presented in this study is typically between 0,1 [s] and 0,5 [s]. The calculation of $S_e(T)$ is carried out using Simqke software [12] developed by the University of Brescia. The SI is ranked in five classes according to the SI previously defined, as shown in **Figure 1c** and **Table 2**.

Table 1. Classification of Climate Indicator in Italian territory for different horizontal surfaces

Class	Cooling Degree Days (CDD), α = 0.3	Cooling Degree Days (CDD), α = 0.6	Cooling Degree Days (CDD), α = 0.9
A (light green colour)	< 225 (K d)	< 560 (K d)	< 950 (K d)
B (yellow colour)	225÷290 (K d)	560÷670 (K d)	950÷1100 (K d)
C (orange colour)	290÷360 (K d)	670÷750 (K d)	1100÷1180 (K d)
D (red colour)	> 360 (K d)	> 750 (K d)	> 1180 K d

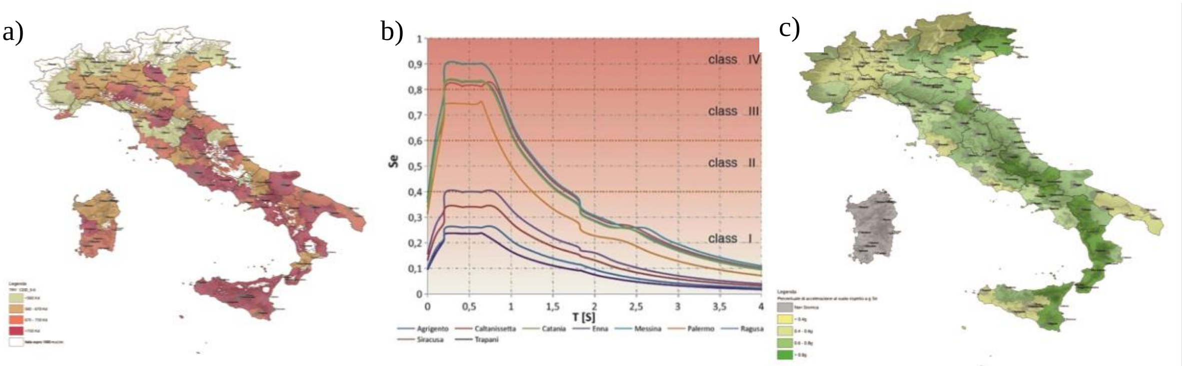

Figure 1 a) Map of CI (α = 0.6); b) Examples of elastic horizontal ground acceleration response spectrum of cities in Sicily; c) Map of SI

Table 2. Classification of Seismic Indicator in Italian territory

Class	Horizontal seismic action ($S_e(T)$)
Non seismic zone (grey colour)	-
I (yellow colour)	< 0.4 (g)
II (light green colour)	0.4÷0.6 (g)
III (green colour)	0.6÷0.8 (g)
IV (dark green colour)	> 0.8 (g)

In order to characterize the territory according to the environmental indicators (EI and SI), which influence the thermal and structural behaviour of buildings, the Synthesis Map using QUANTUM GIS software is created, as shown in **Figure 2**. The Synthesis Map is the result of the overlapping CI and SI maps, identifying nineteen combinations. Each of these maps is referred to the horizontal surface with all three absorption coefficient. Considering the typical use of tiles on roofs, the map with the absorption coefficient value α = 0.6 is the reference for any further evaluation. The Synthesis Map highlights the critical areas, in which contemporary risks of overheating and earthquake occur. This analysis is fundamental for further development of the research, especially for the definition of the improved building components.

Second phase: Energy and structural performance of standard building components

Based on the most common technological solution of timber construction (Benedetti et al., 2010), the research team of Fraunhofer Italia Research individuates samples of standard buildings components (walls, roof, external slab and floors) in two timber technologies – Platform Frame (PF) and Cross-Laminated-Timber Panels (CLT). The dimensions of beams and studs, distance between elements and thickness of panels are calculated by a structural pre-analysis made by CNR-IVALSA according to NTC2008 taking into account the most severe load configuration. The following building components are combined with different types of insulation materials: 1) walls with natural, mineral and synthetic insulation; 2) double-pitch roof with natural, mineral and synthetic insulation; 3) flat roof with synthetic insulation; 4) external slab with synthetic insulation; 5) indoor floors with acoustic insulation. Material characteristics of each layer refer to the database within WUFI software developed by Fraunhofer IBP and UNI 10351:1994. In order to evaluate building thermal performance in the summer period, twenty standard building components have been designed. The evaluated quantities are: 1) thermal transmittance (U-factor, [W m^{-2} K^{-1}]); 2), periodic thermal transmittance (Y_{ie}, [W m^{-2} K^{-1}]); 3) time shift (ϕ, [h]); 4) decrement factor (f, [-]); 5) internal areal heat capacity (k_1, [kJ m^{-2} K^{-1}]); 6) long term thermal capacitance ($d*\rho*c$, [kJ m^{-2} K^{-1}]). Building physics quantities of all components are verified for five climatic zones of the Heating Degree Days (HDD), established by D.P.R. n. 412 26 /08/93 – B, C, D, E, F (zone A in not consider, because no capital city is located there), according to Italian Regulation D.P.R. 59/2009 and UNI EN ISO 13786:2008. The total evaluation of standard building components is equal to 100 combinations.

a) b) c)

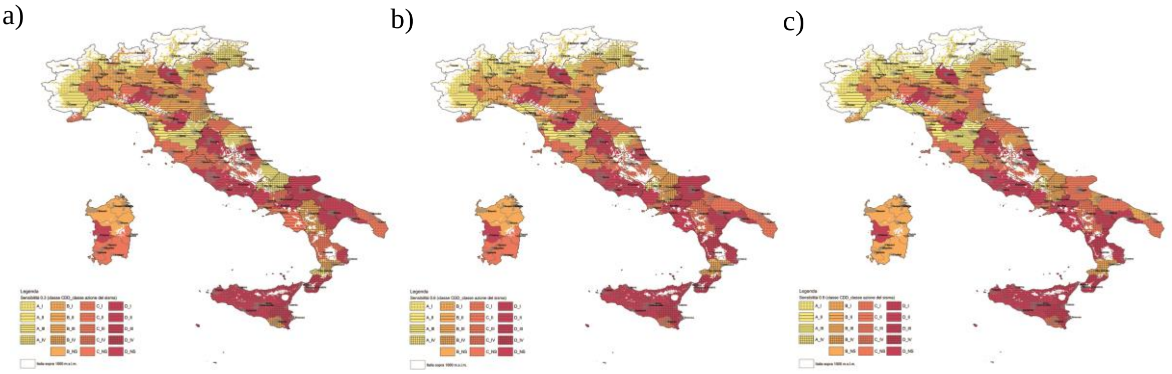

Figure 2 Synthesis Map for surface with: a) α = 0.3; b) α = 0.6; c) α = 0.9.

Based on parameters Y_{ie} and ϕ as assessment criteria, Fraunhofer Italia Research identifies the building components with best and worst summer performance. In all cases the best thermal parameters are registered in walls and double-pitched roofs with natural insulation and in flat roofs with synthetic insulation. The worst thermal performance occurs in building components with synthetic insulation and in case of PF walls with mineral insulation. Synthetic insulation in PF are excluded from the analysis since it is rarely applied. Due to the huge number of calculations, thermal parameters of the best components with lower structural thickness (PF – 8x12 cm; CLT – 10 cm) in climatic zone B are reported only, as shown in **Table 3**.

Table 3. Thermal parameters of standard building components in the Italian climatic zone B (HDD)

Building component	Total thickness [mm]	Insulation thickness [mm]	U-facotr [W m^{-2} K^{-1}]	Y_{12} [W m^{-2} K^{-1}]	ϕ [h]	f [-]	k_1 [kJ m^{-2} K^{-1}]	d*ρ*c [kJ m^{-2} K^{-1}]
WPF_01a	215	150	0.26	0.11	-9.09	0.43	35.68	101.37

FX_02	305	-	0.46	-	-	-	41.28	332.30

These standard building components are combined to a reference model (Pernigotto et al., 2014) with a surface floor of 100 m^2 and 3 m of internal height located in four cities – Messina, Taranto, Firenze, Verona, in order to run dynamic simulations using TRNSYS software. These cities are chosen for two reasons: 1) they belong to D class of equivalent CDD (α = 0.6), being thence under severe summer conditions; 2) they concurrently fall under B, C, D climate zones respectively, which refer to HDD and Italian regulation, and thence consider different winter stress. **Table 4** summarizes the input data used for the dynamic simulations. For each four capital cities Free University of Bolzano-Bozen carries out 34 dynamic simulations (total 256) considering all combinations of input data. The following output data for the period from May to September are given: 1) cooling energy demand (Q, [kWh m^{-2}]); 2) number of days in which the operative temperature (t_o, [°C]) is above 26 °C; 3) number of days in which the operative temperature (t_o, [°C]) is above 28 °C. **Table 5** shows some extract of output data for Messina (HDD zone B) considering the following input data: 1) window surface 25.74 m^2; 2) Solar Heat Gain Coefficient, SHGC = 0.6; 3) Surface Area to Volume ratio, S/V = 0.73 and S/V = 0.4. Simulation results for Messina show that building components with both timber technologies assure already a quite good thermal performance in terms of indoor comfort. The indoor temperature does not reach 28 °C, being almost above 26°C. However, PF building components may have huge improvements, especially in southern areas, where actually the standard technology requires 15 cm of insulation. Traditional massive structure (vertically perforated bricks) requires an insulation thickness of about 4 cm to comply with Italian regulation for the winter season. Therefore, the thermal mass integration in PF structures might decrease notably the insulation thickness. Since CLT components have a massive structure, huge optimization are not required: the thermal mass activation on interior side of wall might be evaluated as an improvement.

Table 4. Simulation input data

Category	Values
Climate input:	
Climate data	TRY (source: *CTI – 05/2013*)
Location	Messina, Taranto, Firenze, Verona
Virtual residential building input:	
S/V ratio	S/V 1: 0.73 (one adiabatic surface – floor) and S/V 2: 0.40 (two adiabatic surfaces – floor and roof)
Dimension of reference case	Volume: 10x10x3 (m)
Building components	- the best and worst configurations of standard components in CLT - the best and worst configurations of standard components in PF
Window position	East, West, South and All without solar shading system
Window surface	Size 1:12.90 m^2 and Size 2: 25.74 m^2
Window characteristics	U_g = 1.2 W/m^2 K; SHGC = 0.6 and U_g = 1.2 W/m^2 K; SHGC = 0.4
Interior gains (W/m^2)	4 W/m² according to UNI/TS 11300
Natural ventilation rate	0.3 vol/h
Interior partition	PF: d = 19 cm; CLT: d = 23 cm (not insulated)
Cooling period	May 1st – September 30th
HVAC system	Ideal system

Table 5. Comparison of best and worst output of thermodynamic simulation for Messina

	Platform Frame				CLT

% of hours > 28 °C	0%	0%	0%	0%	0%	0%	0%	0%

Third phase: Improvement of building components

On the basis of literature review outputs, some technological solutions for Italian climate have been adopted, particularly the one proposed by Al-Sanea and Zedan (2001), which splits thermal mass in two layers. The limit to the mass integration is that it is possible to increase the wall weight up to 1kN per 1m^2 of wall, namely correspond to 20% of the total weight of the considered building model. Such structural constraint comes out of a case study made by CNR-IVALSA. It is a three storey residential building made of two units of the building model described in **Table 4**; 10 [m] x 20 [m] dimension in plan; structural walls and seismic weight are referred to the same building components evaluated with dynamic simulations of the second phase. A linear static analysis is performed according to NTC 2008 and to EC8 in order to define the seismic load and the total base shear force in particular. It is demonstrated the possibility of designing structural walls with increased weight by using standard connectors as hold downs and angular brackets. Taking into account such consideration, Fraunhofer Italia Research designs the improved building components with applied additional thermal mass, as shown in **Figure 3**. The materials considered for the improvement of building components are as follow: 1) double panel of gypsum fibreboard (d = 2x1,5 [cm], ρ = 1800 [kg m^{-3}], λ = 0.32 [W m^{-1} K^{-1}], c = 1200 [J kg^{-1} K^{-1}]); 2) brick (d = 5 [cm], ρ = 1800 [kg m^{-3}], λ = 0.8 [W m^{-1} K^{-1}], c = 850 [J kg^{-1} K^{-1}]); 3) clay panels (d = 2.5-3.5 [cm], ρ = 1600 [kg m^{-3}], λ = 0.73 [W m^{-1} K^{-1}], c = 1000 [J kg^{-1} K^{-1}]). The evaluated solutions for walls are: 1) three types of integration for PF external walls; and 2) four types of integration for CLT external walls. CLT double pitched roof has not been considered as a standard solution because the quantity of timber does not reflect any structural needs. Since it has a better summer thermal performance, CLT double pitched roof is chosen as an improved solution for PF double pitched roof. Due to its better structural behaviour, the indoor floor in CLT technology is preferred to the PF solution. The external concrete slab remains unchanged. The insulation used in all improved walls and roof is a natural one and synthetic one for external concrete slab.

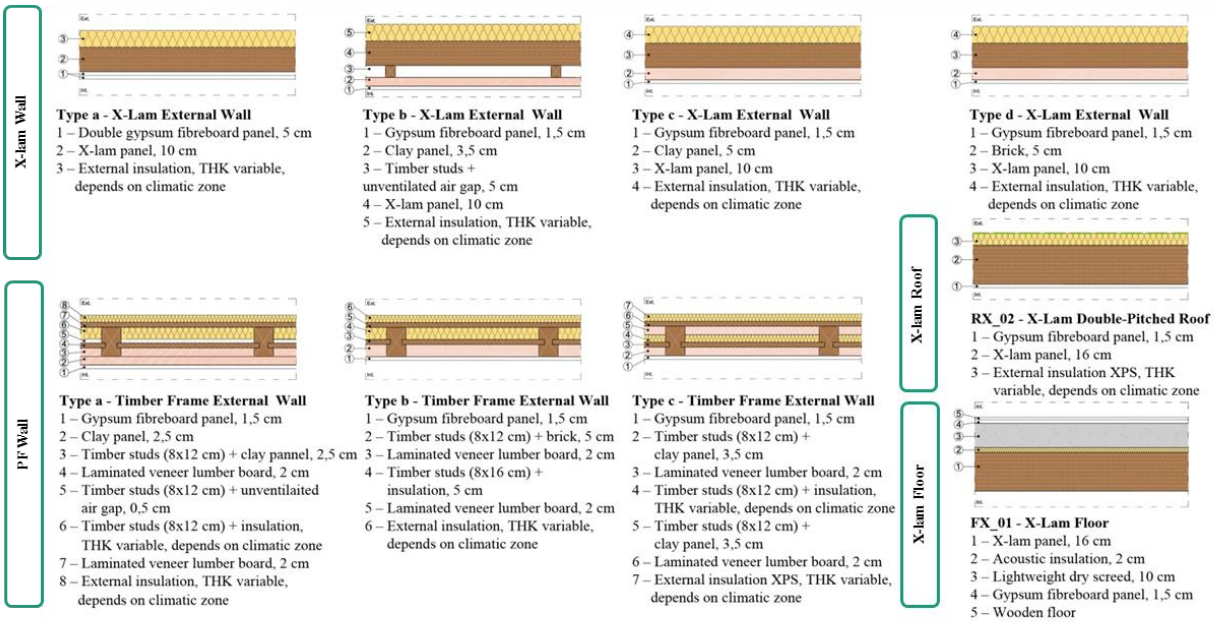

Figure 3 Description of the sample improved building components

In order to find the best solution amongst the proposed improved walls for 110 capital cities, Fraunhofer Italia Research develops a multi-criteria analysis. The three alternatives of integration for PF external walls and the four ones for CLT external walls are compared by four indicators: 1) the average of the percentage difference between Y_{ie} of the improved wall and Y_{ie} of the standard wall with best performance, referred to Y_{ie} of the standard wall with best performance; 2) the percentage difference between U-factor of the improved wall and U-factor of the standard wall with best performance, referred to U-factor of the standard wall with best performance; 3) the percentage difference between total thickness of the improved wall and total thickness of the standard wall with best performance, referred to total thickness of the standard wall with best performance; 4) the percentage difference between insulation thickness of the improved wall and insulation thickness of the standard wall with best performance, referred to insulation thickness of the standard wall with best performance. These four percentage values are weighted by 1-to-3 scale which varies as the combination of climatic zone based on HDD and of class based on equivalent CDD. The multi-criteria analysis supports the selection of the following improved solutions for PF walls:1) type c in areas D, C x B, C, D, E (CDD x HDD) and areas B x C; 2) type b in areas B, A x D, E; and for CLT walls: 1) type d in areas D, C x B, C, D, E and areas B x C; 2) type b in areas B, A x D, E. **Table 6** shows the extract of the multi-criteria analysis referred to class D (CDD) and climatic zone B (HDD) and the selected improved solutions for PF and CLT. GIS-maps of Italy in **Figure 4** represent the percentage improvement or worsening of the indicators which were used for the comparison and selection of the improved building components – insulation thickness, Y_{12}, ϕ, U and total thickness – referred to the chosen improved building components. Thermal parameter values for the chosen improved building components in PF technology referred to class D (CDD) and climatic zone B (HDD) are provided in **Table 7,** while the percentage range of the improvement/worsening of thermal parameters for both technologies are summarized in **Table 8**. There is a huge improvement in terms of decrement of insulation thickness in particular for the PF technology beside an improvement of the thermal parameters which impacts the summer performance.

Table 6. Multi-criteria analysis for CDD class = D and HDD zone = B and selected alternatives

Class D (CDD, α = 0.6)									
Indicators	**PF alternatives**				**CLT alternatives**				
	Weight	**Type a**	**Type b**	**Type c**	**Weight**	**Type a**	**Type b**	**Type c**	**Type d**
Average Y_{ie} and $\Delta\phi$	3	-0.04 (3)	-0.07 (2)	-0.08 (1)	3	-0.33 (4)	-0.69 (1)	-0.54 (2)	-0.49 (3)

N.B. Positive value represents improvement and negative value worsening.
* S refers to the Southern Italy; N refers to the Northern Italy; ** increment of insulation only in climatic zone E (HDD)

DISCUSSION AND CONCLUSION

TIMBEEST project has been described as well as its intermediate results. Typical timber building components of the two main technologies (PF and CLT) have been designed and building model performance made out of their combination has been evaluated. Timber buildings have an acceptable performance even in southern Italy but their environmental footprint is high due to the thickness of the required insulation. On the basis of a climate and structural evaluation of the Italian territory, some timber building improved components have been designed. PF walls allow mass to be combined in more solutions than CLT ones as well as mixed technologies better face the seismic challenge. Further steps of the project will simulate and evaluate the percentage of gained improvement in structural and energy fields. It is expected to define the geographical extent of such technology, to determine the environmental footprint of the improved components and to highlight the most promising technological change towards the improvement of timber building performance during the cooling season.

Beyond the limits of the project, it will be interesting to deepen the evaluation of climate indicators as equivalent CDD and to define synthetic indicators combining structure and energy. There are many mixed timber technologies even coming from the past which should be evaluated as PF and CLT as well as the optimization of the mass quantity and position, considering other passive cooling strategies.

The Triple Bottom Line Benefits of Climate-Responsive Dynamic Façades

2. Center for Environmental Planning and Technology, Ahmedabad, India

ABSTRACT

To achieve net zero energy, façade designs must move from static dark glass monoliths to dynamic, climate responsive layers for balancing daylighting and shading, natural ventilation and mixed mode conditioning. While 5-15 year energy paybacks are sufficient to prompt some level of increased investment in facades, dynamic facades require the addition of triple bottom line (TBL) calculations that capture the economic, environmental and human benefits of high performance buildings. This paper introduces an approach to TBL justifications of climate-specific high performance building façade solutions, to provide professionals and manufacturers compelling arguments for inspiring building investment that will improve the quality of the indoor environment. Given that lighting and space conditioning are 80% of office energy loads in India, arguments for investing in façades that optimize daylighting and shading, natural ventilation and mixed mode conditioning are critically needed. This paper illustrates the triple bottom line of five climate-responsive façade and related system improvements – high visible transmission/ low solar glass, internal light shelves/inverted blinds, daylight dimming, external overhangs/shades, and operable windows - that demonstrate TBL paybacks of less than two years for new and retrofit construction. This ongoing project is funded by the US Department of Energy and LBNL, and undertaken in collaboration with CEPT, India through the Center for Building Energy Research and Development (CBERD).

INTRODUCTION

The development of TBL life cycle data sets for building decision-makers is critical to overcome first-least-cost decision making patterns that prevent owners and tenants from investing in high performance, energy efficient building solutions. While the completion of five to fifteen year energy payback calculations (first bottom line) can prompt increased investments, the addition of environmental and human benefits (second and third bottom line) provides the 'tipping point' for the level of design, engineering and investment needed for high performance facades that save energy and improve the quality of the indoor environment for workers.

The challenge for TBL calculations is the quantification of environmental and human gains, including health, productivity, and organizational performance. This paper develops TBL justifications for five climate-specific building façade solutions that improve the quality of the indoor environment while optimizing energy effectiveness. For each technology, the first bottom line relates to the known Indian costs and literature identified benefits of energy and facility management savings resulting from the investment. The second bottom line relates to the Indian environmental benefits that are directly linked to electric energy savings: reductions in CO2, SOx, NOx, particulates, and water. The third bottom line is based on available international studies that have identified the human benefits directly

Vivian Loftness, University Professor, Rohini Srivastava, PhD candidate, Devanshi Dadia & Hetal Parekh MS students in the School of Architecture at Carnegie Mellon University. Rajan Rawal is a Professor and Agam Shah a researcher at CEPT, Ahmedabad, India.

linked to improved indoor environment quality in terms of human health and productivity.

Carnegie Mellon's studies of daylighting/ lighting retrofits in the U.S., completed for the DOE EEBHub, revealed that with energy savings ranging from 13-85%, simple paybacks will be from 2-8 years - if only energy savings are included in the life cycle calculation. However, when the environmental benefits of electricity savings are included, paybacks are much faster, from 1.5-5 years. Most strikingly, when human benefits identified in international research are included - from reduced headaches and absenteeism to improved task performance or productivity - paybacks for investments in daylighting and lighting retrofits in US offices are less than 2 years (Loftness, Srivastava et al, 2013). Building on these earlier studies, through support from the US Department of Energy and Lawrence Berkeley National Lab, this on-going research advances the TBL evaluation of high performance façade investments for office buildings in each of the five Indian climates identified in the National Building Code.

WHY INVEST IN FACADES?

India is the world's fourth largest energy consumer (EIA, 2013) and fifth largest source of greenhouse gas emissions (GOI, 2010). With the building sector contributing 35% of the total electricity consumption (Rawal et al, 2012), and a projected five-fold growth in the constructed area anticipated by 2030 - from a 21 billion square feet in 2005 to 104 billion square feet, building energy efficiency plays a major role in managing energy use in India (Seth, 2010, Figure 1a).

India's national Energy Conservation Building Code (ECBC, 2008) was revised in 2008, but remains voluntary and has not been adopted by most of the Indian states. To encourage adoption of ECBC, a three-tier approach has been proposed which advocates implementation of the ECBC codes in phases, and allows time for training and capacity building (Rawal et al., 2012). Tiers are categorized based on: ease of implementation within current practice, the energy savings potential, and the ROI offered. Tier one focuses on envelope-related measures, tier two on HVAC, while the third tier regulates lighting measures.

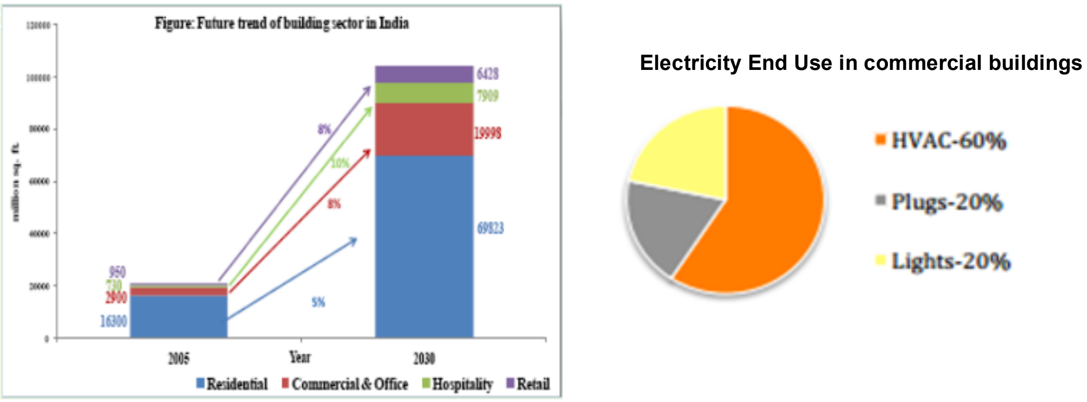

Figure 1 (a)Forecasted five-fold growth for building sector in India; (b) Lighting and Air Conditioning loads account for 80% of the commercial building energy use (Singh et al,2013)

Given the rapid growth in the Indian construction sector, the national government's efforts to improve energy-efficiency in buildings are based on significant reductions in air-conditioning, ventilation, lighting and plug loads. Building façade design and engineering is critical to: air conditioning loads through solar heat control; to natural ventilation and night cooling; to effective daylighting; and even free passive solar heating in cooler climates. High performance, climate responsive facades can significantly reduce both annual and peak electricity demand, and ensure "resiliency" in the face of power outages. Equally critical, high performance facades are critical to occupant health and productivity. This paper explores TBL arguments for five high performance facade measures that can provide up to 25% total energy savings in typical Indian office buildings, reducing the environmental costs of electricity and improving indoor environmental quality for human health and productivity.

Design priorities for new and existing façades

The research team employed a range of techniques to identify climate responsive façade guidelines for Indian climates. A climate analysis using a combination of Koppen climate classifications (Rubel and Kottek, 2010), the National Building Codes (BIS, 2005), Climate Consultant (Milne et al., 2007) and simulation tools (Comfen; NIST Climate Suitability tool; PPG, 2014) supported the identification of representative cities for each of the five Indian climate zones (Table 1) and climatically similar U.S. cities. The companion cities were included to support the development of high performance façade guidelines and provide strong illustrations, quantifications, and product choices. The city of Mumbai was matched with the city of Singapore since there was no climate-comparable city in the US.

The research team then reviewed business-as-usual and advanced Indian office building practices in the five climates, classifying critical characteristics of existing and advanced building facades. Then, the review of existing research, codes and standards, field and simulation studies, was combined with the use of simulation tools to help refine a set of climate specific façade strategies. An illustration of façade design recommendations is shown in Table 1, drawn from a longer list, with 0-3 dots indicating the relative importance of each recommendation for the given climate.

Table 1: Five climatic zones and variations in strategies by climate

Façade Recommendations	 HOT & DRY Ahmedabad (Phoenix)	 WARM&HUMID Mumbai (Singapore)	 TEMPERATE Bangalore (Miami)	 COMPOSITE New Delhi (Dallas)	 COLD Shillong (San Francisco)
Daylighting					
High VLT glass	• • •	• • •	• • •	• • •	• • •
Light shelf/ Inverted blind	• • •	• • •	• • •	• • •	
Daylight dimming	• • •	• • •	• • •	• • •	• • •
Shading					
Shallow Building Plan	• • •	• • •	• • •	• • •	• • •
Avoid E/W Glazing	• • •	• • •	• •	• • •	• •
Low SHGC	• • •	• • •	• •	• • •	
Shading Devices	• • •	• • •	• •	• • •	
Natural Ventilation					
Windows for natural vent.	• •	• • •	• • •	• •	
+ mass for night cooling	• • •	•	• • •	• •	• • •

From the set of shortlisted guidelines in the above table, five strategies were selected to demonstrate the TBL cost benefit analyses that could be applied across all five climates - with climate specific variations:

1. Invest in high visible transmission glass with climate appropriate shading coefficients
2. Invest in light shelves or light redirection louvers in clerestory glass areas
3. Invest in high performance ballasts with daylight sensors in perimeter office lighting
4. Invest in external overhangs or canvas awnings for summer shading
5. Invest in operable windows for natural ventilation and night cooling

Each of the selected recommendations are outlined in the following sections, alongside preliminary information on product or assembly costs, as well as literature studies on occupant health and productivity benefits, in order to complete Triple Bottom Line calculations for each action.

THE TRIPLE BOTTOM LINE FOR FIVE FAÇADE INVESTMENTS

The TBL calculation approach was refined using the United Nations ICLEI Triple Bottom Line Standards, in which benefits are categorized in one of the three categories – (1) Economic/Profit (2) Environmental/Planet (3) Equity/People. The TBL life cycle benefits for each category are illustrated using successive "return on investment" ratios and NPV calculations. For each façade retrofit, the first cost was evaluated against a 15-year life cycle savings calculation. For the range of selected façade technologies, Indian costs were collected from literature and communications with manufacturers and professionals, acknowledging that there are significant variations in the product and labor market across regions. Where the Indian costs for the technologies were not available, the US market prices were used for this paper. The project team collected average technology and labor costs for each recommendation assuming a medium size office of 50,000 square feet on six floors. The energy savings calculations are based on a national baseline of 200 kWh/sqm-yr (approx. 19 kWh/sqft-yr). Load breakdowns are assumed to be: 60% of the total load for HVAC energy use or 120 kWh/sqm-yr; 20% of the total load for lighting energy use or 40 kWh/sqm-yr; with the remaining 20% of energy used for plug loads (Singh et al., 2013). The long-term objective is to build an on-line calculator for building decision-makers to enable the substitution of their own assumptions and numbers.

The first bottom line calculation includes the economic cost benefits of energy and potentially facility management savings resulting from each of the façade actions. The cost of energy was set at \$0.18/kwh, the average all inclusive commercial fixed rate in India (RIL, 2012), which may vary by region (Wilson, 2013). The second bottom line calculations capture the environmental cost benefits that are directly linked to electric energy savings: reduction in CO2, SOx, NOx, particulates (PM) and water demands. These four pollutants are regulated and even taxed in leading countries to reduce global warming, respiratory illnesses, cancers and developmental impairment. Given India's high reliance on coal fired electric power, the societal costs of environmental abatement could range from \$ 0.014 – 0.021/kwh (Table 2), estimated based on EPA (2010), Goodkind and Polasky (2013), Levy (1999) and Ghodke et al. (2012).

Table 2. India's estimated environmental cost impacts of power generation

	CO2	SOx	NOx
India range of emission from coal plant (g/kWh)	783 -1496	5.210 - 9.899	1.612 - 3.490
India Average Emission Coefficients (lb/kWh)	2.18258	0.01907	0.00529
Est. Environmental Cost Premium (/kWh)	**\$0.021**	**\$0.014**	**\$0.016**

The third bottom line captures the human benefits that are linked to improved thermal, lighting and air quality as a result of the building improvement, drawn from the ongoing work of Carnegie Mellon's CBPD to link the quality of the built environment to health and productivity outcomes captured in BIDS: the Building Investment Decision Support Tool (BIDS, 2008). In the absence of Indian field studies that link high performance building systems to health or productivity cost-benefits, the research team relies for now on international laboratory and field case studies to support TBL life cycle decision making.

1. Invest in high visible transmission glass with climate appropriate shading coefficients

20 percent of commercial building energy use in India is for lighting buildings, and much of this is during the daytime when daylight is abundant. Electric lighting also contributes to the air-conditioning demand in Indian office buildings, at a significantly higher cost than solar-controlled daylighting.

Four of the five Indian climates in the codes have cooling dominated seasons, where protection from the sun often becomes a priority. To block solar radiation, use of very dark and reflective glazing is a common practice in Indian buildings. In pursuit of low solar heat gain (low SHGC), designers often mistakenly specify low visible light transmission (VLT). While this type of glazing is effective for shading, it seriously compromises daylight penetration and seated views to the outdoors (Figure 2a). It is imperative for future office facades and façade retrofits to replace yesterday's dark glass (low SHGC and low VLT, see Figure 2a) with today's high performance glass that maintains low solar transmission while maximizing visible light transmission (low SHGC and high VLT, see Figure 2b) in order to lower both lighting and cooling energy while providing views to the outside. Low .30 SHGC with high .65 VLT glass coatings are readily available in India, with incremental costs less than \$1/sqft and paybacks of as low as 39 months (PPG, Saint-Gobain, 2014). For the single heating climate in India represented by Shillong (and companion city San Francisco), the low-solar high-visible glass specification should be replaced by a high-solar high-visible glass specification on southern facades to take advantage of the comfort and free heat provided by direct solar gain.

Figure 2: (a) Use of dark glass in I ICICI Bank in Mumbai specified to reduce solar heat gain vs. (b) Shading while ensuring daylight and seated views to the outdoors (Miami vitHouse, 2010)

The CMU team used existing research to calculate the first, second and third bottom lines of high performance glass. In a 1999 multiple building study of 8 office buildings in the UK, the Probe team identifies an average 64% lighting energy savings in buildings with effective daylighting due to clear glass and perimeter access, as compared to buildings with deep floor plans and/or tinted glass (Probe team, 1999). Increasing the effectiveness of daylighting and providing access to views also improves employee productivity and health, also included in the third bottom line. In a 2003 building case study of the Sacramento Municipal Utility District (SMUD) Call Center, Heschong et al. identified an average 6.7% faster Average Handling Time (AHT) for employees with seated access to larger windows and a view with vegetation content from their cubicles, as compared to employees with no view of the outdoors. Other studies reveal the importance of sunshine for health in winter with appropriate orientation and shading for glare control and summer comfort (Benedetti et al., 2001 and Choi, 2005).

2. Invest in light shelves or light redirection louvers in clerestory glass areas

To ensure daylight effectiveness beyond the first few feet of work area, the second retrofit recommendation is to introduce light shelves or inverted blinds/louvers in the clerestory glass area. Light shelves serve critical purposes that include the distribution of daylight deep into the building, glare control and shading. When well designed, they can ensure high levels of daylighting without glare and overheating, and even reduce heat loss on winter nights (CBPD, 2014 a). A study of the existing building stock revealed that a number of Indian offices already have clerestory glass above the view windows (Figure 3a), and the addition of a light shelf or inverted louvers or blinds will greatly enhance daylight effectiveness.

The ideal light shelves would be highly reflective and diffusing. If louvers or venetian blinds are used they should be inverted (curve upwards) to reflect daylight onto the ceiling for diffusion (see Lightlouver™ profile Figure 3b). The inverted blinds can even have a seasonally "smart" W-profile that reflects high sun angles back outdoors, to reduce solar gain in the cooling season, and reflects low sun angles into the space to increase solar gain in the heating season (Retrosolar™). Inverted blinds and louvers in the clerestory, in combination with a highly reflective ceiling, create a daylighting system that can be used on the east, west and the south façade. The most affordable solution for the Indian market is approximately \$20 per sqft of building façade, based on manufacturer estimates, given 20% of the baseline building surface area as clerestory to be equipped with light shelves (Skyshade™, 2014).

Figure 3: (a) Typical Indian office with no daylight redirection device (b)LightLouver units in clerestory to reflect sunlight into the ceiling

Given that 25-100% of workstations may be within 15 feet of a window wall in many Indian office buildings, daylighting without glare can save up to 35% of a medium size office building's total lighting energy (Figueiro et al., 2002; Schrum & Parker, 1996). The electricity savings is calculated in the first bottom line and the environmental benefits of reduced power generation is calculated in the second bottom line.

The human benefits of investing in light redirection/diffusion are related to the spectral quality of daylight, the management of brightness contrast by bouncing light, the improvement of views, as well as the importance of sunshine in winter and shading for comfort in summer. For example, in a 1992 laboratory experiment conducted using 26 subjects, Osterhaus and Bailey found a 3% improvement in visual tasks related to reduced glare (Osterhaus & Bailey, 1992).

3. Invest in high performance ballasts with daylight sensors for perimeter office lighting

The third cost-effective retrofit is the use of high performance ballasts and daylight sensors to support on/off or dimming control of the first and second rows of lights on each building façade (Figure 4a). This investment in new controls for groups of lights ensures up to 30% energy savings through 'daylight harvesting'(Lee & Selkowitz,2006). In a 1984 simulation study supported by meta-analysis, Verderber and Rubinstein identify 64% lighting energy savings in a 30% daylit building given daylight dimming controls, automatic scheduling, tuning, and lamp lumen depreciation, compared to a conventional lighting system with no controls. To ensure that the sensors are not disabled or covered by occupants, critical attributes for the selection of daylight sensors include: programmable thresholds for acceptable daylight minimums, relocatable sensors to address variations in office layout, and assurance of gradual light level changes through dimming or time limited switching. Daylight sensors and switches can be installed without full automation systems, and can be introduced with wireless interfaces to existing fixtures, making them cost effective retrofits.

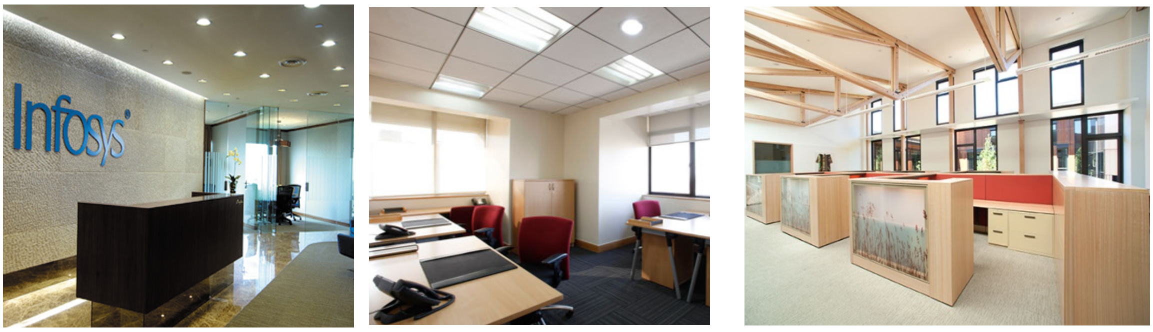

Figure 4: a, b) Electric lighting 'on' most of the time in Infosys and Raheja Tower offices in Bangalore; c) Balanced daylight and daylight harvesting controls in the Packard Foundation offices in California.

Encelium, Lutron, and several other lighting control companies have developed wireless controls that can be added to existing ballasts in combination with well-placed daylight sensors. A web based controller is available for calendar-driven or daylight-sensor-driven switching of each row. Daylight harvesting is a quick and low cost retrofit for the majority of buildings, with costs from \$0.45- 0.90/sqft.

In many medium sized office buildings, up to 100% of spaces could be (and have been historically) daylit, saving up to 70% of total lighting energy. In deeper section buildings, daylight harvesting can save 10-35% of the lighting energy. The human benefits of daylight contributions in the workspace are also measurable. In a 1995 building case study of Lockheed Building 157 in Sunnyvale, California, Thayer et al identified 50% savings in lighting, cooling and ventilation energy and 15% reduced absenteeism due to the daylighting design which integrates layout, orientation, type of glazing, and light shelves in combination with reflective ceilings. The full spectrum light inherent in daylight also has an influence on human health, with research revealing that the natural changes in day light is critical for melatonin production that regulates our sleep cycle (Figueiro, 2010). An earlier field study conducted by Figueiro et al. (2002) identifies a 15% increase in time dedicated to visual tasks in daylit workspaces. With visual tasks constituting 25-30% of time spent at work, there is a potential performance improvement of 3.75% linked to the benefits of daylight. Daylighting should be a priority in the workplace, particularly since higher light levels can be achieved at a lower energy cost.

4. Invest in external overhangs or canvas awnings for summer shading

In four of the five climates of India, shading the facade is a high priority to avoid overheating in summer. While modern office buildings in the past century were often sleek glass towers, today's design community is rediscovering the power of facades articulated by static fins, louvers, and screens as well as the highest performing dynamic awnings. These dynamic shading devices can be daily or seasonally adjusted to reflect sunlight when required, while allowing effective daylight penetration and solar gain during the winter (Lechner, 2009). Today, awnings are made of synthetic fabrics which are fade resistant, water repellant and require less maintenance than they have historically. Fixed overhangs, horizontal louvers and fins, and dynamic awnings are each effective additions to modern facades. They provide shade with daylight, without diminishing our views, and should replace yesterday's dark glass, eggcrate shades and scrim layers.

Given that India ranges from 6^{o} to 37^{o} north latitude, horizontal devices should be the norm for southern orientations, combined horizontal and vertical or dynamic devices for east west, and vertical devices for north facades (Figure 5b,c). Openings along the top and sides of the overhang or awning should be provided to prevent heat from being trapped at the window wall.

Figure 5: a) DLF Center, Delhi with no shading devices vs. b) vertical awnings on the north face of the Phoenix library, and c) horizontal louvers on south face of Stecalite, Noida.

The cost of installing external louvers and awnings varies dramatically based on material and assembly, with $7.50/sqft assumed in the TBL calculations. The use of adjustable awnings as a shading device can reduce solar heat gain and associated cooling loads in the summer by up to 65% on south-facing windows and 77% on west-facing windows, with a 20-25% total cooling energy savings (DOE, 2012; Nagy et al., 2000). The human benefits of light shelves include the value of glare control for productivity and health, as well as shading for improved thermal comfort in summer by reducing direct and radiant solar heat. In a 1998 controlled experiment, Witterseh identifies a 54% increase in mathematics accuracy and a 3.5% typing improvement when subjects feel thermally comfortable, rather than too warm, in quiet office conditions (Witterseh, 2001).

5. Invest in operable windows for natural ventilation and night cooling

The last recommendation for which triple bottom line analysis was completed was to introduce operable windows for natural ventilation and night cooling. The business-as-usual building illustrated in figure 6a, reveals the rising trend of sealing office facades (Figure 6a). This is a serious disadvantage during brown outs or black outs, as the building runs out of air and starts to overheat. Moreover, sealing building facades eliminates the opportunity to use natural ventilation for cooling and breathing, or night ventilation to pre-cool the building to offer hours of free cooling the next day.

To avoid the possibility of rain coming in, and to ensure controlled air flow, the use of awning, drop-kick, and pop-out windows are emerging in modern offices (Figure 6b and 6c). For hot and dry climates like Ahmedabad, natural ventilation can be pursued on moderate days if air quality and noise are not a local issue. More critically, night ventilation cooling can be pursued on nights that are predicted to be cooler than 70°F and combined with thermal mass or phase change materials to store 'coolth' for conditioning on the following day.

Figure 6: a) Infosys, Bangalore with no operable windows, b) 3i Innfotech EPIP Whitefiled with a modest percent of operable windows, but dark glass c) Deutsche Bank, Frankfurt with high Tvis pop-out windows.

The cost of natural ventilation is related to the additional costs of window hardware and the manual or automated system for control, while night cooling requires the addition or exposure of thermal mass in the airstream. Mechanical engineers should be carefully selected for their commitment to "mixed mode" conditioning (CBE, 2014), and integrated early into the design process. Consideration of natural ventilation should address the site-specific limits of climate, outdoor air quality, noise, security, and local building codes.

On the benefit side of the equation, the annual energy savings of natural ventilation in the climate of Ahmedabad includes up to 15% of ventilation loads (Milne et al., 2007) and up to 35% pre-cooling load (Emmerich, *Climate Suitability Tool*). International studies reveal that the human benefits of natural ventilation can be measured in both employee health and productivity. In a 2003 meta-analysis study, Seppänen et al identifies a productivity increase of 4.9% for an eight-hour workday due to night-time ventilative cooling, an energy-efficient method of reducing daytime indoor temperatures by using night-time air to cool a building's structure and furnishings. In a 1988 multiple building study in Berlin and Heidelberg, Kroeling identifies a 33% reduction in reported headaches, a 28% reduction in reported frequency of colds, and a 31% reduction in reported circulation problems for employees in naturally ventilated office buildings as compared to air conditioned office buildings.

TRIPLE BOTTOM LINE RAPIDLY ACCELERATES PAYBACK FOR DYNAMIC FAÇADES

Given these international studies on the human benefits of high performance façade solutions, the research team completed TBL calculation for five façade investments in the hot and dry Indian climate, to demonstrate the applicability of the framework in the building decision-making process (Table 3). For each facade investment, a 15-year life-cycle calculation is completed with the Indian first costs, energy savings and environmental benefits, and combined with international findings on health and productivity benefits, to generate the triple bottom line results shown in Table 3.

Table 3: TBL calculation for five façade investments

		High VLT Glass	Light Louvers	Dimming Ballasts	Awnings for shade	Operable Windows
Economic Considerations	**First cost per employee**	$45	$114	$70	$330*	$120
	Annual Energy savings:					
	Energy Savings (%)	35%	35%	30%	20%	35%
	Energy savings per employee	$24	$23	$20	$40	$70
	ROI (Economic)	**52%**	**20%**	**28%**	**12%**	**58%**
	Payback in years	**2**	**< 5**	**3.5**	**8**	**< 2**
Environmental Considerations	Given Annual Energy savings in kWh	130	130	113	224	392
	Annual Environmental Benefits:					
	Air pollution emissions (CO2, SOX, NOX = $.051/kwH)	$6.7	$6.7	$5.8	$11.4	$20.0
	Water Savings ($0.002/kwh)	$0.3	$0.3	$0.2	$0.4	$0.8
	ROI (Eco + Env)	**68%**	**26%**	**38%**	**16%**	**76%**
	Payback (Eco + Env) in years	**1.5**	**< 4**	**< 2.5**	**< 6.5**	**< 1.5**
Equity Considerations	**Annual Human Benefits**					
	Productivity increase (1- 4%)	$320	$240	$300	$100	$240
	Reduction in absenteeism (6 -14%)	$24	$24	$24	$24	$10
	ROI (Eco + Env+ Equity)	**825%**	**258%**	**500%**	**52%**	**284%**
	Payback (Eco + Env + Equity) in years	**< 0.5**	**< 1**	**< 0.5**	**2**	**<1**

*Awnings have a lifetime of 5 years; first cost includes prices for three changes

The development of Triple Bottom Line life cycle data sets for building decision-makers is critical to overcoming first-least-cost decision making patterns that prevent owners and tenants from investing in high performance, energy efficient building solutions. For example, the investments in high visible transmission glass with climate appropriate shading coefficients shift from 2 year paybacks based on energy savings alone, to 1.5 years including environmental benefits, to less than 6 months given the human benefits. Investments in the most affordable light redirection louvers in clerestory glass areas, high performance ballasts and daylight sensors, canvas awnings, and controls for operable windows also demonstrate reductions in paybacks from 8 years to less than a year as energy, environmental and human benefits are cumulatively calculated. It is critical for building owners and their design-engineering teams to embrace layered and dynamic facades for daylight, shade, natural ventilation and night cooling to significantly reduce India's lighting and cooling loads in commercial offices and improve indoor environmental quality.

The *Bundle-Up!* Game: a collaborative learning tool for net-zero energy design

Mark DeKay, R. A.
University of Tennessee, Knoxville
mdekay@utk.edu

ABSTRACT

The purpose of the Bundle-Up! game is to make learning climatic design strategies and their complex interrelationships fun and easy. The project uses the concept of Bundles developed in the research project, "A New Knowledge Structure for Net-Zero Design." The idea of design strategy bundles is to resolve conflicts and tensions among strategies by proposing related sets of design strategies that address recurring problems designers face. A Bundle identifies several discreet design ideas that apply in a particular situation across three scales. The game outlines a set of rules for users to create their own bundles specific to a particular project. Bundle-Up! is used with a set of instructions like a typical board game. It is designed to use design strategies from the book Sun, Wind & Light*, 3rd edition. There is no one right solution, but some answers are better than others, and solutions that follow the rules are all acceptable. Bundle-Up! can be played by one person or several in collaboration. The game pieces (more than 100) each represent a climatic design strategy, each with a unique graphic and other identifying features and descriptions. A prototype was tested with peer teachers and feedback was very positive. The Bundle-Up! game has since been tested in fifth-year B. Arch design studios and with second-year technology course students. Feedback has helped refine the game and its instructions, along with the curricular exercises that accompany it.*

Keywords: passive design, design process, knowledge structure, education, design strategies

1 INTRODUCTION: DESIGN STRATEGY BUNDLES

In the U.S., the American Institute of Architects has adopted 'Architecture 2030' goals for all new buildings to be carbon-neutral, operating free of fossil fuels by 2030. Carbon-neutral performance can either be achieved by a wasteful building with huge green power systems and purchase renewable energy or by efficient buildings lighted and conditioned by site-based resources, paired with small on-site green power systems. In other words, passive heating, cooling and lighting strategies reduce net loads, which reduce the need for expensive utility green power, photovoltaics and wind generation. To assist designers with this second more architectural and passive energy approach to carbon-neutral performance, this project uses the concept of *design strategy bundles* developed in the research project, "A New Knowledge Structure for Net-Zero Energy Design" and further developed and published in *Sun, Wind & Light: architectural design strategies,* 3rd edition (*SWL*) [1]. Bundles are theoretically a combination and development of Pattern Language theory and holarchic structure, particularly as developed in Integral Theory. The second edition of *Sun, Wind & Light* included 109 discreet analysis techniques and design strategies across a range of scales. These strategies addressed issues of heating, cooling, lighting and power. The strategy bundle was born in part as a result of finding three challenges that surfaced in over a decade of using the second edition in teaching and consulting:

The author is a Professor in the School of Architecture, University of Tennessee, Knoxville, Tennessee.

1. *Difficulty in knowing which strategies to use* for a particular design situation, such as designing the building envelope, especially for novice passive designers
2. *Challenges identifying how the strategies were related* to each other—or not related—was sometimes implied, but often opaque, and required substantial practical experience
3. *Difficulty in knowing how major variables, like climate type, changed which strategies to employ* or to emphasize.

The purpose of design strategy bundles is to resolve conflicts and tensions among strategies by proposing related sets of strategies across three scales. A bundle proposes a set of the almost-always-required strategies that come together to form solutions to design situations encountered repeatedly in buildings. Some design situations are recurring, such as the problem of how to bring in light through a roof or how to use the building to collect and store heat from the sun in a cold climate.

When one is able to generalize about these design situations, one can also generalize about the solutions and the characteristics of these solutions that seem to be workable across a variety of conditions. If a problem is encountered thousands of times in buildings, the building community develops particular solution types from which designers can learn.

A *Bundle* is defned here as a set of related strategies working together to resolve commonly occurring design problems. A bundle may address a single energy issue or it may address two or more energy topics (heating, cooling, daylighting, ventilation or power). In general, a bundle has the following four characteristic organizing principles, as illustrated in Figure 1:

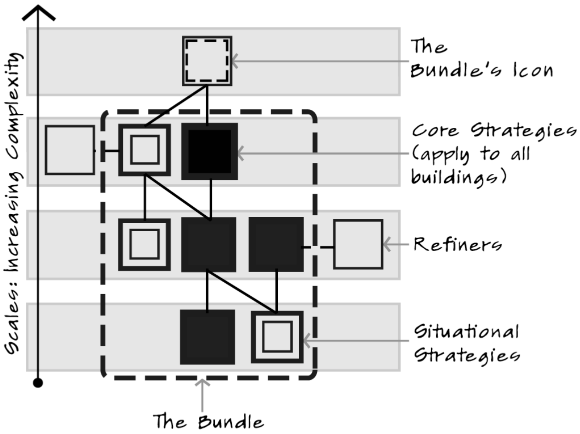

***Figure 1**: The structure of a bundle*

1) *A Bundle covers two or more scales* in the hierarchical system for levels of complexity (*SWL* uses nine scales). Most of the fundamental bundles cover three levels (the gray bars). The black lines connecting the squares represent a particular kind of relationship among the strategies of lower and higher complexity. The levels function to make clear how less complex strategies help to build more complex strategies.

2) *A Bundle has 3–5 invariant core strategies* (the solid black squares) that are always workable in the given design situation. Core strategies are recognized as those that apply to all the bundle's variations.

3) *A Bundle has two or more situational variations*, each with its own bundle diagram. These variations adapt the bundle to a major variable commonly present (such as the difference between designing in a cool climate versus a hot-arid climate) by the addition of situational strategies (the hollow squares inside the dashed line) beyond the core strategies. Remember that core strategies are common to all of the situational variations, whereas situational strategies are more workable or important in one scenario than in the others.

4) *A Bundle may also identify refiner strategies* (the squares outside the dashed line), which are related to the bundle and are recommended to be considered as the design develops to greater levels of detail. These are most likely workable but are less critical strategies.

Because each strategy has a range of variables and can be adapted to variations in its context, the particular combination of strategies suggested for a bundle can yield thousands of formal outcomes. Similarly, the relationship of one strategy to another in a bundle will influence the way in which each strategy is applied. The designer fits one strategy to the others in the network of design strategies that forms the bundle. This network is a context of other more and less complex strategies.

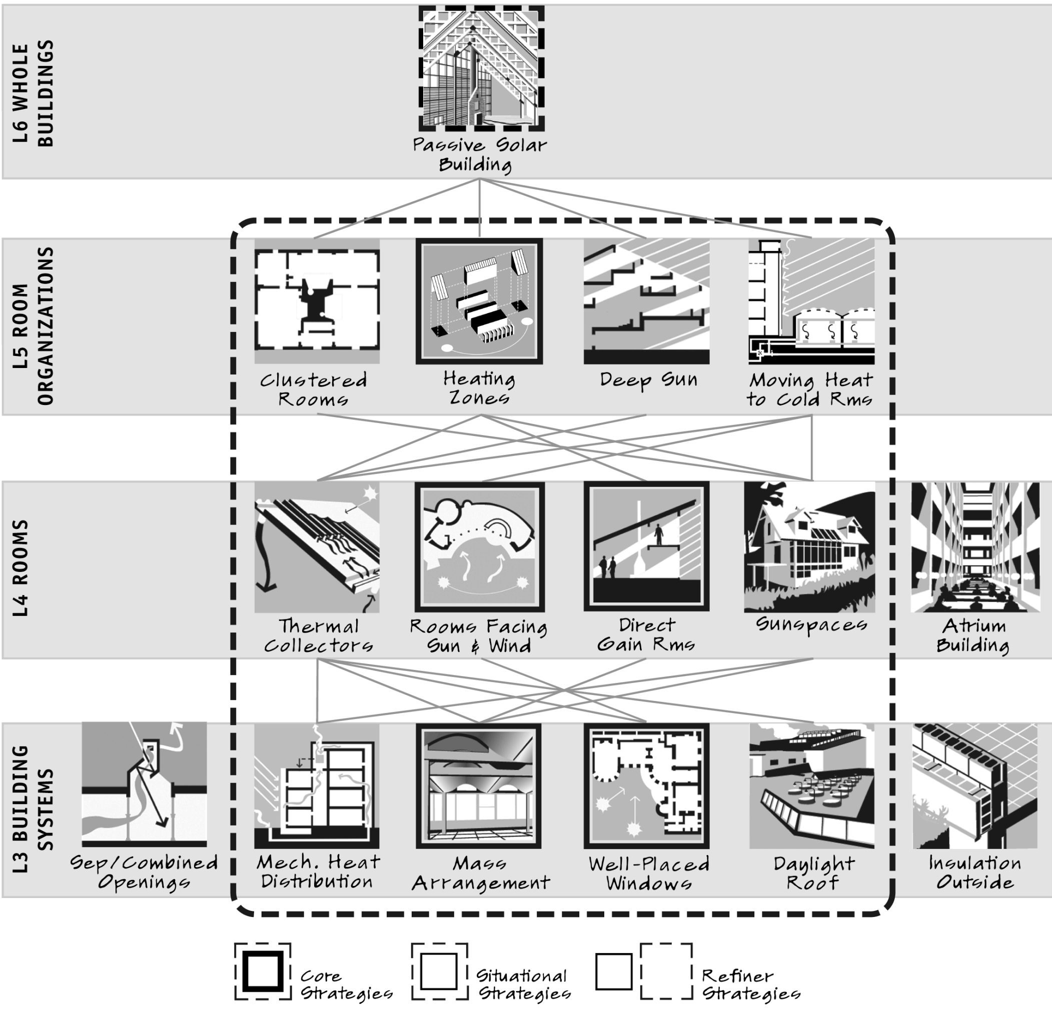

Figure 2: *Passive solar building bundle, thick plan variation*

2. EXAMPLE BUNDLE

The example bundle diagram in Figure 2 for a thick plan PASSIVE SOLAR BUILDING bundle, one of its two variations, illustrates the four organizational principles of a bundle.

1) *The bundle organizes design strategies at multiple scales,* covering three levels of complexity, from lower complexity level three (L3) Building Systems, to L4 Rooms, to higher complexity L5 Room Organizations. These are named in the range of grey bars on the left side of Figure 2. The scale of L6 Whole Buildings is the contextual scale for this bundle and is the level where its particular "emergent characteristics" are evident. The gray lines connecting the squares represent nesting relationships between strategies. For example, the less complex strategies of SUNSPACES, ROOMS FACING THE SUN AND WIND and THERMAL COLLECTORS are all strategies for designing at the L4 Rooms scale; they help to build the more complex strategy MOVING HEAT TO COLD ROOMS, which operates at the more complex scale of L5 Room Organizations to orchestrate heat distribution between rooms that collect heat and those that do not. SUNSPACES helps build MOVING HEAT TO COLD ROOMS, while the higher, deeper, larger strategy also depends on the lower strategy. Bear in mind that the bundles represent some important associations of strategies, and that many additional strategies may be used. Note that, for simplicity, the relationship lines for *refiner* strategies are not shown in the diagrams, but they can be seen on the design strategy maps in *SWL's* chapter on "Navigation by Design Strategy Maps" [1].

2) *The bundle has five core strategies*. Each graphic icon represents an individual design strategy in *SWL*. Core strategies are shown in Figure 2 with a bold outline: HEATING ZONES, ROOMS FACING THE SUN AND WIND, DIRECT GAIN ROOMS, MASS ARRANGEMENT and WELL-PLACED WINDOWS. These will apply to almost all PASSIVE SOLAR BUILDINGS of both Thin Plan and Thick Plan variations.

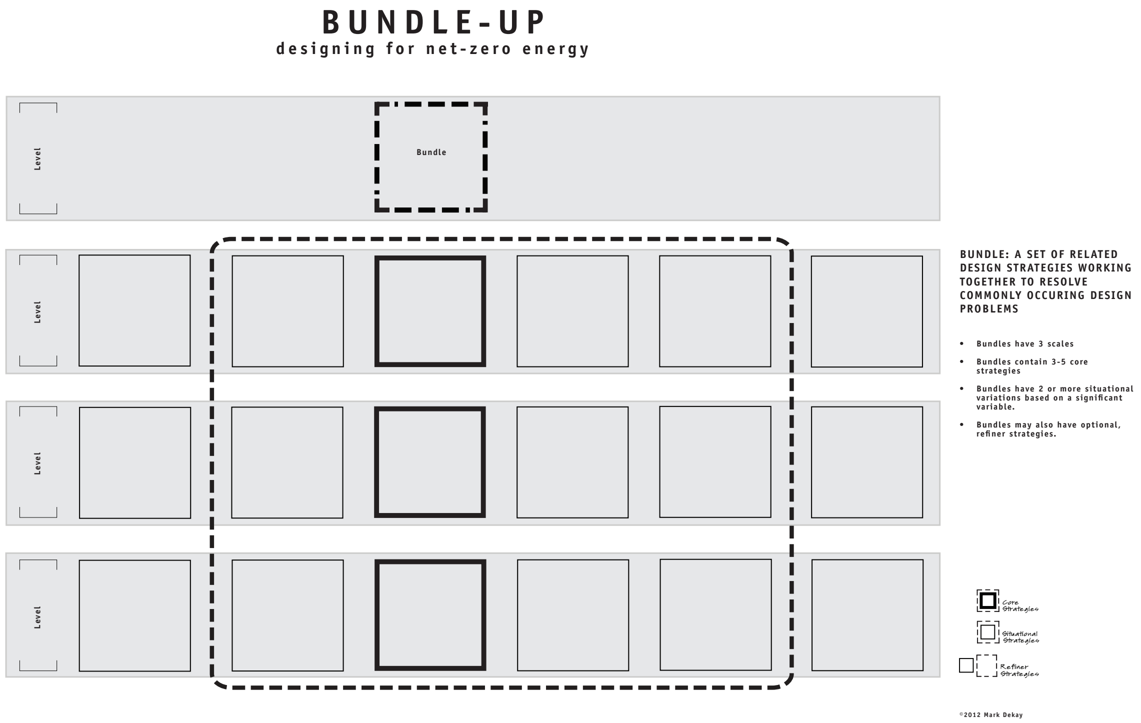

Figure 3: *Bundle-Up! game board*

3) *The bundle has two situational variations,* one for a *thick plan building* (shown in Figure 2), in which a significant portion of rooms do not face the sun, and one for a *thin plan building,* in which access to the sun by each room is easier. The *situational strategies* are located *within* the bundle boundary (bold dashed line); their icons have no border, for example: CLUSTERED ROOMS, SUNSPACES and MECHANICAL HEAT DISTRIBUTION. These design strategies will typically apply to one of the bundle variations, but not to all of the variations. The situational strategies are appropriate almost all of the time, yet not every strategy need be used in every project. For example, most Thick Plan Variation buildings will need MECHANICAL HEAT DISTRIBUTION to move heat from rooms or surfaces that collect solar heat to remote rooms that do not have direct access to solar heat, but a Thin Plan building can usually use passive radiation or local passive convective loops to distribute heat.

4) *Refiner strategies are less critical* to the bundle's success or have less impact on architectural form than core or situational strategies. However, they may still have a large impact on performance in Figure 2. The refiner strategies are located *outside* the bundle boundary (*bold dashed line*) and their icons have no borders: ATRIUM BUILDING, INSULATION OUTSIDE and SEPARATED OR COMBINED OPENINGS. For example, in a thick plan PASSIVE SOLAR BUILDING, a light court may be used in an ATRIUM BUILDING arrangement; the atrium may also double as a SUNSPACE to collect heat if its roof or one wall has SOLAR APERTURES oriented to the sun. This refiner strategy will not apply to all buildings, but if used, could improve the performance the bundle offers.

4 THE *BUNDLE-UP!* GAME

The *Bundle-Up!* game was developed as a fun way to learn about designing with bundles. It allows players to build their own bundles of design strategies that are more specific to their design's program, site, and climate than the more generic "fundamental bundles" in *SWL.* The game board (Figure 3) follows the structure of bundles as described above. Users select "Scale Cards" from among nine options (Figure 4a). Scales must be sequential from smaller to larger. A colored "Bundle Tile" from among nine current options (Figure 4b) is placed in the top position, or, alternatively, a blank tile may be selected and given any original name by players who wish to create a custom bundle for a new problem type. Each fundamental bundle and design strategy (currently 115 total) from *Sun, Wind & Light* [1] is represented by a "Strategy Tile" (Figure 5). The front of the tile shows its *SWL* strategy icon, abstracted

a) 

b) 
Figure 4: *(a) Cards for scale/level of complexity (b) Bundle tile example*

from a built example, along with its name, strategy number, and level of complexity designation (L1, L2, etc.). The back side gives more information: the strategy or bundle number, its defining "strategy statement," the energy issues it addresses (heating, cooling, daylighting, etc.), and its level name.

5 OUTLINE OF INSTRUCTIONS FOR PLAYING *BUNDLE-UP!*

The game can be played by one person (as solitaire) or several people in collaboration. It can also be played by having different teams create variations on the same bundle. This is a good way to arrive at *core* strategies (ones that have workability in all of a bundle's variations). Instructions for play:

1) Place your colored Bundle Tile (or create one) in the dashed bundle square on the top.

2) Each strategy has a scale and can only be used at that scale.

3) Choose critical strategies (or your best guess for candidates) from the deck of Strategy Tiles and place them inside dashed bundle "wrapper." These will become either core or situational strategies. You may start with any strategy that you think would be very important to the design scheme.

4) Place less critical refiner strategies at their designated scale, but outside the bundle wrapper.

5) Examine your set of strategies for their interactions and add, subtract or substitute strategies to create greater synergy between strategies to solve the bundle's energy issue(s). Debate the importance of different strategies, moving them inside or outside the bundle wrapper.

6) Now identify the strategies that are the three most critical—at least one at each scale—that are critical to "almost every building" in your situation. Place these in the bold core squares. If desired, you may add up to 2 more core strategies.

7) To test your choice of core strategies, think about whether or not each would still be effective in the other situation(s) of the bundle problem. If playing in teams, debate with the other team. If playing in one group, it is useful to assign different players to advocate for the needs of a particular bundle variation.

8) There is no one right solution, but some are better than others, and solutions that follow the rules are all acceptable. When satisfied with your solution, or your group has reached consensus, record it on the Bundle Capture Form (a reduced version of the game board).

9) HAVE FUN!!! Design. Repeat.

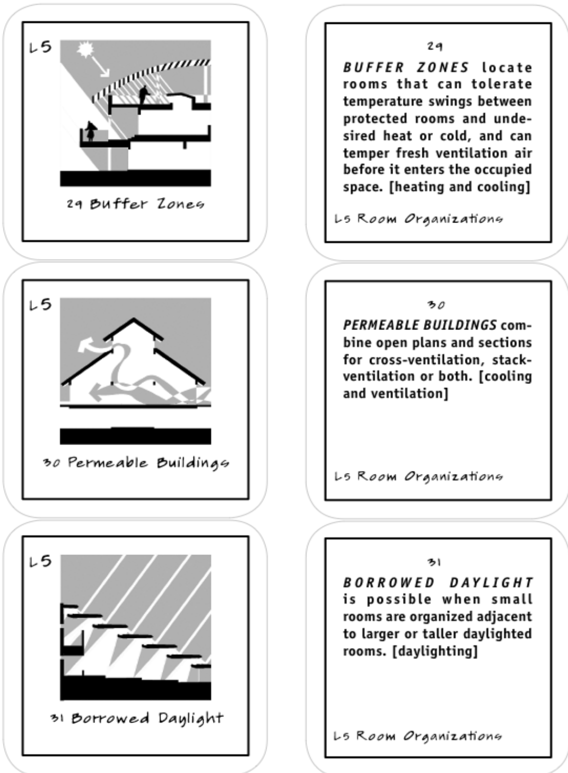

Figure 5: *Strategy tile examples*

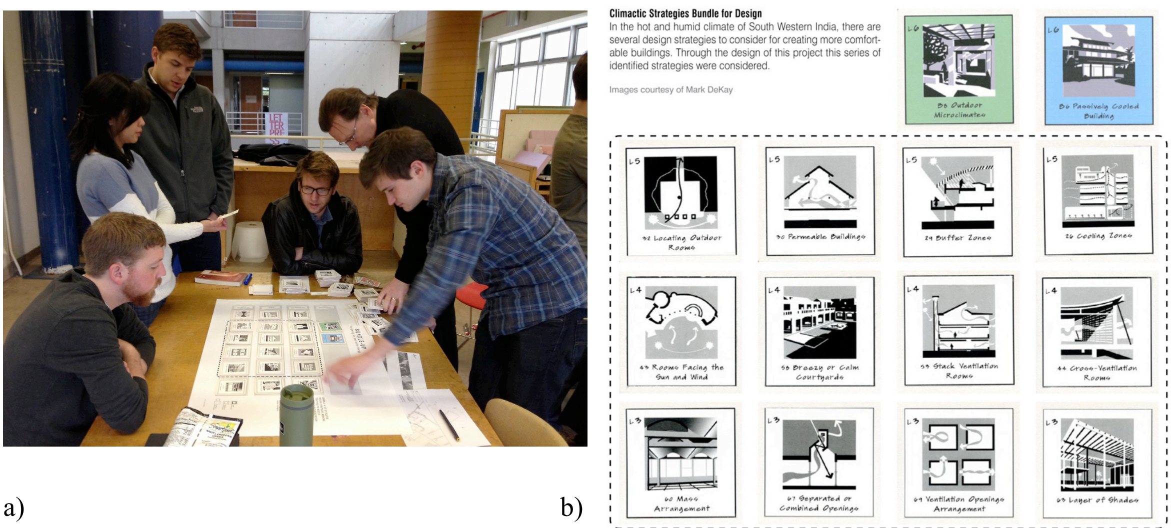
6 PROTOTYPES AND TESTING

A rough, limited scope prototype with one bundle and only cooling strategies was created, and an initial test was run with peer teachers at the 2012 annual curriculum meeting of the Society of Building Science Educators. Two teams of architects and design professors debated over and created bundles for hot-humid and hot-arid variations of a PASSIVELY-COOLED BUILDING bundle. Feedback was very positive. The members offered suggestions for improvement, mainly to the instructions and options given to users. Overall, they agreed that the game was a good learning tool and that they had actually learned something themselves in the process of playing. The teachers enjoyed learning in a group together and saw possibilities for transforming the typical architectural technology class that primarily uses individual learning approaches and also noted the potential as a design tool in design studio classes.

Figure 6: *Testing Bundle-Up! with the Society of Building Science Educators*

The next prototype, with a complete set of bundles and strategies, along with revised instructions, was then tested in two classroom settings: fifth-year undergraduate design studios in Spring and Fall terms of 2013 and a second-year "Introduction to Architectural Technology" course in Spring of 2013 and 2014. The lower level instruction in a class of 65 students made use of an instructional video created by the author with two advanced students. In one semester, upper level students designed housing for a village in Gujarat India, collaborating with Professor Sharad Sheth's fourth-year students from Sardar Vallabhbhai Patel Institute of Technology, Vasad. University of Tennessee students are shown playing *Bundle-Up!* in Figure 7a. A team working on housing design for the village of Waghnagar developed a composite bundle for a PASSIVELY-COOLED BUILDING and an OUTDOOR MICROCLIMATE, shown in simplified form in Figure 7b. Their scheme for two variations on low-energy climate-responsive courtyard houses built with local materials and labor skills is shown in Figure 8.



a) b)

***Figure 7**:* *(a) Bundle-Up! in design studio (b) Hybrid custom bundle for Gujarat housing design*

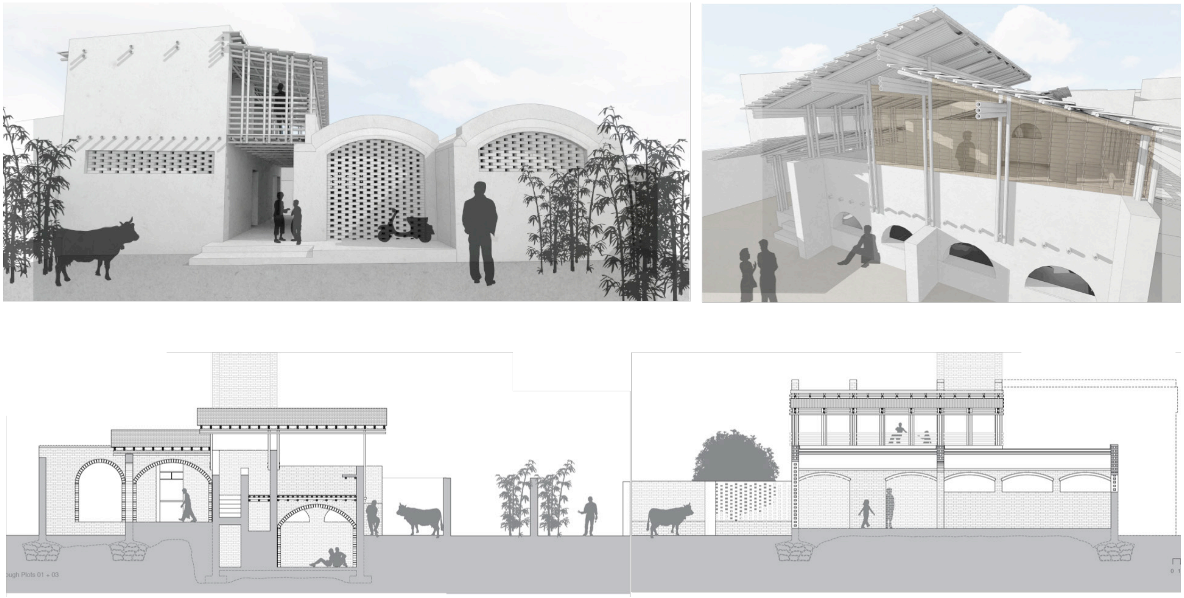


Figure 8: 5th-yr studio project, housing in Waghnagar, Gujarat, designed using SWL bundles

Figure 9: 5th-yr studio project, brewpub in Marfa, Texas, designed using SWL bundles

In another semester, fifth-year students used *Bundle-Up!* to help design a net-zero energy brewpub and beer garden in seven different U.S. cities, each set in a different climate. One team's design for warm-dry Marfa, Texas is shown in Figure 9. It includes passive cooling, heating, and daylighting strategies from *Sun, Wind & Light*, 3rd edition [1]. They also used the new *SWL Tools* spreadsheets to calculate energy demand and size photovoltaics to become a plus-energy project.

The lower-level students used *Bundle-Up!* as a part of a sequence of passive design exercises that design a net-zero energy bioclimatic residence, again in multiple climates. In all of these cases, students developed their designs in collaborative teams of two to four students. Figure 10 shows an example a PASSIVELY-COOLED BUILDING bundle developed in the exercise, a student team using *Bundle-Up*! in the design process, and a second-year scheme for a net-zero energy residence in the mixed-humid St. Louis climate. As a result of these and other classroom innovations, the instructor/author was awarded the Chancellor's Award for Teaching Excellence 2014 at the University of Tennessee.

CONCLUSIONS AND FUTURE PLANS

The next step in testing and revision will be a workshop for practicing architects in October 2014. In theoretical terms, observing users playing *Bundle-Up!* many times and applying their results in designing buildings have suggested the need to expand the *Sun, Wind & Light* knowledge structure. Bundles, as defined in *SWL,* cross a limited range of three scales in the nine-scale system of *SWL* that ranges from materials to neighborhoods. The development question is, “Can the bundle concept and the *Bundle-Up!* game be expanded to include mapping the full range of design strategies employed in a specific design?”

While the game is clear and useful as a learning or design activity, it is important to place it for students within a clear design process context. Students need assistance in knowing when to employ the bundle concepts and more specific guidance about what to do with the game results. To this end, future class exercises will guide a more explicit design process that involves multiple uses of the game in a sequence of different problem variations. Examples might include generating building design bundles for passive heating, cooling, and lighting, or using *Bundle-Up!* to explore a responsive envelope that addresses multiple energy issues.

Perhaps the most common request is for an iPad app or other electronic version of the game tied to its *SWL* knowledge base. The author is currently seeking technical collaborators and funding.

Through application and feedback in different settings and class types over a two-year period, several conclusions may be drawn. Students have found the *Bundle-Up!* game useful as a step in the process of designing passive and net-zero buildings. It requires them to choose carefully and to narrow their design options strategically. Via the game, the relatively complex *SWL* knowledge structure becomes more accessible to both beginning and advanced students. Playing *Bundle-Up!* seems intuitive and fun. Making more fun of understanding climatic design was the game’s real purpose. One peer teacher found, “It teaches systems thinking across multiple scales with none of the systems thinking jargon.” Another reported, “This really supports integrative ecological thinking in a very concrete architectural way.” Students’ responses from feedback surveys are consistent in their appreciation of learning in collaborative dialogue and the teamwork required by *Bundle-Up!,* in contrast to many of their other classes. They enjoy learning in a hands-on, project-based setting, working together with their peers, rather than working in competition with them.

Digital files for printing and making *Bundle-Up!* are available from the author.

ACKNOWLEDGMENTS

The author thanks the following for their important roles in this project: Susanne Bennett for the initial game idea; Jordan Etters, research assistant, for graphics and game production; the AIA Upjohn Research Initiative Award for financial support to develop the underlying knowledge structures; the University of Tennessee College of Architecture and Design for a faculty development award to produce and test the prototypes, and the SBSE and University of Tennessee students for prototype testing and feedback.

Integrated dehumidification and downdraught evaporative cooling system for a hot-humid climate

ABSTRACT

Unlike in hot-dry climates, in hot-humid climates evaporative cooling techniques are not readily suitable for space cooling. In order to effectively use evaporative cooling in hot-humid climates, dehumidification of ambient air is necessary before it passes over an evaporative medium for cooling. The present study explores the combined process of dehumidification and evaporation and its effect on thermal comfort in a typical small residential building located in a hot humid climate. A novel system has been investigated with the combination of an Earth Tube Ventilation (ETV) (for pre-cooling of air), a rotary wheel desiccant dehumidifier (for dehumidification) along with a Passive Downdraught Evaporative Cooling (PDEC) tower (for evaporation) in that order.Parametric simulations using the EnergyPlus tool have been conducted in order to determine the critical dimensions and parameters of the proposed system, such as desiccant system sizing, PDEC tower height, and air and water flow rate at various points of the system. Results of indoor air temperature, humidity levels and volumetric air flow rates in the building spaces were obtained to study the influence of the proposed combined system on human thermal comfort. On a typical hot day the results from the proposed system show a relatively constant indoor air temperature of 28 °C (as opposed to peak indoor temperature of 36 °C occurred by means of natural ventilation) and indoor relative humidity in the range of 62 % - 68 %. The volumetric airflow rate from the outlet of the PDEC tower is in the range of 2.97 - 3.41 m^3/s which is well within recommended levels for a dwelling unit. The proposed system displays a significant potential for providing space cooling in hot-humid climates as it paves an alternate way to the conventional energy consuming vapour compression Air Conditioning units.

INTRODUCTION

Space cooling techniques become inevitable in extreme hot-dry and hot-humid climates where building form and construction alone cannot ensure indoor thermal comfort. Evaporation of water has been one of the available techniques used for space cooling. Special architectural features such as wind towers were used in hot-dry climates to direct the prevailing winds over a wet body like *khuskhus* pads, water filled clay pots etc. to enhance evaporation. However, high humidity in the ambient air inhibits the use of direct evaporative cooling in hot-humid climates and dehumidification of the air is necessary before it passes over an evaporative medium for cooling. This study explores an alternate to conventional vapour compression based domestic air conditioning units by using dehumidification and evaporation in a typical residential building in a hot- humid climate in India. A combination of a cooling system

Sriraj Gokarakonda is a research fellow at Wuppertal Institute for Climate, Environment and Energy, Wuppertal, Germany.

consisting of a rotary wheel desiccant dehumidifier along with a Passive Downdraught Evaporative Cooling (PDEC) tower has been devised. An Earth Air Tunnel (EAT) for precooling of intake air has later been added to the original cooling system after analysing the preliminary results. Simulations were run with EnergyPlus to conduct a parametric analysis of the proposed system and to study its influence on thermal comfort.

PASSIVE DOWNDRAUGHT EVAPORATIVE COOLING SYSTEMS

Evaporative cooling is based on the conversion of sensible heat to latent heat. When water evaporates, it uses up the heat from the surrounding air to change phase from liquid to vapour and this result in lowering the temperature of the surrounding air. A typical configuration of a passive downdraught cooling system has a tower to draw in air into the space. The air is passed over an evaporative medium placed below the tower inlet, gets cooled and enters the space through an outlet at the bottom of the tower. A passive downdraught was thus created through the evaporation of water within this air-stream and the necessary air circulation was achieved through either by buoyancy or by wind assisted natural ventilation.

However, modern PDEC towers include energy intensive components like fans and pumps to enhance downdraught or to increase flow rates and are referred to as Passive and Hybrid Downdraught Cooling (PHDC) (Ford, Phan, & Francis, 2009). To increase the evaporation of water, large droplets of water are sprayed into the air stream (e.g. by a shower tower) or a mist of water is added to the air stream (e.g. by misting nozzles in a misting tower) instead of letting the air passing over wetted pads and clay water pots. In this paper, shower tower configuration of PDEC is selected as it represents a typical system used in practice. A shower tower PDEC (PHDC) proved to be a worthy option in meeting the cooling needs of the Torrent research centre building in Ahmedabad (Leena & George, 1997). The system provided an alternative to the use of conventional Air Conditioning in such hot climates during hot-dry season. However, reliance on conventional air conditioning was recommended for the hot-humid season. This system can also be well integrated to the existing buildings. An example of such an application is in Portugal, where an existing chimney of a building has been modified to be used as a PDEC tower (Melo & Guedes, 2006). Its performance was studied by measuring the thermal parameters and humidity levels and compared against a mathematical model. The results for PDEC were encouraging, but it was concluded that a PHDC was performing better over a PDEC (Melo & Guedes, 2006).

DESICCANT DEHUMIDIFICATION

Desiccant dehumidification is based on the principle of sorption with the use of desiccant chemicals. Sorption occurs due to difference in the vapour pressure exerted by the moisture in the air on the surface of desiccant which offers an area of low vapour pressure (Munters Corporation, 2002). Liquid desiccant dehumidifiers in general are large systems and are used to condition large spaces. Solid desiccant dehumidifiers are available in different sizes, configurations to suit for application in residential buildings. Two popular solid desiccant configurations that suit residential applications are packed bed and rotary desiccant wheel.

Packed bed dehumidifier consists of loosely packed silica gel beads. Ambient air is passed over this desiccant bed and the dry air is circulated into the space. It has found application in residential units in a configuration called desiccant enhanced nocturnal radiation (DESRAD) cooling and dehumidification. Chung et al., 1995, Satio (1993), Techajuntaa et al. (1999) further investigated DESRAD concept in various configurations and concluded it can be used in domestic air-conditioning in tropical humid climates.

Rotary Desiccant Wheel (DW) dehumidifier consists of finely divided desiccant silica gel beads that are impregnated into a semi-ceramic structure, which in appearance resembles corrugated cardboard that has been rolled up into the shape of a wheel. The wheel rotates slowly between two air streams called the process air and reactivation airstreams. The process air flows through the flutes formed by the corrugations, and the desiccant in the structure absorbs the moisture from the air (Figure 1 process A-B). Re-activation (Figure 1 B-C) is the hot air (blown by a hot air blower) necessary to regenerate the saturated desiccant. Following reactivation, the hot desiccant rotates back into the process air (Figure 1 C-A), where a small portion of the process air cools the desiccant so it can collect more moisture from the balance of the process airstream. (Munters Corporation, 2002). Commercial desiccant products in the HVAC industry are mostly available in rotary desiccant wheel (DW) configuration.

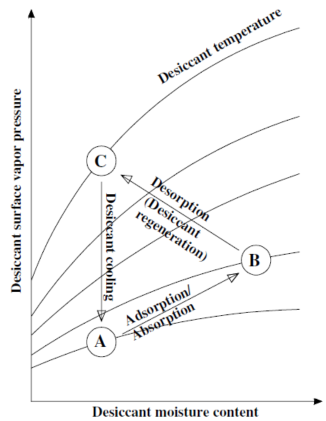

Figure 1 Desiccant dehumidification and regeneration processes (Mazzei et al. 2005)

While a rotary DW dehumidier consumes more energy than a packed bed it has been chosen for the present study because the DW system can be easily and precisely sized with available modelling tools to fit a building case. Modelling a packed bed on the other hand involves dependence either on experimental data or rigorous analytical calculations with assumptions to be made which was beyond the time scope of the study.

METHODOLOGY

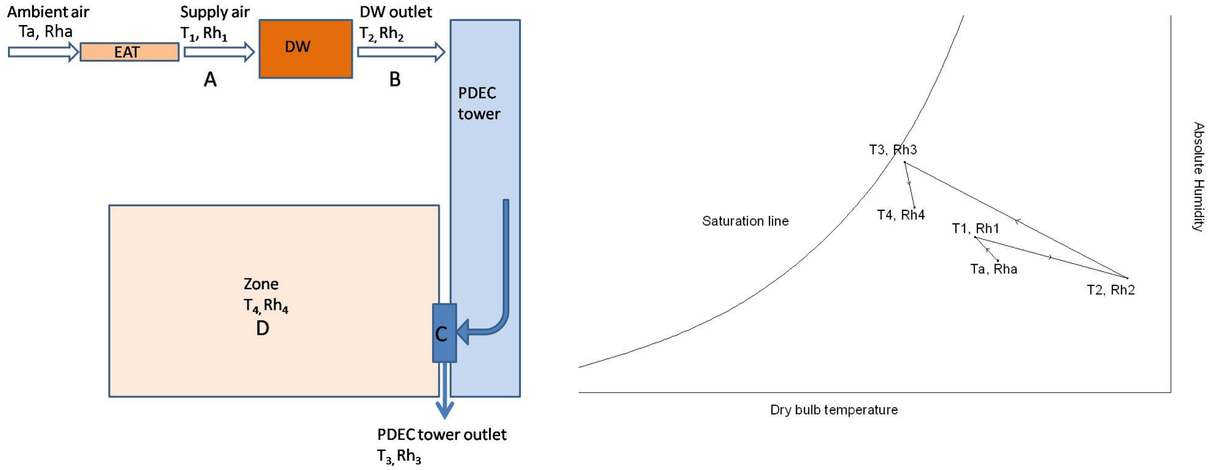
Location and Climate analysis

The location selected for the current study is Visakhapatnam city (Lat 17.72, Lon 83.23) in the state of Andhra Pradesh in India and where the climate is categorised as tropical hot-humid climate. In peak summer the temperature reaches as high as 38 °C and in winter it reaches a minimum of 15 °C. The diurnal variation of temperature during hot summers is usually 5-6 °C. The outdoor relative humidity levels are in general above 60% for most of the year. Relative humidity is low at noon and reaches peak during early morning before the sunrise and again drops as the day progresses .

Description of the proposed system and sequence of operation

The proposed system consists of a rotary Desiccant Wheel dehumidifier (DW) which is integrated with a Downdraught Evaporative Cooling shower tower (PDEC tower) through which the air is supplied into the space (Figure 2 a). An Earth Air Tunnel has later been added to the DW+PDEC system after observing the preliminary results in order to pre cool the supply air drawn into the Desiccant Wheel.

The ambient air at temperature T_a and relative humidity Rh_a is drawn into the EAT and leaves the EAT at a temperature T_1 and relative humidity Rh_1. The air at T_1 and Rh_1 is then drawn into the inlet of DW from the outlet of the EAT. The air at the outlet of the DW is called the process air and it has been dehumidified and conditioned to a temperature T_2 and relative humidity Rh_2. The process air at T_2 and Rh_2 is then supplied to the top of the PDEC. T_3 and Rh_3 are the air temperature and relative humidity at the outlet of the PDEC tower which is directly supplied for cooling the indoor space. T_4, Rh_4 is the final temperature and relative humidity in the zone and it is expected to be less than the ambient T_1 and Rh_1 for the system to be able to perform well. The psychrometric representation of the proposed system can be seen in Figure 2 b.



a) b)

Figure 2 a) Graphical representation of the proposed system b) System representation on a Psychrometric chart

Description of a typical dwelling unit to which the proposed system is attached

A typical dwelling unit has been modelled as three thermal zones (Figure 3). Zone 2 is connected to the proposed system of integrated dehumidifier and PDEC tower and it is referred to as zone henceforth. All rooms have a wall to window ratio of 33% which is typical in the region. The floor to ceiling height is 2.8m. The worst possible scenario is assumed for shading during the cooling period, i.e. there are no shading devices or overshadowing from the surroundings. Typical building materials used in the region are assumed for the constructions and their U-Values (in W/m^2K) are: exterior walls - 1.946, interior walls - 1.735, roof slab - 4.6, floor slab - 0.894 and windows 5.71 (with an SHGC of 0.567).

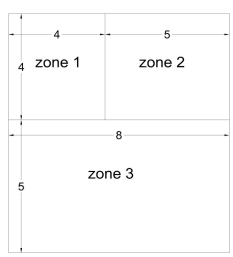


Figure 3 Typical dwelling unit (all dimensions in meters)

MODELLING THE PROPOSED SYSTEM

The EnergyPlus whole building dynamic simulation program was used to simulate the EAT, DW and PDEC components. However, the whole proposed system of this study (i.e. ambient air→ EAT→ DW → PDEC → Building zone) could not be modelled in one simulation because of the limitations of the tool to assemble such a configuration in a single sequence. For this purpose, a total of four simulations were carried out in a way that is explained below and summarised in Figure 2:

1. Ambient air→ EAT (A in Figure 2): Precooling of air was simulated using an Earth Air Tunnel. The results of the simulation provide the supply air temperature at T_1, Rh_1 from the outlet of the EAT. The EAT has been modeled with a fan to provide an EAT outlet flow that matches with the supply flow rate demand of the DW dehumidifier.

2. EAT→DW (A to B in Figure 2): The DW was simulated in EnergyPlus using a modified weather file with temperature and relative humidity values obtained from the previous simulation i.e., T_1 and Rh_1 as inputs. The results of this simulation provide the process air at T_2, Rh_2 from the outlet of the DW.

3. DW→PDEC (B to C in Figure 2): The PDEC tower was modelled in the third simulation. Technically, in the EnergyPlus program the PDEC tower simulation takes the inlet temperature and humidity data at the top of the tower from the original weather file. Therefore, the values of actual ambient air temperature and relative humidity in the original weather file were replaced by the output obtained from the 2nd simulation, i.e., with T_2, Rh_2. When this 2nd simulation was run PDEC tower takes T_2, Rh_2 as the inlet values at the top of the tower and the tower outlet temperature and humidity T_3, Rh_3 are obtained. The conditions in zone 2 (T_4 and Rh_4) can in theory be calculated from the same simulation, however in this case the zone conditions cannot be obtained because the temperature and relative humidity values (T_2 and Rh_2) in the weather file for the 3rd simulation were modified from the actual ambient temperature and relative humidity (from T_a and Rh_a) to the DW outlet temperature T_2 and relative humidity Rh_2 in order to be used as inlet conditions of the PDEC tower. This means that the weather file during the 3rd simulation did not include the actual weather conditions and could not therefore be used to define the boundary conditions of the building.

4. PDEC→Room (C to D in Figure 2):The fourth simulation was run to obtain the zone temperatures and relative humidity levels (T_4 and Rh_4). In this simulation boundary conditions were properly set based on the original weather file with ambient air conditions at T_a and Rh_a. The air supplied into the zone from the PDEC tower outlet (i.e. T_3 and Rh_3) has been mimmicked by using a customised EnergyPlus component that supplies air into the zone at desired parameters. The results of this simulation provide the zone air conditions at T_4, Rh_4.

Parametric studies have been done at each component level to optimise the critical parameters that impact in achieving the lowest temperature and relative humidity of the air at each of the outlets. The focus was on optimising pipe length and depth for EAT, velocity of the wheel for the Desiccant Wheel, and water flow rate and height of the tower for PDEC tower. Table 1 gives a summary of the sequence of optimization of various components, which was done based on the above listed parameters. The physical parameters of the proposed system were optimized based on the conclusions drawn from the parametric results. The highlighted area shows the selected case from each stage, which was then carried forward to the subsequent simulation stage.

Table 1 Optimization process

Earth Air Tube	Case 1	Case 2	Case 3	Case 4	Case 5
Pipe length	30	30	30	50	70
Depth	3	5	7	3	3
DW	Case 1	Case 2	Case 3	Case 4	
Velocity (m/s)	2.5	3	3.5	4	
PDEC	Case 1	Case 2	Case 3	Case 4	
Max water flow rate (m^3/s)	0.00001	0.0005	0.005	0.016	
PDEC - height (m)	5.0	5.0	5.0	5.0	
PDEC	Case 5	Case 6	Case 7	Case 8	Case 9
Max water flow rate (m^3/s)	0.0005	0.0005	0.0005	0.0005	0.0005
PDEC - height (m)	3.00	5.00	7.00	9.00	11.00

RESULTS

A period of two representative weeks during which peak outdoor temperatures occur is taken for study (Figures 4 and 6). It can be observed from Figure 4 that there is a significant decrease in the zone temperature in the range of 3-8 °C after adding the proposd system (without EAT) in comparison to the zone temperature without any system and open to natural ventilation. The addition of the EAT further decreases the zone temperature and brings it close to the comfort limits (in the range of 28 – 30 °C).

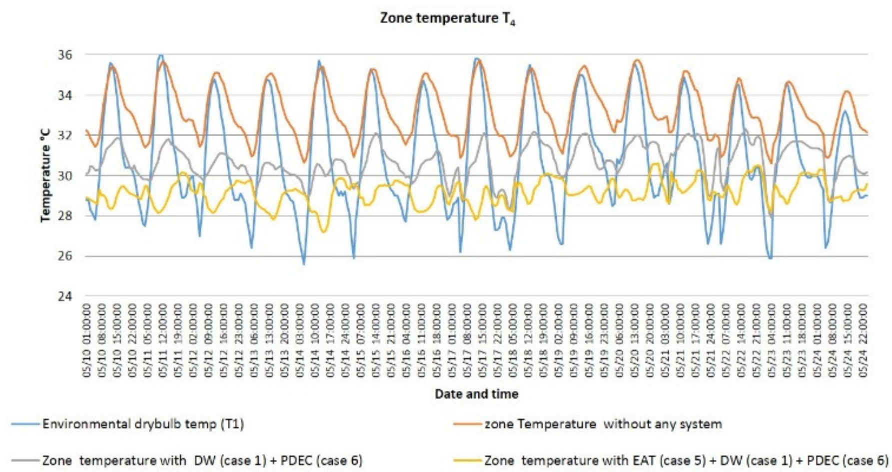

Figure 4 Zone temperature (T_4) after adding EAT (case 5) to pre cool the supply air

A typical warm day chosen from the above two-week period to analyse the diurnal variation in zone temperature and zone relative humidity levels. From Figure 5 it can be seen that zone temperatures during the day are lower than that of the night for the system configuration with EAT (case 5) + DW (case 3) + PDEC (case 6). The zone air temperature increases in the night and at times exceeds the ambient air temperature (see Figure 5).

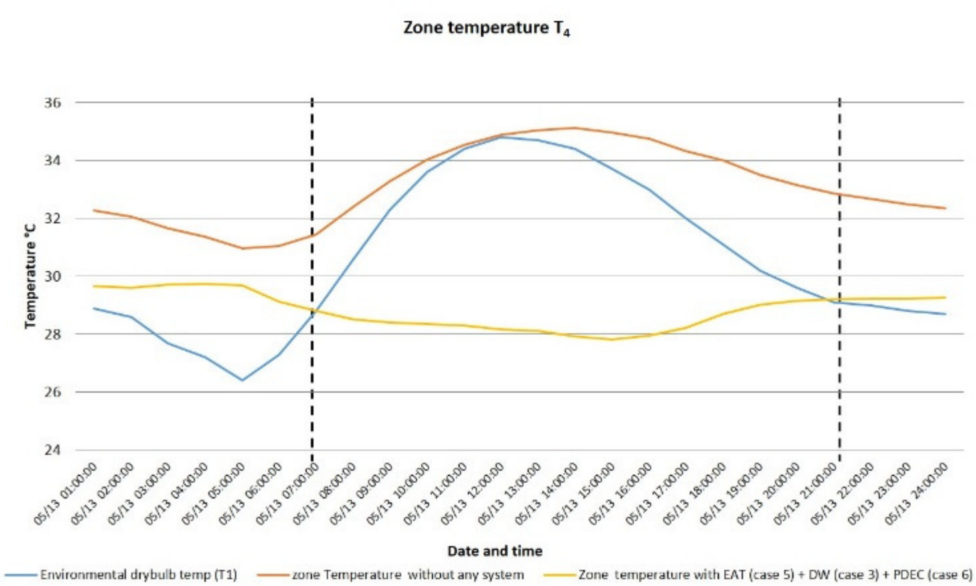

Figure 5 Diurnal variations in zone temperature (T4)

The relative humidity in the zone with the proposed system was lower during daytime and higher during the nights than the relative humidity values of the naturally ventilated case. However, zone relative humidity levels are maintained well below the maximum permissible level of 75% (Figure 6) (CIBSE, 2006) throughout the period of the study.

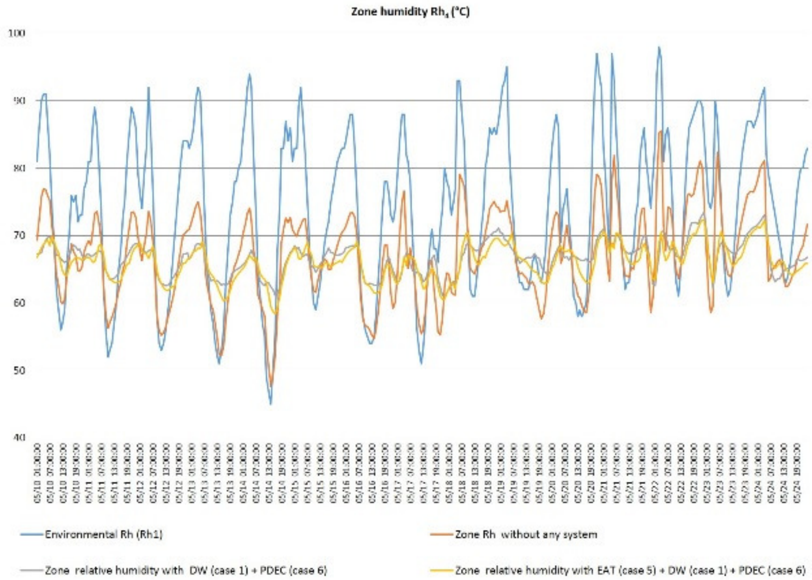

Figure 6 Zone humidity (Rh4) after adding EAT to pre cool supply air

Figure 7 shows that the proposed system results in a slightly higher relative humidity (up to 8%) compared to the naturally ventilated zone humidity levels during the day. However, during the nights the system reduces (by up to 7%) the relative humidity in the zone. An air flow rate of 2.97 - 3.41 m^3/s was also observed at the outlet of the PDEC tower ensuring the recommended ventilation levels within the space as per ASHRAE (2009) for redidential dwellings.

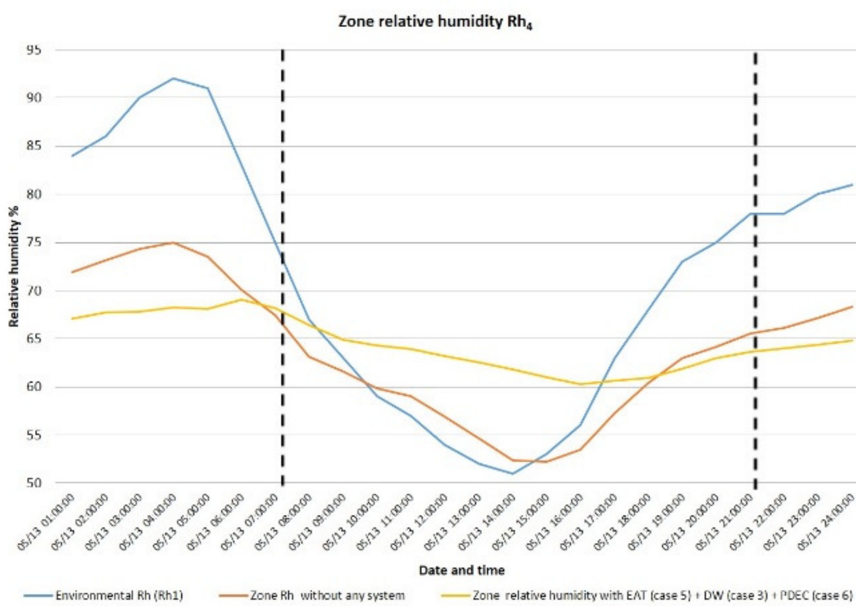

Figure 7 Diurnal variation in zone relative humidity (Rh4)

CONCLUSION

An integrated cooling system of desiccant dehumidifier and PDEC was evaluated for a typical dwelling in a hot humid climate in India after being combined with an earthtube ventilation system. A process for enabling the simulation of the proposed system has been reported. The system's performance was investigated with a parametric analysis and it was found that by using the EAT+DW+PDEC system as opposed to using natural ventilation the peak indoor summer temperatures were reduced by about 8 °C while indoor relative humidity remained below 75%. The proposed system could provide space cooling in hot-humid climates and could be an alternative to high energy consuming conventional vapour compression AC units.This study analysed a worst-case scenario of a building without any shading and by assuming typical materials that are not of high thermal standards. With improvements however in building designs, the proposed system could ensure good levels of indoor thermal comfort.

ABSTRACT

A passive cooling louver system (PC louver), which is an aluminum louver partition coated with hydrophilic and water absorbing film, was developed in order to form a cool microclimate in urban residential outdoor spaces in hot and humid regions. The combination of hydrophilicity and water absorption of the film enhances water diffusion of the surface of PC louver. Hence, when a PC louver is watered from the top, the entire surface becomes wet, which enhances its evaporative cooling effect. The PC louver was designed to shade direct solar radiation, provide radiation cooling and ventiration cooling with cooled airflow. In this research, the thermal performance of the developed PC louver in outdoor environment was evaluated. As a result, the PC louver's surface was fully wetted and its surface temperature was approximately the ambient wet bulb temperature throughout the day. Temperature of the air passing through the PC louver decreased 2–3 °C, which achieved the expected cooling performance as a passive cooling system.

INTRODUCTION

In urban cities in hot and humid regions, the outdoor thermal environment has become a serious issue as the danger of heat stroke has increased. In these regions with a large amount of rainfall during the summer, the application of a passive cooling design using solar shading and evaporative cooling is focused (Hoyano et al., 1995). In residential area, it is expected to form cool microclimate in semi-outdoor spaces, so as to improve thermal comfort for both indoor and outdoor spaces.

Therefore, we developed a "Passive Cooling Louver System (PC louver)" as a residential exterior item (Figure 1). Louvers in general are able to shade solar radiation while penetrating air flow. In addition, by wetting the louver's surface, the surface temperature of the louver is expected to decrease by the latent heat of the evaporating water. Thus by adding the function that enables to wet the louver's entire surface, the following passive cooling effects can be expected : 1) solar shading, 2) radiation cooling, 3) ventilation cooling with cool airflow.

In this paper we first summarize required performances of PC louver and approaches to satisy these requirements. Subsequently, we verified the thermal performance of the PC louver through experiments in an outdoor environment. Besides, since it is necessary to predict the cooling effects at the architectural design stage, the thermal performance of the PC louver is evaluated in means of revealing the heat balance of the PC louver, in order to build a heat transfer model. However, this paper describes the achievements of thremal performances of the PC louver compared to the required performances, and the construction of modeling is performed in the next step.

DEVELOPMENT OF A PASSIVE COOLING LOUVER SYSTEM

Cooling Potential and Required Performance of the PC louver

Among hot and humid regions, there are cities that the relative humidity during the daytime decreases significantly. For example Tokyo, Japan is a seasonally hot and humid climate, but while the air temperature is above 30 °C during the day, relative humidity tends to decrease to 40–50 %, and wet bulb temperature at about 20–25 °C, which indicates enough potential as a cooling source (AIJ, 2005).

In the previous research (Hoyano et al., 1995), they developed a moist and void brick wall as a passive cooling wall (PCW), and verified that the wet bricks' inner surface temperature lowered to almost the ambient wet bulb temperature in an outdoor environment. Moreover, in the previous measurement and simulation of a semi-enclosed space using PCWs, the mean radiant temperature near PCWs were 2–4 °C less than the ambient air temperature and the air temperature passing through the PCW was lowered to 3 °C at the maximum. (Shirai et al., 1997; He et al., 2009).

The high performance of a PCW is well known through the previous research, but since a PCW is a wall of bricks, its form and utilization is more suitable in public spaces rather than in residences. Besides, moist bricks are effective to provide cooling effect continuously, but being moisted constantly is not a good condition for durability. Therefore, as shown in Table 1, we summarized the requirements for the development of the PC louver to satisfy performances as a passive cooling system together satisfying requirements as an exterior item in residences.

Surface Specifications of the PC louver

For the basic material of the PC louver, aluminium was chosen for its strength and durability. For the surface layer, it is important to wet the entire surface of the louver in order to minimize the surface temperature distribution. Thus, a hydrophilic resin with porous particles (Figure 2(a)) and photocatalyst

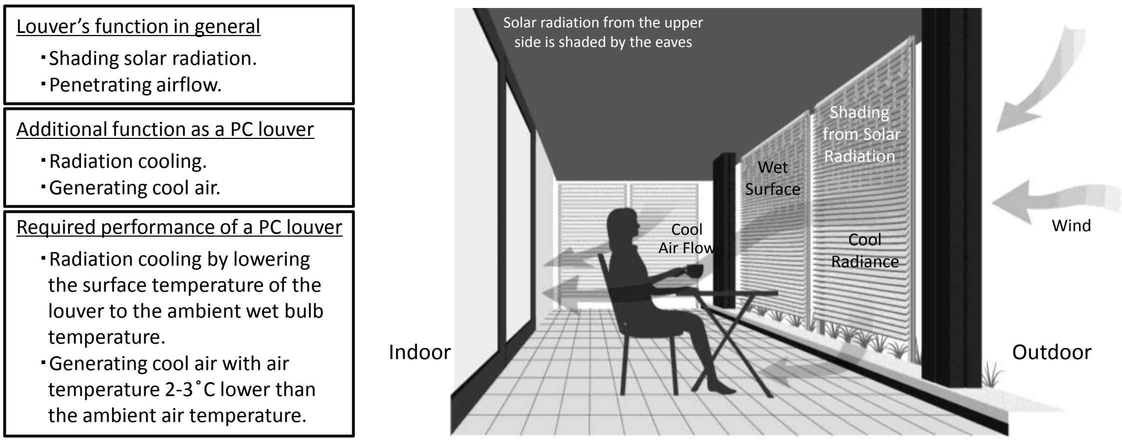

Figure 1 Image of passive cooling effects using a PC louver in semi-outdoor space of a residance.

Table 1. Required performances and methods for the development of a PC louver.

Required performances	Methods
1) Shade direct solar radiation to the subject space.	Adjust pitch of the louver's slats.
2) Wet the entire surface of the louver and create uniform surface temperature distribution.	Enhance the hydrophilicity of the louver's surface.
3) Prevent algae, mold or smudge by letting the louver's surface dry easily when it is not in use.	Separate surface layer and base layer, and wet only the surface layer.
4) Enhance heat transfer between cooled louver's surface and air passing through the louver.	Enhance the surface ratio of the louver's slat to the louver's vertical plane.
5) Lower surface temperature of the louver immediately after watering.	Lower heat capacity of the louver by using the hollow aluminium slats.
6) Enable to maximize the shape factor to the subject space.	Manufacture the louver with compact depth and flexible width and height.

Principal component	SiO_2 66.7 %

(TiO_2) was coated to the aluminum base (Figure 2(b)). Hydrophilicity of the resin and the porous particles were enhanced by the photocatalyst, and the capillary force of the porous particles aided the diffusibility of the surface water.

Form and Sectional Composition of the PC Louver

The form and the sectional composition of the PC louver were determined mainly with the consideration of water flow and the solar radiation transmittance. The louver's slats are titled 3° down toward the terrace side in order to drain water mainly to the terrace side. In addition, by cutting the edge of slats toward the center, water is led to drop near the center of the next slat (Figure 3(a)).

Space between slats affects the quantity of solar radiation transmittance, evaporation, air permeability, and heat transfer between louver's surface and air passing through the louver. Among these factors, we mainly focused on the effect of solar shading because the amount of solar energy is larger compared to other factors. By narrowing a space between the slats to 10 mm, the louver system allows direct solar radiation to transmit only at solar altitude lower than 13°, which corresponds to approximately an hour before and after the sunset and sunrise (Figure 3(b)).

THERMAL CHARACTERISTICS OF THE PASSIVE COOLING LOUVER SYSTEM

Aim of the Experiment

An outdoor experiment was conducted in order to verify thermal performance of the PC louver in means of clarifying the heat balance of the PC louver's surface. The heat transfer model is expected to be inserted in a microclimate simulation tool (Asawa et al., 2008), which the authours have developed. In order to analyze the spatial distribution of the microclimate in the simulation, the heat transfer model of PC louver is required to be simplified to reduce calculation load. Therefore, a distribution of the surface temperature of the PC louver is verified at the experiment in order to discuss the possibility to treat PC louver's surface as a thermally equivalent semi-permeable vertical plane. A description of the PC louver's heat transfer model is shown in Figure 4.

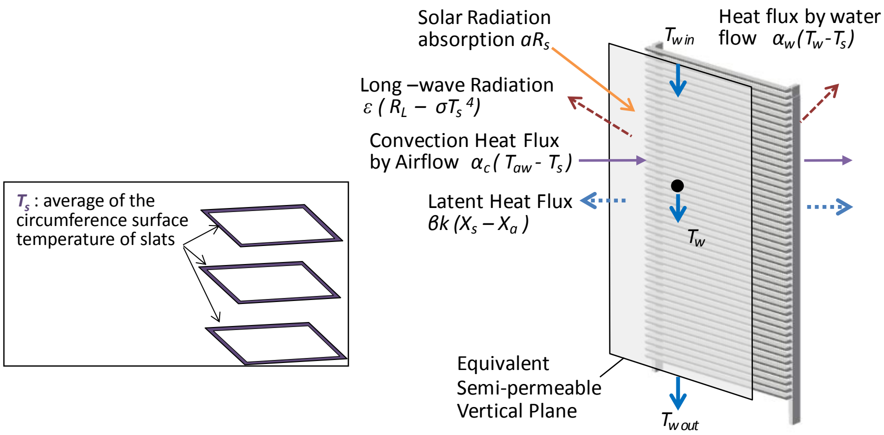

Figure 4 A description of heat balance at the PC louver's surface.
Modeled as an equivalent semi-permeable vertical plane

Measurement Methods

A terrace with the PC louver was constructed in semi-outdoor space of a detached house, facing the southwest direction (220°). The site was open to the predominant wind direction, thus wind flowed into the terrace from the front to diagonal direction of the louver. Two PC louver planes on the front side of the house were attached to the pergola, which the east side louver was wetted during the experiment (the wet PC louver) and the west side louver was kept dried (the dry PC louver) for comparison purposes. The scheme of the PC louver and the measurments are shown in Figure 5 and Table 2.

The measurement was conducted on Oct.1st 2012 and Aug. 4th 2013 to Nov. 29th 2013. Air temperature at at the vicinity of the PC louver was measured using aΦ = 0.1 mm T-type thermocouple set inside a forced draft Φ = 13 mm polyvinyl cylinder (air velocity of approximately 1.5 m/s), in order to reduce the influence of solar radiation. Ambient dry bulb and wet bulb temperature were measured inside a forced draft Φ = 150 mm aluminum cylinder (air velocity of approximately 3 m/s). A water tube with Φ = 6 mm was inserted through the strut to the beam of the pergola. The amount of water supplied was measured right below the water drip tube and the amount of water drainage was measured at bottom of PC louver using a tipping-bucket rain gauge. During the experiment, tap water was supplied at approximately 0.04 kg/min per PC louver's vertical plane. Although, for hot and humid regions with a large amount of rainfall during summer, where the amount of precipitation is enough to cover the evaporation amount, we are working to construct a system to use rain and supply it to the PC louver.

Measurement Results

Wet and Dry PC Louver's Surface Temperature The distribution of the wet state of the louver was difficult to measure, thus surface temperature distribution was measured using an infrared camera. Figure 6 (a) shows the surface temperature distribution of the terrace side and the outside of the PC louver at 13:00 on Aug. 7th 2013, as a representative day of a clear sunny day. Overall, there was about a 3 °C range in surface temperature distribution of the wet PC louver. As shown in Figure 6 (b), the outside surface of the louver had a large distribution of solar radiation due to its ragged form, but the difference in surface temperature was small. This indicates that the quantity of solar radiation does not determin the surface temperature of the wet louver, but the latent heat, as the quantity of evaporation shown in Figure 9, is the main factor. The small distribution in the wet PC louver's surface temperature also indicates that the convective heat flux of water flow is small compared to other heat fluxes at the experimented amount of watter supply. This is also confirmed by the calculation of He et al., (2008) that only a few centimeters of the wet surface's temperature are affected by the water's temperature.

From these result, the small range of surface temperature distribution was confirmed when the entire surface is wet. The range was small enough to use the average temperature as a representative temperature for an equivalent vertical plane, when discussing on the microclimate in residential space.

Figure 6 Surface temperature distribution of the PC louver.

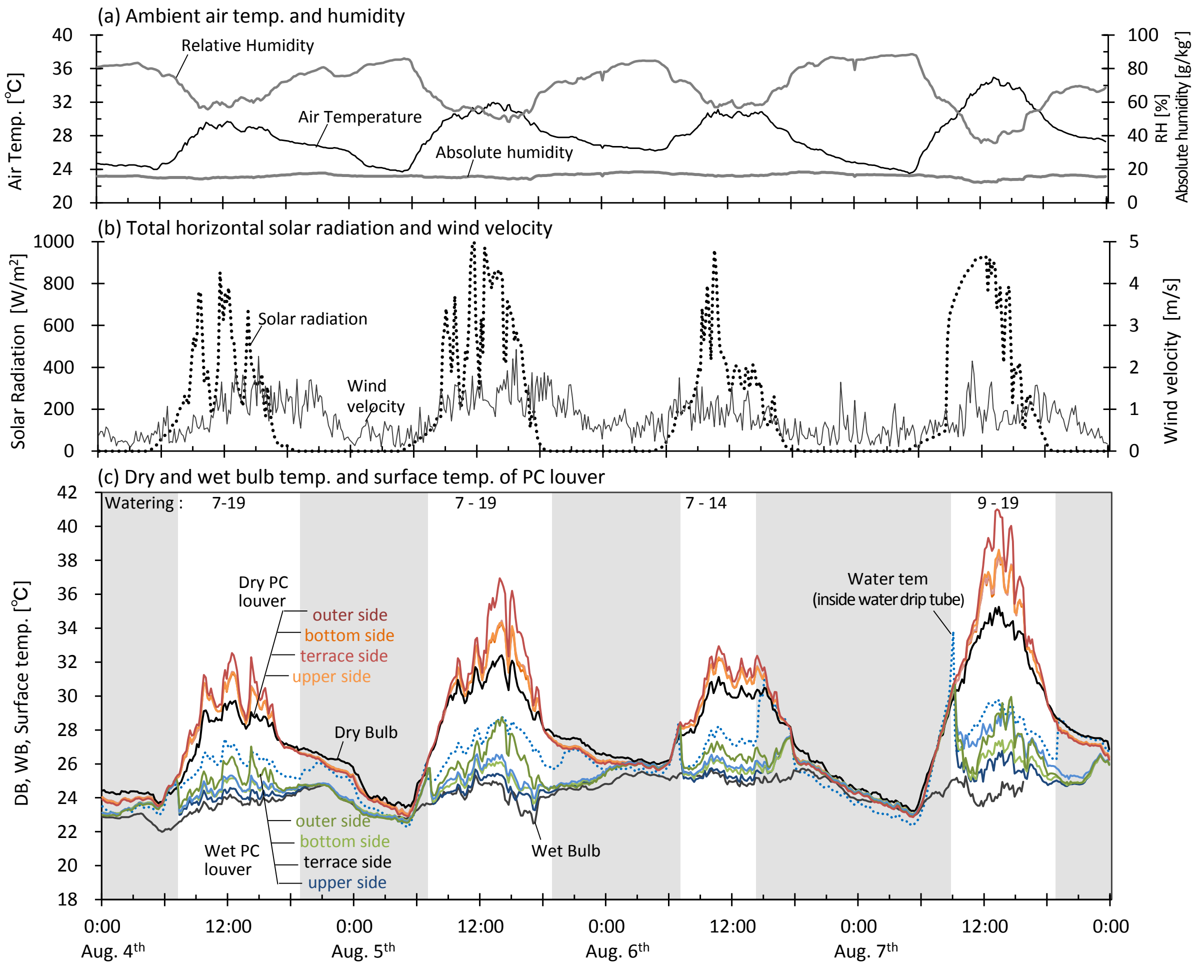

Figure 7 Diurnal surface temperature change of the wet PC louver and the dry PC louver.

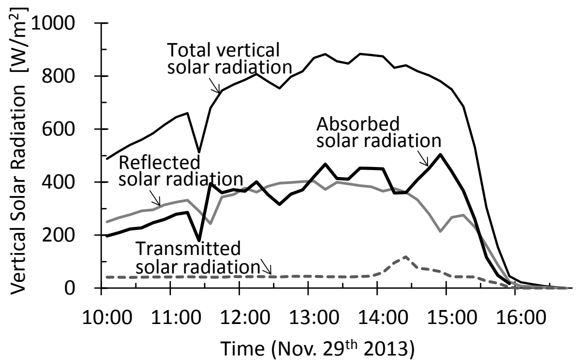

Figure 8 Quantity of Solar reflectance and transmittance.

Diurnal surface temperature change of the PC louver is shown in Figure 7. From Aug. 4th 2013 to Aug. 7th 2013, water was supplied continuously during the daytime as shown in the white bands in Figure 7. Surface temperature of the dry PC louver exceeded 40 °C, while the surface temperature of the upper side and terrace side of the wet PC louver was only 0–1.5 °C higher than the ambient wet bulb temperature, which indicates the effect of evaporative cooling at the louver's surface.

Transmittance and Absorption of Solar Radiation The amount of transmitted solar radiation was approximately 50 W/m^2 during daytime in a sunny day, which is about 5 % of the incident solar radiation (Figure 6). Direct solar radiation was calculated to transmit at an hour before and after the sunset and sunrise, but solar transmittance did not increase, since the quantity of solar radiation was already small at these times. Solar radiation absorption was calculated by the deduction of transmitted solar radiation and reflected solar radiation from incident solar radiation, and the solar radiation absorption was approximately 47% during the daytime.

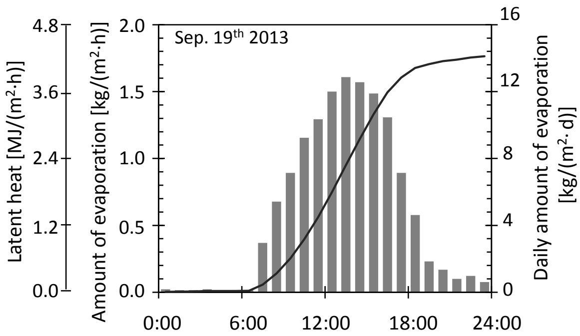

Figure 9 Evaporation rate and daily amount.

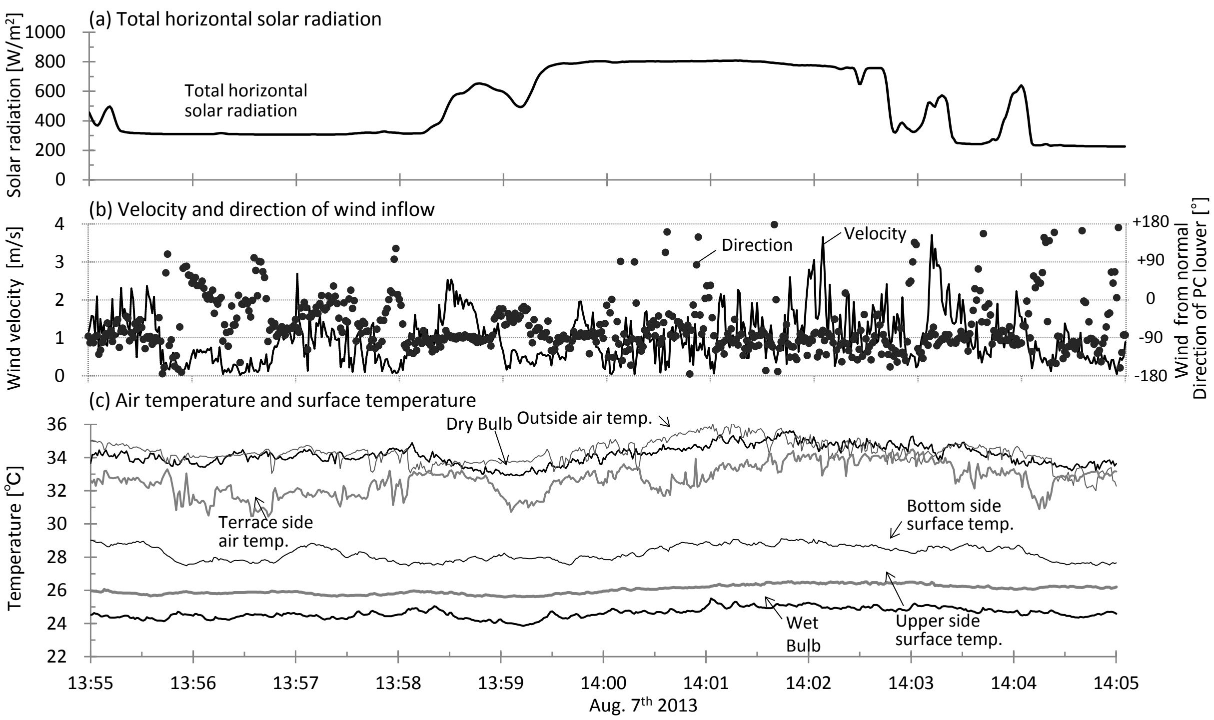

Figure 10 Air temperature at the vicinity of the PC louver. (Data interval: 1sec.)

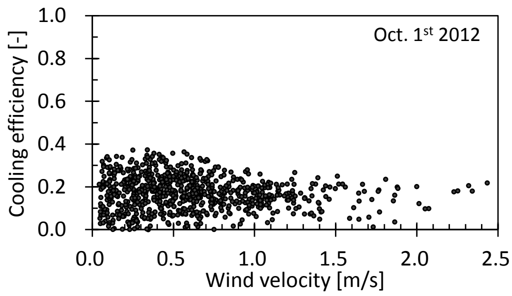

Figure 11 Cooling efficiency of air passing through the PC louver.

Evaporation Rate Evaporation rate per vertical surface plane of a representative sunny day is shown in Figure 9. Water was supplied continuously for 24 hours during this period. From the experimental results, 14 kg/m^2 of water evaporated in a day, which is equivalent to 34 MJ/m^2 of latent heat flux. This is about two to three times larger than that of standard water retentive pavements.

Air temperature in front and behind the PC louver Wind direction in Figure 10 is shown by considering the normal direction from outside to PC louver as 0°. When wind speed was larger than 0.5 m/s, air temperature at the vicinity of the PC louver varied depending on wind's direction. When wind direction is 0° to ±45° at 13:56–13:58, air temperature decreased approximately 2 °C in the terrace side compared to the outside air temperature. When wind direction is ±45° to ±90°at 14:02–14:03, air temperature difference was not significant. Air temperature in terrace side also decreased with a breeze (wind velocity less than 0.5 m/s) at 13:59 and 14:04. Here, the cooling effeciency of wind penetrating the PC louver is evaluated by the following index η, based on the ambient wet bulb temperature:

$$\eta = (T_a - T_l)/(T_a - T_{wb}) \tag{1}$$

Figure 11 shows the calculated data when wind continuously passed through the louver from the normal direction for more than 3 sec. η tended to stabilize at 0.2 when wind velocity is larger than 2 m/s, and distributed between 0–0.4 at breeze. This is a similar feature to the former PCW that the maximum value of η is recognized at breeze, but stabilizes at smaller value as wind velocity increases.

CONCLUSION

This study investigated the potential use of an evaporative cooling system during daytime in urban cities in hot and humid regions. A "Passive Cooling Louver System," coated with hydrophilic resin, porous particles, and a photocatalyst was developed as an exterior material for residences.

From the outdoor experiment the following thermal performances were revealed: 1) The surface temperature of the wet PC louver was approximately the ambient wet bulb temperature. 2) The distribution of the wet PC louver's surface temperature was small enough that it can be modeled as an averaged value of an equivalent vertical plane. 3) Transmittance of direct solar radiance is few. 4) The maximum amount of daily evaporation of the PC louver is approximately 14 kg/m^2 (≈ 34 MJ/m^2 of latent heat) per vertical plane. 5) Air temperature at the vicinity of PC louver decreased by 3 °C at most. From these results, the required cooling performance as a development of the PC louver was confirmed. For the next step, we will construce a thermal transfer model of the PC louver and incorporate it to a microclimate simulation tool, in order to aid spatial design to form cool microclimate.

ABSTRACT

The objective of this study is to evaluate the current building material stock and future demolition waste for urban houses using a material-flow analysis in Jakarta and Bandung. Their embodied energy and CO_2 emissions are also analyzed by using an input-output analysis method. The actual on-site building measurements were conducted in Jakarta (2012) and Bandung (2011), focusing on unplanned houses, to obtain building material inventory data. A total of 297 and 247 houses were investigated in Jakarta and Bandung, respectively. These houses were generally classified into the following three categories: simple (45%), medium (39%) and luxurious houses (16%). The results show that overall, the averaged material quantity per m^2 used for the houses is 2.14 ton/m^2 in Jakarta and 2.06 ton/m^2 in Bandung. Two scenarios with zero and maximum reuse/recycling rates were designed to predict future demolition waste and embodied energy/CO_2 emissions of building materials in Jakarta. Closed- and open-loop material flows were applied. The maximum reuse/recycling rates not only decrease material waste (0.93-1.22 ton/m^2) but also their embodied energy (16.8-151.1 GJ) and CO_2 emissions (1.6-14.9 ton CO_2-eq). In contrast, the minimum reuse/recycling rates increase environmental burden, and the expansion of unplanned houses is anticipated to cause further urban sprawls and drastic land-use changes by 2020.

INTRODUCTION

One of the obstacles to analyze embodied energy and CO_2 emissions of building materials in developing countries such as in Indonesia is considered to be relatively poor data availability of life cycle building materials from material input to material output (waste) including construction and demolition waste (C&D). The majority of urban housing stocks in Indonesia are unplanned houses. These houses are not designed and constructed in a formal way. Therefore, there is a serious lack of building material inventory data which are required for the analysis of material flow and their embodied energy/CO_2 emissions.

This study analyzes flow of building materials and their embodied energy/CO_2 emissions for urban houses in Indonesia, focusing on unplanned houses, through the material-flow analysis and the input-output (I-O) analysis methods. The actual on-site building measurements were conducted in Jakarta (2012) and Bandung (2011), to investigate building material inventory. The current status of material stock was evaluated. Further, life-cycle material flows, focusing on demolition waste and their embodied energy/CO_2 emissions of urban houses are predicted in different scenarios with various reuse/recycling rates.

METHODOLOGY

Case study cities and houses

Jakarta and Bandung were selected as case study cities. Jakarta, the capital city, had a population of 9.99 million in 2012 (Jakarta, 2013) while that of Bandung had 2.45 million as of 2012 (Bandung, 2013). Both cities experience hot and humid tropical climates. However, the monthly average temperature in Bandung (22.9-23.9 ºC) is not as high as Jakarta (27.1-28.9 ºC) because of its relatively high altitude. On average, Bandung and Jakarta are located at 791 and 7 m above the sea level, respectively.

In most of the major cities in Indonesia, unplanned houses called '*Kampungs'* account for the largest proportion of the existing housing stocks. These dwellings settled in unplanned and overcrowded urban villages without being provided with basic urban infrastructure and services properly. These unplanned houses accounted for about 74% of the total housing stocks in Jakarta as of 2012 (Jakarta, 2013) and about 89% in the case of Bandung (Bandung, 2013). Moreover, these unplanned houses can be further classified into three house categories based on its construction cost and lot size, namely simple, medium, and luxurious houses (**Figure 1)** having a lifespan of 20, 35, and 50 years, respectively (SNI, 1989).

A total of 297 and 247 residential buildings were investigated in Jakarta and Bandung, respectively (see **Table 1**). As shown, the average household size is about 4-5 persons with a small variation between the three categories for both cities. The monthly average household income was also investigated by a multiple-choice question. As expected, the average income increases with house category from simple to luxurious houses. In general, the average income in Jakarta is slightly higher than that of Bandung. The total floor area also increases with house category in both of the cities. The major building materials used are found to be almost the same in both cities among the above three house categories, though slight differences can be seen in terms of materials for floor and roof.

Current material stock in urban residential buildings

The limitations of data for building, economy and environment in Indonesia make it difficult to clarify the current material stock in urban residential buildings, and to design and implement concrete policies to deal with the issues of C&D waste management. In this study, firstly, we attempt to evaluate a) the current building material stock in urban residential buildings in Jakarta and Bandung at the city level respectively, b) the future demolition waste in unplanned urban houses, and c) the future urban expansion due to demolition of unplanned houses in both of the cities, based on the survey results.

The mathematical equations used to estimate the current material stock for urban houses are described as follows. In this analysis, it is assumed that 1) the number of housing stocks are equal with the number of households determined by number of populations and household size, 2) the income distribution in urban settlement areas of Jakarta and Bandung is the same as the status of whole Jakarta city assuming that low, middle and high income people live in simple, medium and luxurious houses, respectively.

$$TS = \sum_{i}\sum_{j} S_{i.j} \, . \, H_j \tag{1}$$

$$S_{i,j} = \gamma_i \left(PI_{i,j} + MI_{i,j} \right) \tag{2}$$

Source: Building material inventory surveys in Jakarta (2012) and Bandung (2011)

$$H_j = \alpha . \beta_j \frac{TP}{\overline{HS_j}} \tag{3}$$

$$SA_{i,j} = \frac{S_{i,j}}{F_j} \tag{4}$$

Where, *TS*: current total material stock of urban houses (kg), $S_{i,j}$: stock of material *i*, included in the house type *j* (kg/house), subscript *i*: materials shown in **Table 3**, subscript *j*: house type (simple, medium and luxurious) shown in **Figure 1**, and H_j: number of house type *j*, γ_i: the density of material *i* (kg/m^3) shown in **Table 3**, $PI_{i,j}$: volume of primary material *i* input for each type of house for production activities (m^3), $MI_{i,j}$: maintenance volume of material *i* for each type of house (m^3), α: share of population living in urban houses among the total population (Jakarta: 0.74; Bandung: 0.89), β_j: current income distribution (low income (living in simple houses): 0.75, medium income (living in medium houses): 0.20, high income (living in luxurious houses): 0.05) (Mizuho, 2010), *TP*: total population in 2012, $\overline{HS_j}$: averaged household size for each type of houses, $SA_{i,j}$: stock of material *i* per unit gross floor area in house type *j* (kg/m^2), F_j: averaged gross floor area in house type *j* (m^2).

The mathematical equations used to estimate demolition waste from unplanned houses until 2020 are described as follows. In this analysis, we only focus on the demolition waste, generated from the current material stock, estimated by Equation (1). It is assumed that 1) the predicted population of Jakarta and Bandung would be 11.6 and 2.9 million in 2020 (UN, 2011), 2) the share of each type of houses in unplanned residential buildings will be changed in proportion to the significant change in income level; 4% for high, 73% for medium and 23% for low income class (JETRO, 2011), 3) the medium and luxurious houses will not be demolished until 2020, based on the assumption of 2) and buildings' life-spans (i.e. medium houses: 35 years, luxurious houses: 50 years), 4) zero reuse/recycling rates of each material.

$$TW = \sum_i W_{i,simple} . H_{simple} \cdot \eta_{simple} \tag{5}$$

$$\eta_{simple} = \frac{\beta_{simple} - \beta^F_{simple}}{\beta_{simple}} \tag{6}$$

$$WA_{i,simple}=W_{i,simple}/F_{simple} \quad (7)$$

Where, *TW*: total demolition waste from unplanned residential buildings until 2020 (kg), $W_{i,simple}$: demolition waste of material *i* from a simple house (kg) (equal with material stock of simple houses), η_{simple}: demolition ratio of simple houses by 2020, $S_{i,simple}$: stock of material *i*, included in a simple house (kg), β^{F}_{simple}: income distribution of low income group in 2020 (0.23), $WA_{i,simple}$: demolition waste *i* per unit gross floor area in a simple house (kg/m^2), F_{simple}: average gross floor area of a simple house (m^2).

The mathematical equations used to estimate the urban expansion caused by the demolition of unplanned simple houses and the transformation from these simple houses to larger medium houses by 2020 are described as follows. In this analysis, it is assumed that all the demolished simple houses will be reconstructed to be medium houses in the same cities.

$$FE=\left(F_{medium}-F_{simple}\right).H_{simple}.\eta_{simple} \quad (8)$$

Where, *FE*: future urban expansion by 2020 (m^2), F_{medium}: average gross floor area of a medium house (m^2).

Flow of materials and their embodied energy/CO_2 emissions for each type of houses

Secondly, this paper analyzes the per-floor area flow of building materials and their embodied energy/CO_2 emissions for each of the house categories by taking Jakarta for example. Embodied energy/CO_2 emissions of building materials generally includes energy for productions in several phases, including material extraction, production, construction, maintenance, and demolition phases. However, construction and demolition phases were not considered in this paper due to the data unavailability.

The design records such as building drawings are required for the analysis of embodied energy of building materials. These data were available for most of the planned houses and unplanned luxurious houses only. The other houses including most of the unplanned simple and medium houses were not constructed in the formal way (normally constructed by non-professional neighbors) and therefore the required design records could not be obtained. Thus, the actual on-site measurements by using laser-distance meters and tape measures were conducted for unplanned simple and medium houses in order to acquire the data.

Since it was impossible to trace all the production processes for most of the building materials due to the data unavailability, this study adopted the I-O analysis-based method to calculate the embodied energy of materials and estimate their CO_2 emissions, which consistently followed the method described by Nansai et al. (2002). The latest Indonesian nationwide I-O table published in 2005 (Indonesia, 2005) consisting of 175 x 175 sectors was used for calculating the embodied energy/CO_2 emissions, which was measured in the form of primary energy. The detailed procedures of the embodied energy/CO_2 emissions were described in the previous paper (Surahman & Kubota, 2012).

In this analysis, we assess the effects of policy of promoting reused and recycled material use through a scenario analysis. The first scenario (Scenario 1) assumes that both recycling and reuse rates are set to be zero (minimum) and the second scenario (Scenario 2) is designed under the assumption that both reuse and recycling rates for respective building materials are increased to the maximum values (see **Table 2**). The effects of the promotion of reused and recycled building materials use are evaluated through the comparison between two scenarios. The per-house material stock and demolition waste for respective house categories are estimated based on the following equations.

$$W_{i,j}=S_{i,j}\left(1-RU_{i,j}-RC_{i,j}-TR_{i,j}\right) \quad (9)$$

$$WA_{i,j}=W_{i,j}/F_j \quad (10)$$

$$S^R_{i,j}=\gamma_i\left[PI_{i,j}\left(1-RU^p_{i,j}-RC^p_{i,j}\right)+MI_{i,j}\left(1-RU^M_{i,j}-RC^M_{i,j}\right)\right] \quad (11)$$

Where, $W_{i,j}$: demolition waste of material i from a house type j (kg/house), $S_{i,j}$: stock of material i, included in a house type j (kg/house), $RU_{i,j}$: reuse ratio of material i, applied to a house type j (as shown in **Table 2**), $RC_{i,j}$: recycle ratio of material i, applied to a house type j (as shown in **Table 2**), $TR_{i,j}$: treatment ratio of material i, applied to a house type j (assumed to be zero), $WA_{i,j}$: demolition waste i per unit gross floor area of a house type j (kg/m^2), F_j: average gross floor area of a house type j (m^2), $S^R_{i,j}$: Stock of virgin material i in a house type j (kg/house), $RU^p_{i,j}$: reuse ratio of primary input (construction), $RC^p_{i,j}$: recycle ratio of primary input (construction), $RU^M_{i,j}$: reuse ratio of maintenance, $RC^M_{i,j}$: recycle ratio of maintenance. The potential reuse/recycling rates of building materials were studied from some references as shown in **Table 2**.

Table 2 Potential reuse and recycling rates

RESULTS AND DISCUSSION

Current building material stock

This section discusses the current total material stock and future demolition waste in urban houses at the city level in Jakarta and Bandung. The current building material stocks in urban houses in two cities in 2012 were calculated utilizing Equations (1)-(4). **Table 3** shows the composition of the current building material input, including those for maintenance, in the two cities. As shown, overall, the average material quantity per m^2 is 2.14 ton/m^2 in Jakarta and 2.06 ton/m^2 in Bandung. The average material quantity slightly varies among the different house categories in Jakarta and Bandung: 2.26 and 1.88; 2.06 and 2.23, and 2.05 and 2.26 ton/m^2 for simple, medium and luxurious houses, respectively. Overall, stone accounts for the largest percentage in Jakarta and Bandung (32% and 31%), followed by sand (31% and 30%), clay brick (19% and 19%), cement (8% and 8%), etc. The current total material stock in urban houses of Jakarta is measured at 232.0 million ton, while that of Bandung was 77.2 million ton. The difference between the two cities is mainly due to the number of houses difference.

Future demolition waste from unplanned residential buildings until 2020

If both reuse and recycling ratios are assumed to be zero, then the total demolition waste of unplanned houses (i.e. only simple houses) in Jakarta is found to be 41.5 million ton/m^2 until 2020 and all of them go to the landfills (Equations (5)-(7)). Meanwhile, the corresponding amount of waste in Bandung is predicted to be lower (12.6 million ton/m^2) due to less households of simple houses. This scenario will cause the waste to landfills would be very huge, thus results in the overload in the landfills. As a consequence, this scenario anticipates that both Jakarta and Bandung would be forced to construct new landfills to deal with the increased waste in the near future.

Urban sprawl caused by the transformation from simple houses into medium houses

The future demolition of unplanned houses and the transformation of these houses to the larger medium houses by 2020 would cause the further urban expansions in both of the cities: at least, the additional area of 20.0 km^2 is required for the new constructions in Jakarta while the area of 5.7 km^2 is required in Bandung (Equation (8)). These expansions would accelerate urban sprawls.

Scenario analysis: Policy effects of promoting reused/recycled materials use on reduction of building waste and embodied energy/CO_2 emissions

*: (SNI, 1989)

Scenario 1; zero reuse and recycling rates. The following section analyze the flow of building materials per-house for each of the house categories by taking Jakarta for example. As described before, we assess the effects of policy of promoting reused and recycled material use through scenario analysis. In this scenario (Scenario 1), the zero reuse/recycling rates are applied to all building materials used for a house. **Figure 2** shows the results of flow analysis for average material input and output of urban houses in Jakarta utilizing zero reuse/recycling rates for whole sample as example. As shown, the total average material inputs including those for maintenance for whole sample ('B' in the **Figure 2**) are derived from **Table 3**. A few materials are imported such as ceramics (37.5 kg/m^2) in the case of luxurious houses. There is no materials reused/recycled for other buildings/products ('E' and 'F') in this scenario. Thus, all materials go to the landfills ('G'). Equations (9)-(10) were used to calculate demolition waste for each of the house categories. The total average waste to landfills is larger than the average material input due to additional waste of soil derived from the surplus soil extracted in the construction phase ('C'), accounting for 2,931.1, 2,521.3, 2,371.5 and 2,665.1 kg/m^2 for simple, medium and luxurious houses as well as whole sample. Overall, mortar accounts for the largest material waste (23%), followed by soil (20%), stone foundation (17%), concrete (16%), clay brick (15%), etc.

Scenario 2; maximum reuse and recycling rates. In this scenario (Scenario 2), we apply the maximum potential for reuse/recycling rates (see **Table 2**). **Figure 3** shows the results of flow analysis of building material input and output for urban houses in Jakarta in Scenario 2 for whole sample. As shown, the total average material input including those for maintenance for respective houses in Jakarta are still the same as those in the Scenario 1 ('B' in the **Figure 3**). However, some materials (589.9 kg/m^2) were reused for other buildings ('E'), including stone (77%), wood (11%), clay brick (7%), etc. Meanwhile, several materials (464.0 kg/m^2) are recycled ('F'), including clay bricks (79%), wood (13%), steel (6%), gypsum (1.5%) and zinc roof (0.5%). There is no material composted/burned ('I'). The rest of materials (soil, mortar, concrete, ceramic and asbestos) are assumed to be reclaimed to other products or infrastructure ('H'). The total waste used for reclamation accounts for 1,715.3, 1,596.3, 1,412.0 and 1,611.1 kg/m^2 for simple, medium and luxurious houses as well as whole sample. Overall, mortar accounts for the largest percentage (39%) followed by soil (32%), concrete (27%), and ceramic tile and asbestos (2%). These materials can not be reused/recycled for other building constructions due to difficulty of separation from mixed materials. Thus, it was found that closed-loop material flow is not enough to fully reclaim building materials and eliminatebuilding material waste to the landfills. Nevertheless, these materials can be reused/recycled by crushing them and used to reclaim for infrastructure such as road and building site. In this case, the total waste to the landfills would become zero.

Figure 4 shows the average material waste of respective houses for both scenarios. As shown maximizing reuse/recycling rates would decrease the average material waste dramatically by 41%, 37% and 40% for simple, medium and luxurious houses, respectively.

... puts were obtained by utilizing Equation (11) for analyzing their em... The total embodied energy and CO_2 emissions were estimated by co... d recycling embodied energy/CO_2 emissions for respective houses thr... analysis-based method. The potential energy saving through recycling wa... lied energy/CO_2 emissions (Thornmark, 2002). **Figures 5-6** show the tot... onsin the two scenarios (i.e. zero and maximum reuse/recycling rates). The results indicate that the reused/recycled materials reduce not only material waste but also diminish embodied energy/CO_2 emissions. The maximum reuse/recycling ratesare expected to decrease embodied energy by 16.8 (27%), 58.1 (28%), 151.1 (27%) and 58.6 (27%) GJ for simple, medium, luxurious and whole houses, respectively (**Figure 5**). Meanwhile, the reduction patterns of embodied CO_2 emissions are similar with those of embodied energy (**Figure 6**).

The results of the above scenario analysis prove that the promotion of reuse/recycling are important to ensure the building material stocks and to reduce not only material waste but also their embodied energy/CO_2 emissions.

CONCLUSIONS

This study analyzed flow of building materials and their embodied energy/CO_2 emissions for urban houses in Indonesia, focusing especially on unplanned houses. The actual on-site building measurements were conducted in Jakarta (n=297) and Bandung (n=247) to investigate building material inventory.

- Overall, the average material quantity per m^2 was 2.14 ton/m^2 in Jakarta and 2.06 ton/m^2 in Bandung.

The average material quantity slightly varied among the different house categories in Jakarta/Bandung: 2.26/1.88, 2.06/2.23 and 2.05/2.26 ton/m^2 for simple, medium and luxurious houses, respectively. On average, the stone accounted for the largest percentage for all houses (32%/31%), followed by sand (31%/30%), clay brick (19%/19%), cement (8%/8%), etc.

- If both reuse and recycling rates are assumed to be zero, then the total demolition waste of unplanned simple houses in Jakarta was found to be 41.5 million ton/m^2 until 2020 and the corresponding waste in Bandung is predicted to be lower (12.6 million ton/m^2). All of them go to the landfills. Moreover, the transformation of these simple houses to the larger medium houses by 2020 would cause further urban expansion in both of the cities: at least, the additional area of 20.0 km^2 is required for the new construction in Jakarta, while the area of 5.7 km^2 is required in Bandung.
- A scenario analysis was conducted for Jakarta to assess the effects of policy of promoting reused and recycled material use. The two scenarios with the zero and maximum reuse/recycling rates were compared in the analysis. The results showed that maximizing reuse/recycling rates would decrease the average material waste dramatically by 37% to 41%. The promotion of reuse/recycling were proved to reduce embodied energy/CO_2 emissions of building materials effectively (27% to 28%).
- The lack of policies for promoting 3Rs (reduce, reuse and recycling) specifically target C&D waste (Indonesia, 2008) at the national level is considered one of the crucial problems in Indonesia.
- The increase in larger landed houses would directly result in the rapid horizontal expansions of the cities, thus accelerates urban sprawls. Provision of mid-to-high-rise apartments to the growing middle class in the cities would be one of the effective housing policies for already crowded Indonesian cities.

Urban Climate mapping of an Institutional Campus in Hot-Humid Climate using GIS

Surya Rajkumar, BArch **Lilly Rose Amirtham, PhD** **Ebin Horrison, M.Arch**

Sathyabama University, Chennai
surya.archie@gmail.com

ABSTR ACT

Urbanization modifies the built form to a greater extent and exerts extreme heat stress due to the urban heat island (UHI) effect in hot and humid climates. Sathyabama University - an institutional campus in Chennai experiences a UHI intensity of 6°C to 10°C during the day. The students in the campus often use the outdoor spaces for their interactions and discussions. This paper aims to map the urban climate in an institutional campus and analyze the outdoor comfort conditions. The urban climate mapping is done through field measurements and comfort conditions are analyzed through a questionnaire survey. The field measurements include the recording of hourly air temperature and humidity data using HOBO U20 datalogger on a hot summer day. Isopleths are derived using ArcGIS and the heat and cool pockets in the campus are identified. The questionnaire survey records the thermal sensation of the students and is compared with the isopleths to arrive at a climate sensitive design. The survey results can aid in improving the outdoor comfort through increase in vegetation cover in the campus.

INTRODUCTION

Urbanization modifies the built form to a greater extent and exerts extreme heat stress due to the urban heat island (UHI) effect in hot and humid climates. Also the urban land uses and the related activities increase the urban air temperatures. The increased temperatures in urban areas results in the formation of heat pockets and are termed the “Urban Heat Island” (UHI) (Landsberg 1981). This thermal difference between urban and rural areas determines the intensity of heat island. The rate of cooling of open spaces when compared to that of the dense built up spaces, contributes significantly to the intensity of UHI (Givoni 1998).

Studies on climate change due to urbanization have gained momentum, and have become the main focus of research in the recent past. Urban climates are distinguished from those of less built-up areas by differences in air temperature, humidity, wind speed and amount of precipitation. These differences are mainly due to the alteration of natural surfaces with highly reflective parking lots, concrete masses, asphalt roads etc., resulting in higher absorption of solar radiation, thereby affecting the thermal environment. Oke (1981) states that the rate of cooling of urban areas at the micro level depends on two parameters; the street geometry and the sky view factor. Todhunter (1990) explains that at the canyon layer, urban geometry plays an important role in defining the spatial and temporal distribution of the UHI compared to surface materials. Saito et al (1990) found that even small green areas can reduce the temperatures by 3°C, when compared to the built up surfaces in the city of Kumamoto. Akbari et al (1992) identified that large number of trees and urban parks can reduce local air temperatures by 0.5°C to 5.1°C. Unger et al (1999, 2001) found that there exists a strong relationship between urban thermal excess and land use features and built up density in Szeged, Hungary. Johansson and Emmanuel (2006) analyzed the influence of street canyon geometry on the outdoor thermal comfort in Colombo and identified that the differences in air temperatures were higher during the day, especially in the afternoons when compared to the night and a maximum difference of 7°C was found between sites. Amirtham et al (2009) investigated the land cover changes due to urbanization in the city of Chennai from 1991 to 2000 and found a significant increase in hot spots in the city mainly attributed to the increase in the urban built up. Rose (2010) found the existence of UHI in Chennai city through the study of historic climate records from meteorological stations and also found a statistically significant increasing trend in the discomfort due to urbanization.

Thermal comfort indices combine two or more parameters into a single factor. Spagolo and de Dear (2003) found the outdoor thermal comfort index OUT SET* in the subtropical Sydney as 26.2^0C and that of the indoor SET* as 24^0C. Taib (2010) in the assessment of thermal comfort parameters in landscape gardens in high rise buildings identified significant variation in air temperature, humidity, wind speed and radiation; but the survey on users perception revealed differences only in lighting level and wind speed. Also the behavioural adaptations of users in urban open spaces in Taiwan revealed that the attendance in urban parks was influenced by sun and thermal conditions (Lin et al 2013). Yang et al (2013) found that the neutral operative temperature and preferred temperature as 28.7°C and 26.5°C in Singapore. And the study also found that people in outdoors generally have a higher tolerance level to comfort conditions when compared to indoors especially in the tropics. The study also suggested that the combination of lower density spaces with higher building heights would reduce the sky view factor value and the incoming solar radiation thus improving the outdoor thermal comfort.

Chennai, a tropical city characterized by high temperatures and humidities, suffers extensively due to the urban heat island effect which affects the outdoor thermal comfort conditions significantly. Therefore, this study aims at the enhancement of outdoor thermal comfort conditions, through urban climate mapping in an institutional campus in Chennai.

AREA OF STUDY

Sathyabama University is an institutional campus in the suburbs of Chennai experiencing hot humid climate (Figure 1a). The maximum air temperatures during summer (May and June) varies between 38°C and 42°C and the minimum air temperatures during winter (December and January) varies between 18°C and 20°C. The average monthly relative humidity ranges from 63% (June) to 80% (November) and the vapour pressure varies between 22.6hpa and 32hpa. The institution houses several academic blocks of varying street geometry. Five different locations in the campus were selected considering various parameters such as the percentage of vegetation, orientation of streets and canyon geometry (H/W ratio). The thermal properties of the built surfaces were similar in all locations. Figure 1b shows the measurement locations in the campus.

a) b)

Figure 1 a) Sathyabama University Campus, Chennai b) Measurement locations in the academic zone

1 2 3 4 5

Figure 2 Images of Measurement locations (1-5)

The data loggers placed at five strategic locations within the academic zone were based on the percentage of vegetation, orientation of streets and canyon geometry as shown in figure 2. Logger 1, 3 & 5 is placed in the N-S orientated streets with canyon geometry of 1, 2 and 1.67 respectively. Logger 2 & 4 has been positioned in the E-W streets with canyon geometry of 0.5 each.

METHODOLOGY

The air temperature and relative humidity data were measured continuously on an hourly basis using HOBO dataloggers (HOBO U20 Temp/RH) in the selected locations. The wind speed and the cloud cover data from the Nungambakkam Meteorological station were used for the study. The urban climate mapping of the campus was derived using ArcGIS. Temperature isopleths on a typical summer day are derived for 02:00 hrs, 06:00hrs, 10:00hrs, 14:00hrs, 18:00hrs & 22:00hrs. The analysis of the daytime and night time isopleths reveals the temperature distribution pattern in the campus. Also, a questionnaire survey on thermal sensation in the selected locations was conducted to study the subjective response of students to the outdoor thermal environment during daytime. The sample questionnaire used for survey is shown in appendix 1. The subjective response of the respondents and the temperature isopleths during daytime were compared to identify the appropriate built geometry for a thermally comfortable environment.

RESULTS AND DISCUSSION

Analysis of the Daytime and Night time Isopleths

The campus has various functional spaces and the present study is confined to the academic zone where most of the student interaction takes place, thus highlighting the need of a thermally comfortable outdoor environment. Table 1 shows the ambient air temperature on a typical summer day and Table 2 shows the recorded relative humidity.

Table 1. Daily Air Temperatures at Various Locations

Air temperatures and relative humidity recorded on a typical summer day has been mapped at 02:00 hrs, 06:00hrs, 10:00hrs, 14:00hrs, 18:00hrs & 22:00hrs with a four hour interval. The isopleths derived using ArcGIS is shown in Figure 3 which revealed a distinct temperature difference between the streets with greenery and non green spaces. The canyon geometry and the street orientation also had a significant impact on the temperatures.

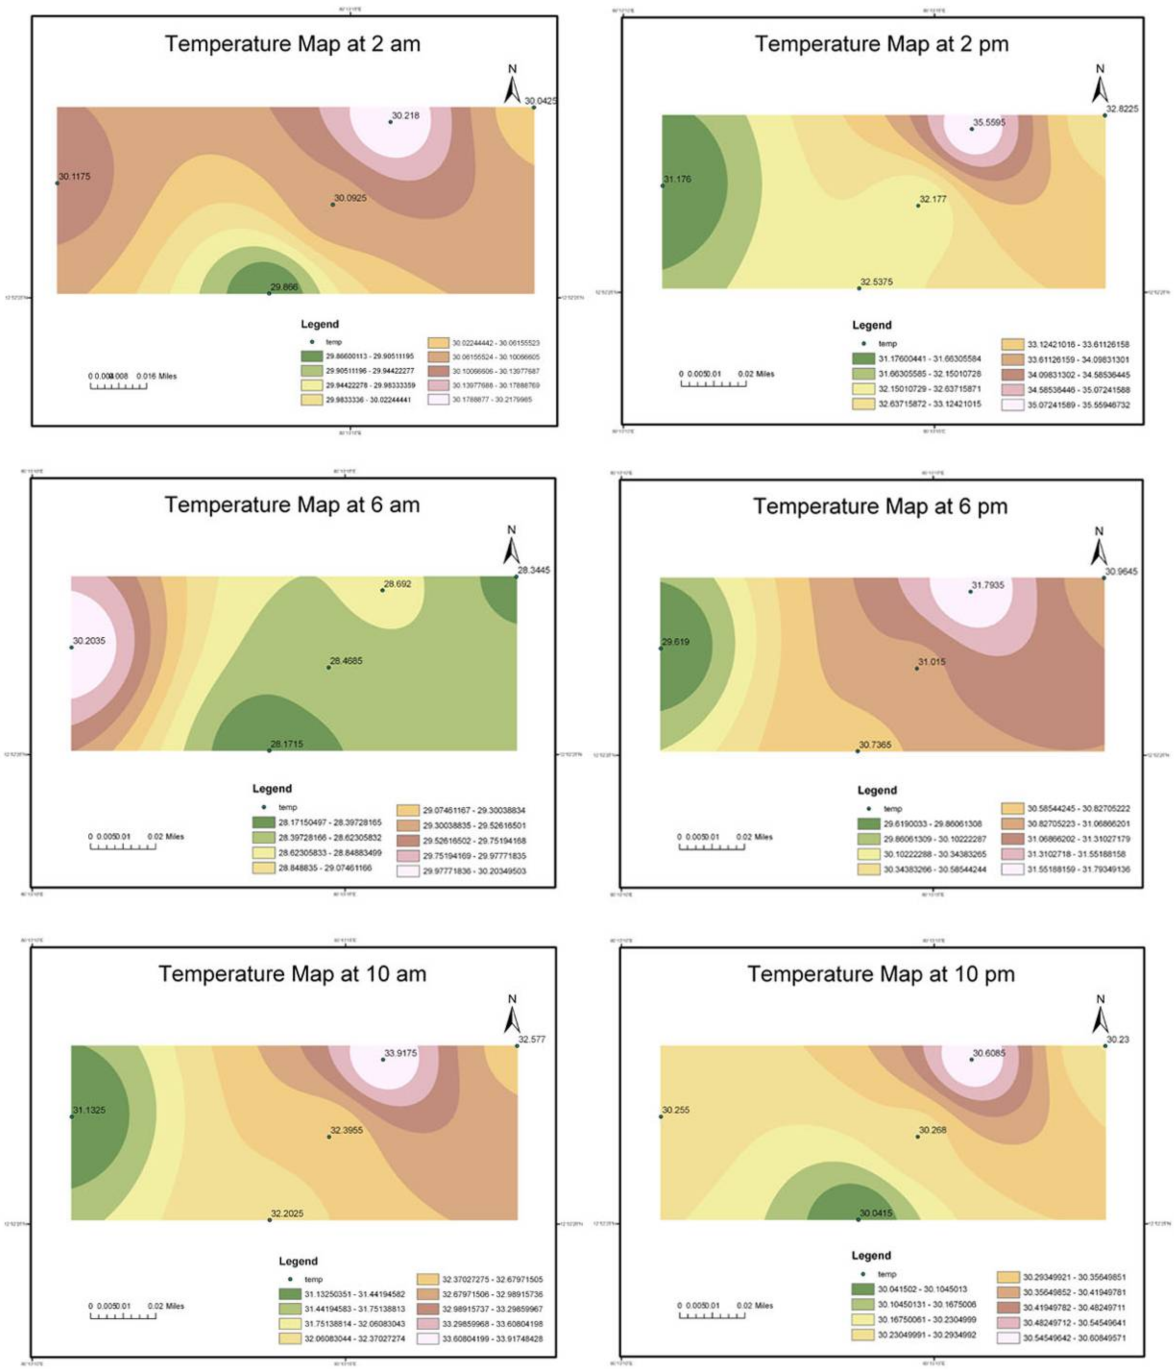

Figure 3 Temperature isopleths in the academic zone of the institutional campus at 4 hrs interval

At 6:00 am locations 1 & 4 experienced the lowest temperature and location 5 recorded the maximum temperature with a difference of 2.03^{0}C. Location 5 situated in the N-S oriented street has a higher canyon geometry of 1.67, attributed to the increase in temperature. The narrow street geometry reduces the reradiation of longwave radiation back to the sky and also because of the differential heating of the surfaces. Determining the mean radiant temperature (MRT) by measuring the long wave and short wave radiation (VDI 1994, Ali-Toudert 2005) from different directions would be more effective in calculating the outdoor comfort conditions more precisely but has not been done in this study. At 10:00hrs Location 5 experienced the lowest temperature and maximum temperature was recorded at location 2 with the temperature difference of 2.8^{0}C. The presence of vegetation at location 5 shaded the streets and also reduced the incoming solar radiation. At 2.00 PM, when the maximum temperatures are recorded, location 5 experienced the lowest temperature when compared to the other locations with a maximum heat island intensity of 4.40^{0}C. At 6.00 PM during sunset location 2 experienced the maximum temperature of 31.8^{0}C. The temperature isopleths at 6.00 PM shows clearly the existence of UHI around location 2 where the E-W orientated streets, the street geometry and non greenery play a vital role. The concrete roads, the wider streets with the reflected radiation from the abutting buildings increased the air temperatures at location 2. The cool spots throughout the day is identified at location 5 followed by location 4 which is attributed to the presence of greenery. Thus the study reinforces the fact that existence of vegetation and trees reduces the ambient air temperatures significantly. During night time, the temperature remains almost the same in all locations at 10.00 PM and 2:00 AM. Thus improvement of daytime outdoor comfort is essential in hot humid climates like Chennai.

During daytime, the relative humidity varies from 61.65% to 84.63% and the maximum humidity is recorded at location 5, due to the presence of vegetation and the minimum humidity recorded at location 2. At night, maximum humidity is recorded at location 4 and minimum at location 5. During night, the ambient air temperature at location 5 is high as the trees reduce the sky view factor thereby restricting the reradiation to the sky. The elevated air temperatures at location 5 reduce the humidity during night as shown in Figure 4.

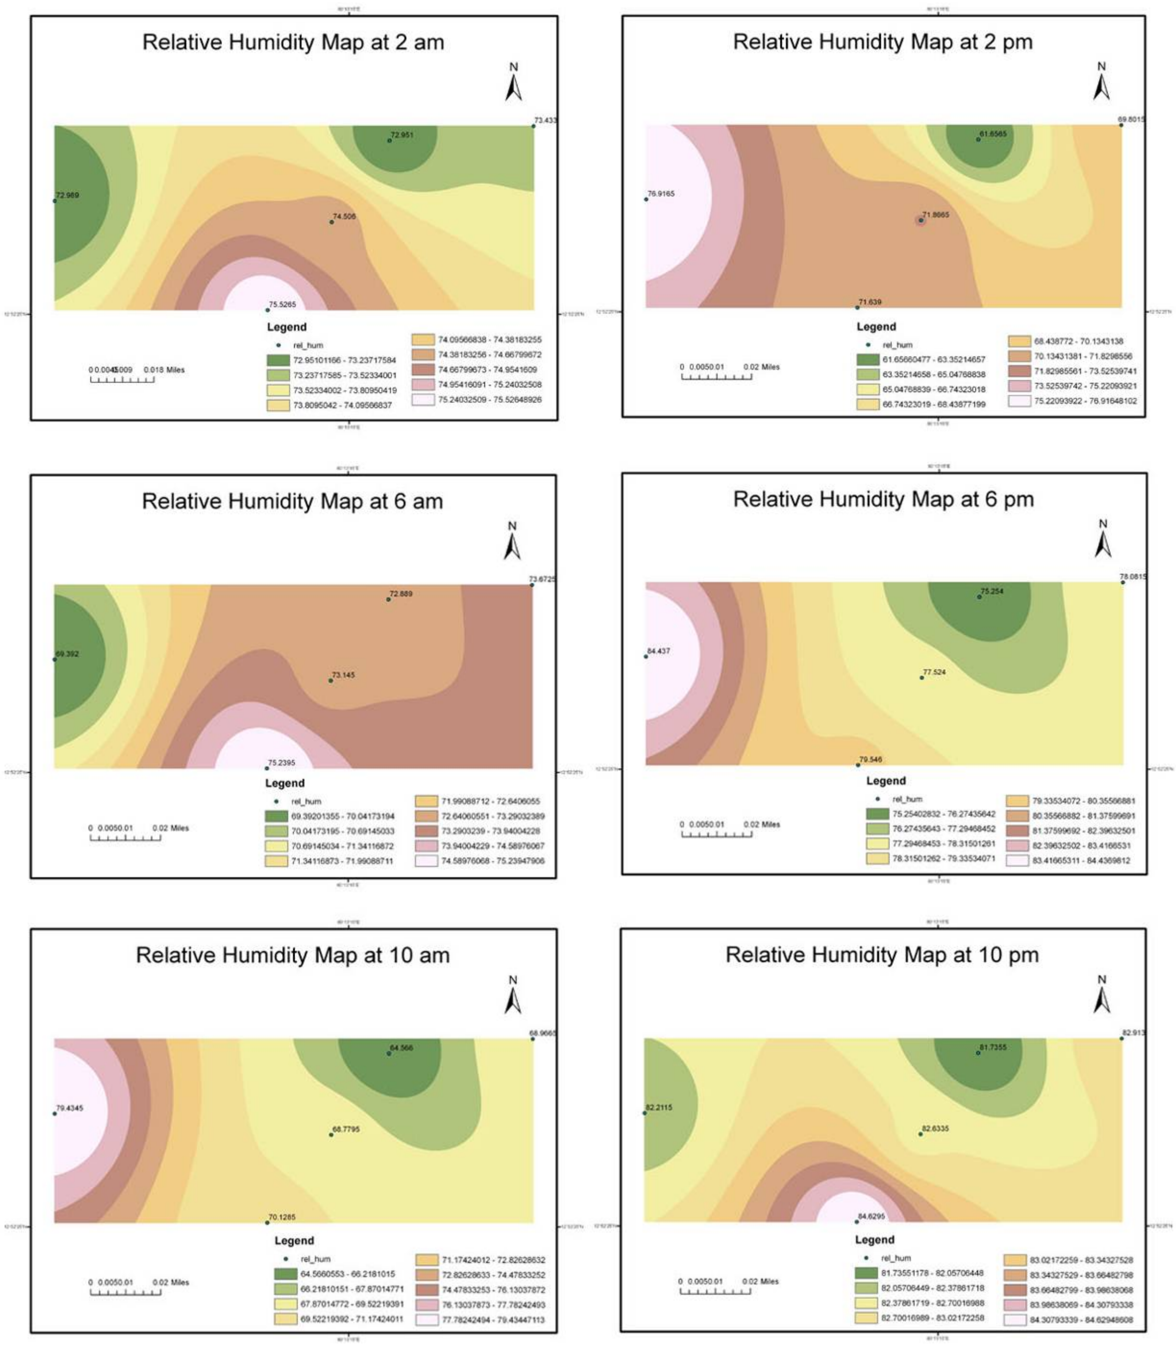

Figure 4 Relative humidity Isopleths of in the academic zone of the institutional campus at 4 hrs interval.

Analysis of Questionnaire Survey

The results of questionnaire survey in the selected locations are compared with the isopleths to comprehend the thermal sensation of the users in the academic zone. Figure 5 show the thermal perception of human with respect to the thermal sensation, feeling of comfort, satisfactory level of comfort in the place and the overall conditions of acceptance. The result on thermal sensation revealed that the respondents felt the heat and were almost tolerable at location 5 due to vegetation shading and none of the other locations were comfortable. At locations 1 & 2, the thermal perception the respondents were too warm due to the absence of shading and the reflective nature of the abutting buildings.

The users were not satisfied with the ambient air temperature in the campus. The dissatisfaction is more at locations 1 & 2 and satisfaction rates are high at locations 3 & 5 due to the presence of greenery. The overall conditions inside the campus are acceptable for the users near the locations 3 & 5 due to the N-S orientation and the presence of vegetation at location 5, thus providing a comfortable environment.

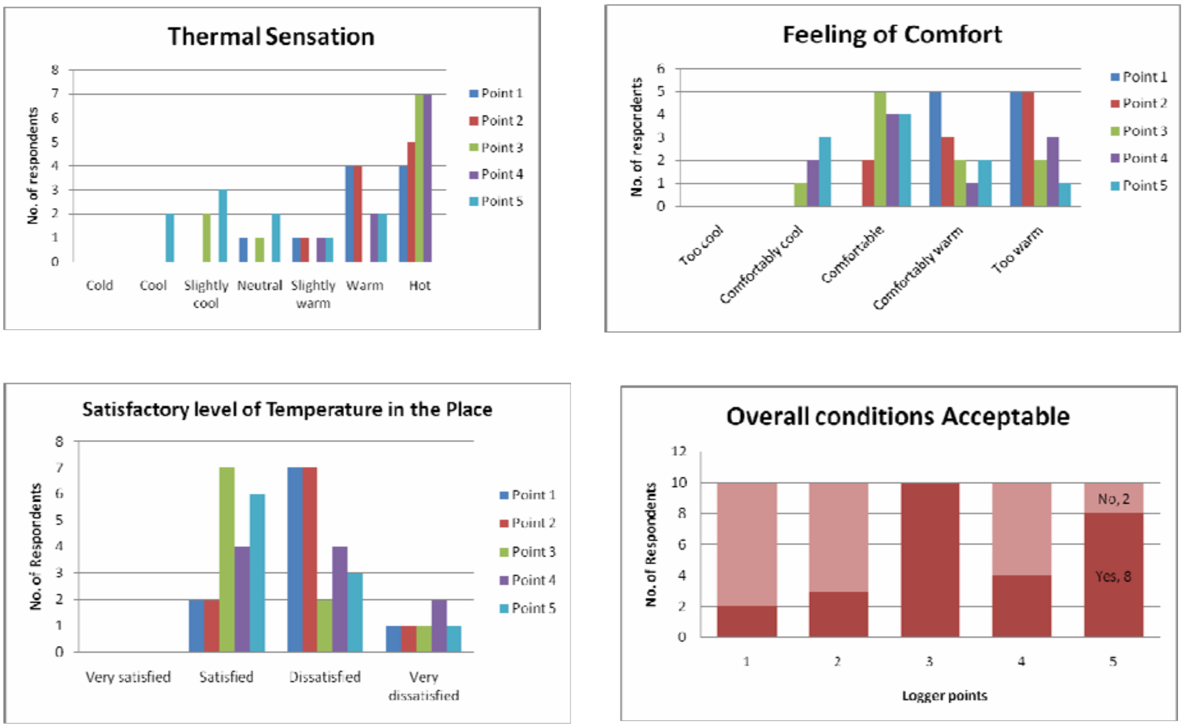

Figure 5 Bar charts showing the survey results of the respondents in the campus at various logger locations.

CONCLUSION

The study revealed that heat pocket exists in the campus at location 2 in the academic zone both during day and night. Temperature difference as high as 4.4^{0}C exists during the peak time of 2:00 PM. The radiation of heat from the buildings and pavement and the street orientation increases the ambient air temperature at location 2. Also, the absence of vegetation at location 2 accelerates the air temperature thus attributing to the heat stress. The isopelths highlights the importance of the greenery in the built form which helps in the reduction of ambient temperatures. At locations 4 and 5, the existing greenery keeps the place comfortable when compared to other locations and the respondents expressed the feel of comfort. The subjective response of students on the comfort levels of outdoor thermal environment during daytime also revealed the heat stress at location 2. Increasing the shading through vegetation in the campus and the internal shading of buildings as in location 3 with a height to width ratio of 2 can provide better daytime comfort.

APPENDIX 1

STUDY ON THERMAL COMFORT IN AN INSTITUTIONAL BUILDING

I like your participation in answering this questionnaire based on your thermal comfort, the inputs from this survey helps us to analyze occupants comfort level in this institutional building.

Age:	**Sex:**	**Time:**
Clothing:	**Are you under Fan:**	(Yes/ No/ Partial)

Please Tick (   ) the suitable bubble against the various scales:

1.Orientation of the Location:

North	South	East	West

2.Vegetation Index of the Location:

No vegetation	Sparse Vegetation	Existence of Shrubs	Existence of Trees

3.Thermal Sensation:

Cold	Cool	Slightly cool	Neutral	Slightly warm	Warm	Hot

4.Feeling of Comfort:

Too cool	Comfortably cool	Comfortable	Comfortably warm	Too warm

5.Satisfactory level of temperature in the place:

Very satisfied	Satisfied	Dissatisfied	Very dissatisfied

6.Level of Air movement should be:

Lesser	As it is	More

7.Level of Humidity should be:

Lesser	As it is	More

8.How would you like to be :

Cooler	As it is	Warmer

9.Are the overall conditions acceptable:

Yes	No

Passive Cooling Techniques in an Outdoor Space and its Effects on the Indoor Climate

ABSTRACT

Passive cooling techniques such as evapotranspiration from plants and watering are effective for ameliorating outdoor microclimates in hot summer. Natural ventilation also helps to make an indoor thermal environment more comfortable. However, in Japan's humid and hot summer climate, there is a limited opportunity to gain a cooling effect by ventilation. Therefore, this study focuses on passive cooling techniques to improve the outdoor microclimate near the window of a residential building to achieve a cooling effect by ventilation despite the hot climate and to reduce the demand for cooling energy. Measurements were conducted two cases during one summer on a target building located in a residential area with a window which located at the floor level to help natural ventilation. The first case had no additional plants in front of the window, and the second case did. The results show that when the ground and in front of the window were kept wet by watering and shaded, the radiant temperature, measured by a thermal infrared camera, was about 1−7 °C lower than the outside air temperature at the 3p.m. Consequently, the air temperature near the window was 2−4 °C lower than the outside air temperature. However, due to watering and evapotranspirating of plants, absolute humidity increased 2 g/kg' in the after adding plants case in front of the window. Although the indoor wind velocity came to a tenth of the roof wind speed, because of adding plants, inflow rate through the window was not changed. Therefore, the cooling potential was created at the outdoor space by applying the passive cooling techniques. When this cooling potential was used by ventilation, the sensible heat flux decreased 200–300 W through the daytime, and latent heat flux increased 100–300 W at the nighttime.

INTRODUCTION

Natural ventilation is known to be one of the most effective passive methods for creating a comfortable indoor climate and to conserve energy consumption. The outdoor microclimate, including air temperature, humidity, wind velocity, wind direction and solar radiation, has a direct impact on the effectiveness of ventilation for cooling. Fig. 1(b) shows the average, maximum, and minimum monthly temperatures from April to October in Tokyo from 2000 to 2013(Obeseved by Japan Meteorological Agency). Maximum temperatures in midsummer (July and August) are higer than 30 °C. Therefore, Tokyo's air temperatures in July and August are too high to utilize outside air for natural ventilation. Many studies show that maximum suitable outdoor air temperature for natural ventilation is between 28 and 30 °C (Givoni, 1992; Habara et al., 2012). Therefore, not only the indoor thermal environment but also the outdoor microclimate around the house must be improved in order to utilize natural ventilation in the midsummer season.

Many passive cooling techniques and designs have been developed and studied. Solar shading (Nikoofard et al., 2011; Berry et al., 2013) by structures and trees reduces the amount of solar radiation in the summer season, and contributes to a decrease in a building's surface temperature and energy demands. The transpiration of trees can prevent increases in the air temperature around trees (Umeda et al., 2006). Atmospheric radiation cooling is a phenomenon by which heat is lost by the emission of longwave radiation toward the sky at night-time. Nocturnal ventilation cooling (Givoni, 1991) with cold storage lowers the daytime temperature and makes possible to reduce the length of the periods requiring the operation of additional cooling systems. Each of these examples is individual approaches to improve and evaluate indoor, and outdoor microclimates. However, there has been little research about evaluating the change of the indoor thermal environment utilizing multiple passive cooling systems.

This study aims to introduce the passive cooling systems at an outdoor space and to evaluate its effect on the indoor thermal climate utilizing the natural ventilation by measurement. We measured the cooling effects of plants and water retentive blocks as well as the negative influences of increased humidity and air flow decrement by analyzing the microclimatic parameters around the actual house quantitatively. Then, we focused on changing the indoor thermal climate by introducing cooled air through an open window which helps the natural ventilation located at the floor level.

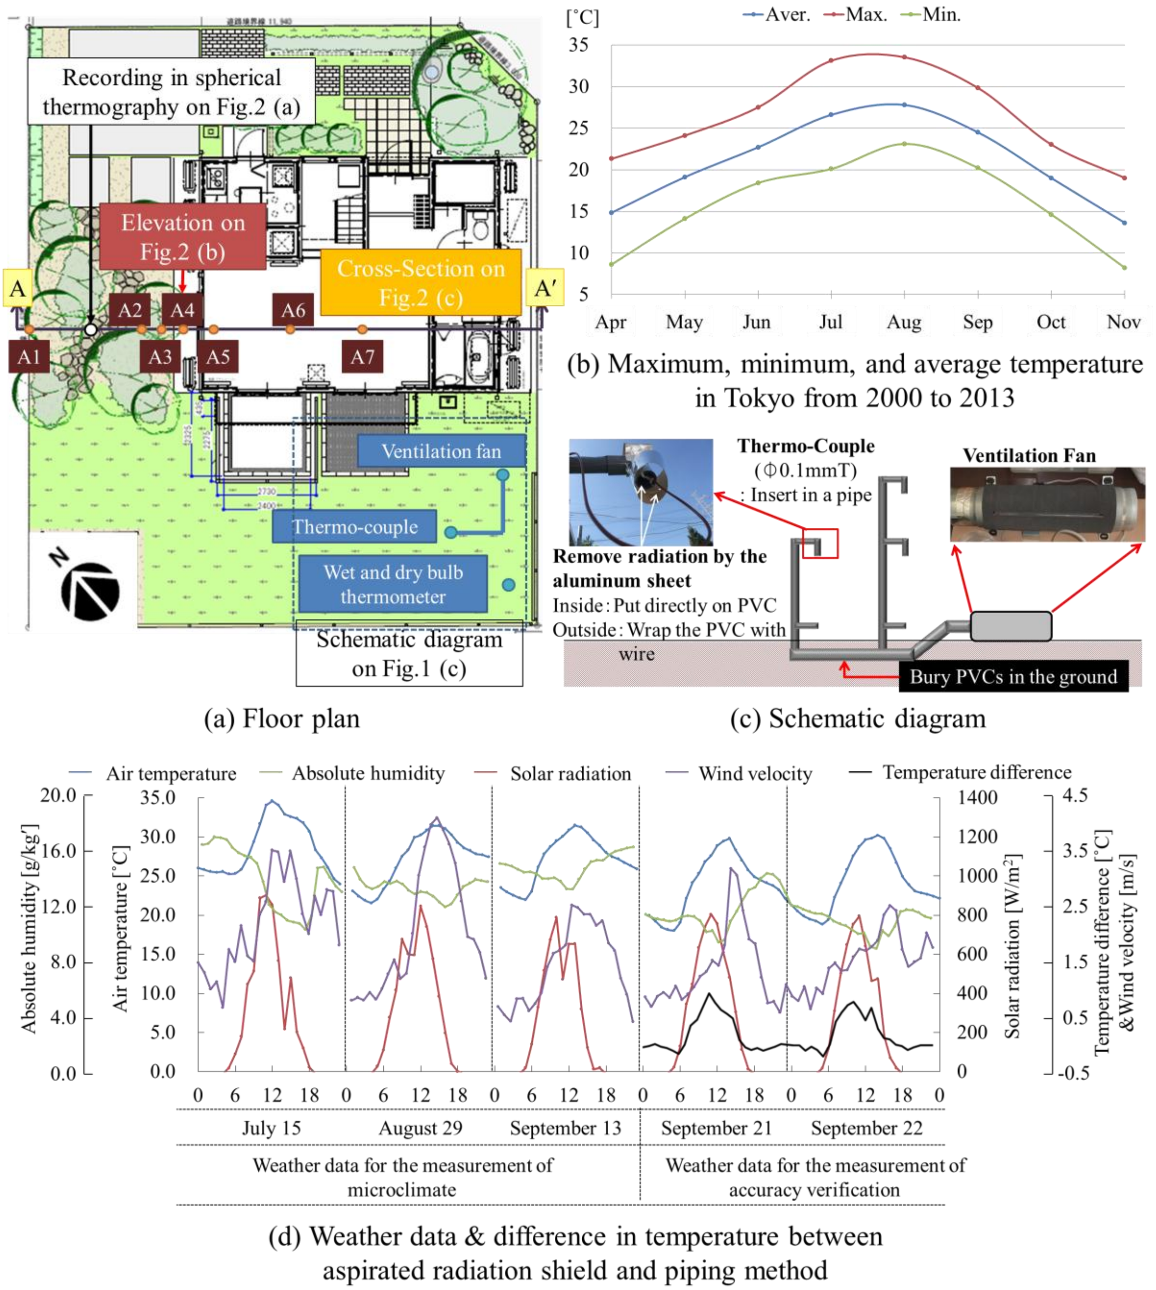

Figure 1 Outlines of measurement

MEASUREMENT DETAILS FOR HORIZONTAL AND VERTICAL AIR TEMPERATURE DISTRIBUTION

In order to adequately investigate the space where cooled air is created and where the air flows into building, the spatial distribution of the microclimatic parameters must be measured minutely. In this section, we propose a method for measuring the air temperature using polyvinyl chloride (PVC) piping with fan-aspirated ventilation. We then, describe the measurement method and the improvements made to the microclimate with plants and watering.

Measurement Method

When the measurement of air temperature and humidity is conducted at the outdoor space, solar and other radiation factors in the immediate surroundings must be removed. To do so, an aspirated radiation shield is often used. However, as the aspirated radiation shield is large, it is not suitable for measuring vertical and multipoint temperature distributions. We used PVC pipes (Φ13 mm) and ventilation fans (air volume: 75 m^3/h, static pressure in the pipe: 100 Pa) to measure outdoor air temperature and humidity accurately. Each of the measurement points was connected by piping. The measurement sensors were a thermo-couple (Φ0.1 mm type T thermo-couple) and a resistance change type humidity sensor (TDK, CHS-UPS), which were inserted into a pipe. When taking measurements using the PVC pipe, to prevent overestimation due to radiation from the surroundings, the pipe diameter was controlled to maintain sufficient wind speed (3 to 5m/s) at each measurement point. Ventilation fans were then connected to PVC pipes. In addition, the PVC pipes at the measurement point were screened two times with an aluminum sheet (Fig.1(c)).

The measurement results using this proposed PVC pipe method were compared with forced ventilation thermometer with aspirated radiation shield to verify accuracy. The measurement comparisons were made at intervals of 10 s for two days (September 21 and 22, 2013). Fig. 1(d) shows the differences in air temperatures between the PVC pipe method and the forced ventilation thermometer. Air temperature is almost identical at night when there is no solar radiation and a temperature error maximum of +0.9 °C exists at daytime when insolation is elevated. The results show an accuracy of +0.6 °C with a 95% confidence interval.

Measurement Conditions

Table 1. Details of the measurements of the effect of plants and water retentive blocks

	July 15(Case 1)	August 29(Case 2)
Condition	Trees (height 0.8 – 3 m) were 0.7 m away from the window.	Additional planting, water retentive blocks were added.
Watering	Automatic watering at 7a.m, 11a.m, 3p.m, and 7p.m by mist sprayer for 5 min.	Continuous watering from 7 a.m. to 7 p.m. by hosepipe.
Photographs		

Measurements of the microclimate around the building were made on July 15 and August 29, 2013. The measurement conditions are detailed in Table 1. In the July measurement, there were trees 0.7 m away from the window. There was nothing except the PVC pipe for measurement in front of the window. In the August measurement, we added additional plants and water retentive blocks as passive cooling materials in front of the window. Moreover, the watering method and times were changed to wet more surfaces of the leaf and block. In addition, vertical measurement points were added in front of the window to measure in detail the cooling effect of the additional plants. The indoor air temperature was measured near the window (A5 in Fig. 1(a)) and in the living room (A6, A7 in Fig. 1(a)).

EFFECTIVENESS OF EVAPORATIVE COOLING IN CASE OF UTILIZING PLANTS AND WATER RETENTIVE BLOCKS NEAR THE OPEN WINDOW

In order to analyze the cooling effect around the house, we used the abovementioned method to measure the effects of the passive cooling system applied outside the house. This section focuses on the following factors: improvement in surface temperature, decrease in air temperature, increase in humidity, and wind velocity decrement.

The Improvement in Surface Temperature

Thermal infrared images of the area in front of the window were obtained using spherical thermography (Asano, 1996). Fig. 2(a) shows an image obtained at 3p.m on August 29. The surface temperature of the wall was over 40 °C due to the afternoon insolation. However, the surface temperature of leaves and blocks in front of the window (shown in the inside of white rectangle on this thermal image) was 1 °C to 7 °C lower than the air temperature. Therefore, we have confirmed the cooling potential created by additional plants, watering, and shade near the window. In particular, the surface temperature of the water retentive blocks under the window is about 8 °C lower than the air temperature. However, we must also address how to introduce this cooled air into the indoor area.

The Decrease in Air Temperature

Fig. 2(b) shows the vertical air temperature distribution in front of the window (A4, Fig. 1(a)). While the vertical distribution was almost similar as that before the additional planting (Case 1), a temperature discrepancy of 2 to 4 °C occurred after the additional planting (Case 2) during the daytime.

An A – A′ cross-section (Fig. 1(a)) of the air temperature distribution can be seen in Fig. 2(c). At noon, the air temperature near the window (A4) was 1.5°C to 2 °C lower than the air temperature outside the target area (A1). At 3p.m, the air temperature near the window (A4) showed a decrease of about 2 °C in comparison with the A1 air temperature in the case 2 measurement, while the air temperature near the window (A4) was 1 °C higher than the A1 air temperature in the case 1 measurement. This difference occurred because the afternoon solar radiation was blocked and evapotranspirating was more conducted by the additional plants, so the A4 air temperature was lower on August 29. In addition, the indoor and outdoor air temperature difference was just 1 °C at night-time. It is clear that the decrease in the nighttime indoor air temperature was due to ventilation.

The Increase in Humidity

Fig. 2(d) shows the absolute humidity at each of the measurement points (A1, A4, A5, and A6 of Fig. 1(a)). Before the additional planting (left side of Fig. 2(d)), humidity decreased as the daytime air temperature increase. However, with the addintional plants and watering, the humidity of the indoor space (A6) on August 29 had increased to 14 g/kg′, while the outdoor (A1) humidity was about 10 g/kg′. Thus, even when the initial indoor humidity was higher than the outdoor humidity, the humidity of the indoor space in the case 2 was shown to be 2 g/kg′ higher than the outdoor measurement.

The Wind Velocity Decrement

To analyze the wind flow frequency, we conducted a test on September 13(A5) using a 3D supersonic anemometer. The wind direction on the date of the main measurement and that on September 13 are shown in the left side of Fig. 2(e). The July 15 wind direction (before the additional planting) was a little different than the September measurement. However, wind direction data for the August 29 and September 13 cases, both occurring after the additional planting, are almost identical. Graph, right side of Fig. 2(e), shows the inflow and outflow frequency at the window. In day-time, the inflow rate was recorded to be 40 % on average after additional plants.

Fig. 2(f) shows the decrement of wind speed after the additional planting, both in the velocity at the roof and near the window. However, the difference of the inside velocity in the before and after the additional planting cases near the window was approximately 0.2 m/s. Although wind speed decreased, the results shows that cooled air flowed to the inside area through the window. Thus, the cooled air created in front of the window did effectively replace the indoor air.

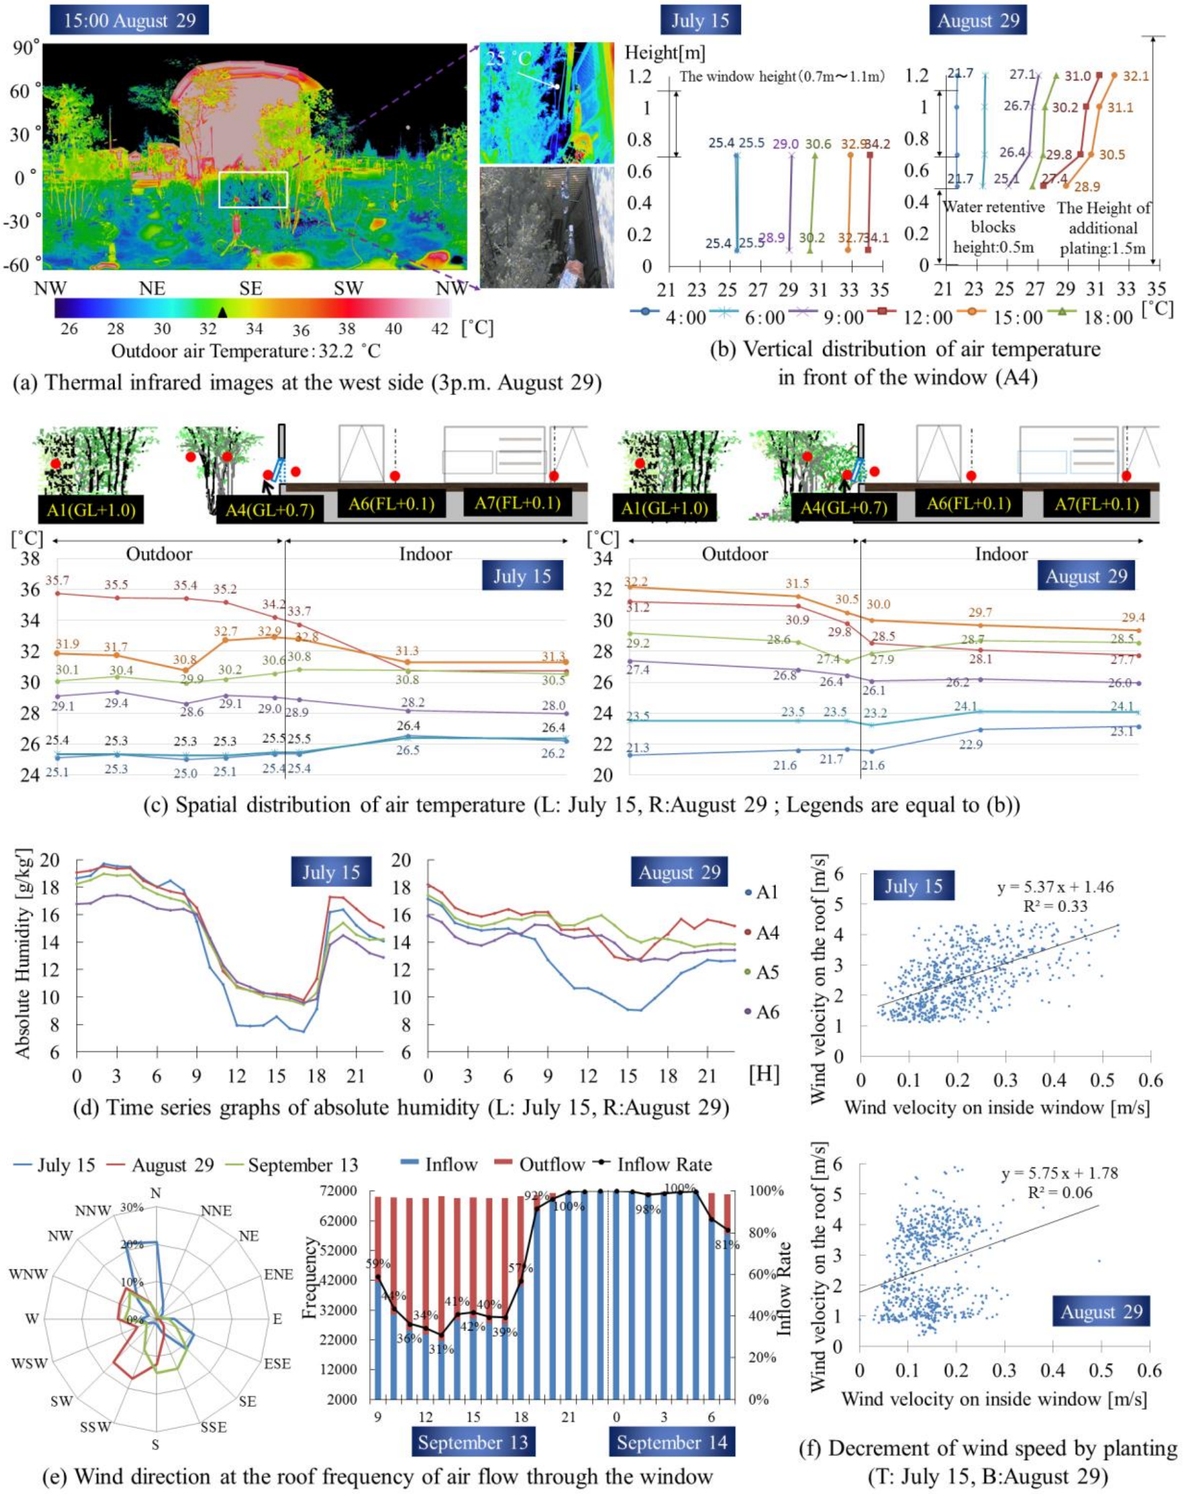

Figure 2 Spatial distributions of the microclimates

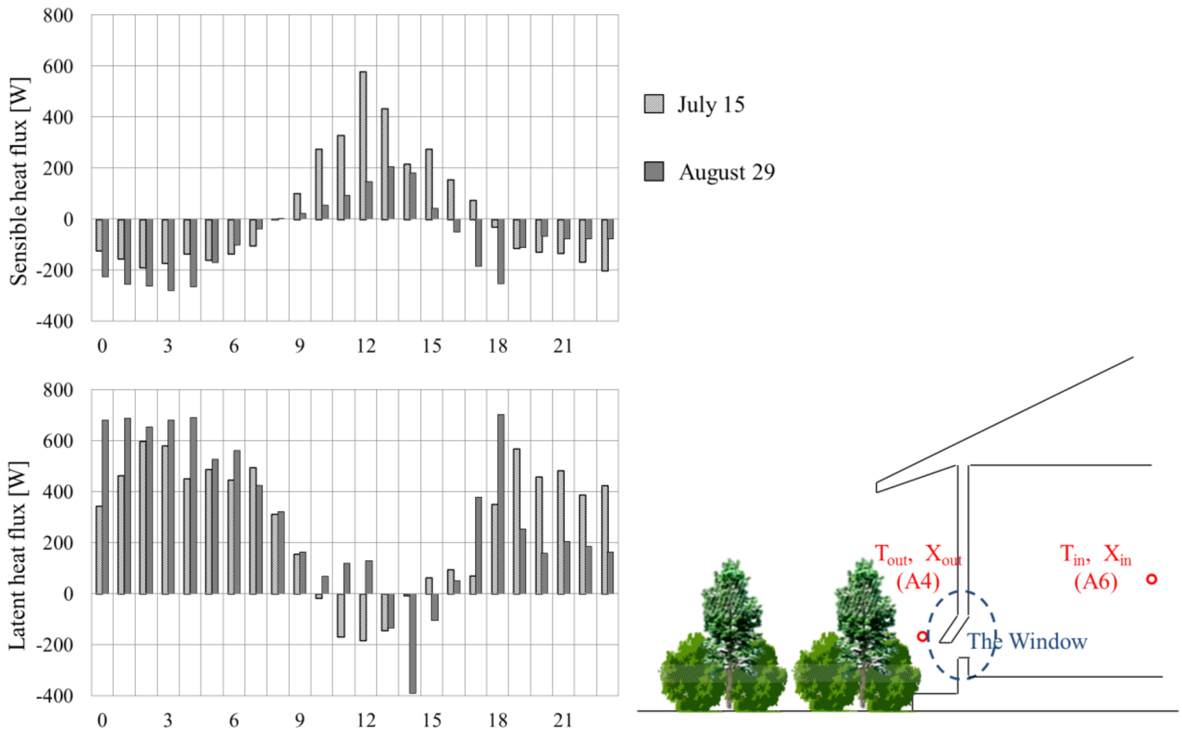
Evaluation of the Passive Cooling Effect by Heat Flux

In order to evaluate the effect of the passive cooling techniques at the outdoor space to the indoor space, we calculated the sensible and latent heat fluxes using the following equations. A comparison of these fluxes is shown in Fig. 3.

$$\boxed{\text{Sensible heat flux}} \qquad q_s[W] = C_p \cdot \rho \cdot V \cdot (T_{out} - T_{in}) \cdot 1000$$

$$\boxed{\text{Latent heat flux}} \qquad q_L[W] = \gamma_\gamma \cdot \rho \cdot V \cdot (X_{out} - X_{in}) \cdot 1000$$

The August 29 sensible heat flux decreased maximum 200–300 W compared with that on July 15 in the daytime. Furthermore, the length of time when the sensible heat flux was above zero diminished from 9 to 4 h. In the midnight, 100 W or more of sensible heat was removed from the indoors to the outdoors through the window on August 29. Conversely, the August 29 latent heat flux at nighttime was higher by 100–300 W than that of July 15. However, although latent heat flux of August 29 was high, the indoor humidity was lower than that on July 15. It means humidity increases due to the plants and water retentive blocks, however, its effect on the thermal comfort of indoor is small because the absolute humidity is influenced by the weather conditions.



(a) Sensible and latent heat fluxes(A4-A6)

(b) Cross-section of target building

Figure 3 Estimation of the passive cooling effect near the window

CONCLUSION

By locating plants and water retentive blocks in front of a window, we created a cooling potential at the outdoor space. We then quantitatively evaluated the influence of the cooling potential by evaporative cooling using the plants and water retentive blocks on the thermal environment of the indoor space by ventilation through the window.

1) To measure in detail the microclimate around the building, air temperature measurements were taken using a PVC piping method. The accuracy of this method verified to be +0.6 °C with a 95% confidence interval.

2) A decrease in the air temperature was observed 2 to 4 °C by passive cooling due to solar shading and evaporative cooling.

3) Although the wall surface temperature was over 40 °C at 3p.m due to the afternoon sun, the surface temperature of leaves and blocks with watering and shading in front of the window was 1 °C to 7 °C lower than the surrounding air temperature.

4) Due to the presence of additional plants near the window, the inside wind speed came to a tenth of the roof wind speed.

5) The length of time when the sensible heat flux was above zero diminished from 9 to 4 h.

The results show that application of passive cooling techniques can enhance the microclimate at the outdoor space, create a cooling potential around the building in the daytime. And there was little effect of the increase in humidity on the indoor climates by the passive cooling techniques. In the next study, we are going to measure the effect of nighttime ventilation with cold storage at floor and to evaluate how it can control the increase in the indoor daytime air temperature.

NOMENCLATURE

Cp : Specific heat at constant pressure of air (=1.006[kJ/kg・°C])

ρ : Density of air (=1.2[kg/m^3])

V: Air Volume [m^3/s] (=H0.5 [m] × W0.7 [m] × 2 × Wind velocity [m/s])

T_{out} : Air Temperature at A4 [˚C]

T_{in} : Air Temperature at A6 [˚C]

X_{out} : Absolute humidity at A4 [kg/kg (DA)]

X_{in} : Absolute humidity at A6 [kg/kg (DA)]

γ : Latent heat of vaporization (=2430 [kJ/kg])

The Effects of Energy-efficient Buildings on Facilities Management and Usability with a Focus on Passive House Schools in Norway

Antje Junghans, Dr.-Ing.
[Norwegian University of Science and Technology]
antje.junghans@ntnu.no

ABSTRACT

The objective of this paper is to improve the understanding of energy-efficient buildngs' management and usability. The intention is to contribute to overall improvements in the energy efficiency of built environments through an integrated approach to considerations of building design, facilities management, and user perspectives. An overview of the development of highly energy-efficient buildings with a focus on passive house school buildings is presented. The passive house standard is defined considering a newly developed and recently implemented passive house standard for non-residential buildings in Norway. The effects of energy-efficient buildings on facilities management and usability are comparatively studied with a focus on Norway's first and one of the newest passive house schools. Finally, the benefits and risks, the need to develop highly energy-efficient buildings, and the management and user interaction are discussed and summarized.

1 INTRODUCTION

Energy-efficiency of the built environment is of high importance all over Europe and on international level. Since it has become common knowledge that buildings contribute to 40% of the total energy consumption in European countries much effort has been input into improving existing building stocks and further improvements are still needed (EU, 2012). While the energy-efficiency improvement of the built environment lasts for some time, the development of management concepts and a better understanding of the buildings users' behavior merits more attention. Such integrative understanding would help to achieve buildings' projected performance and close the research gap recently highlighted by Bordass and Leaman (2013, p. 1): "Research into building performance continues to reveal that even the best buildings often fail to perform as anticipated." Consideration of the effects of interaction between building design, management, and use would also contribute to a better understanding of the processes or mechanisms that occur within building stocks. Buildings themselves do not consume energy, but rather the users or mechanisms within them create the demand for energy (Sartori, Wachenfeldt, & Hestnes, 2009). The development of innovative technology and its implementation in highly energy-efficient buildings such as passive houses and nearly zero-energy buildings is driven by policy and legislation, including for example Directive 2012/27/EU on energy efficiency. This energy efficiency directive states requirements regarding the improvement of energy efficiency in the public building sector: "Member States shall encourage public bodies, including at regional and local levels, with due regard to their respective competences and administrative set-up, to follow the exemplary role of their central governments to purchase only products, services and buildings with high energy-efficiency performance" (EU, 2012, p. 15). If the implementation of Directive 2012/27/EU is accepted as performance-based norm, it might also increase the demand for facilities management competence with reference Joanna Eley's vision—published before the implementation process of the EU's Energy Performance of Buildings Directive (EPBD) had begun——that "In the fullness of time, if performance-based building and regulations are accepted as the norm, facility managers will become key players in assessment" (Eley, 2001, p. 5).

The decission to study passive house schools is based on the fact that school buildings form the largest group of public buildings and belong to one of the three largest groups of non-residential buildings in Europe. Non-residential buildings are more complex and less studied than residential buildings. The European non-residential building stock includes mainly wholesale and retail buildings (28%) a large amount of office buildings (23%), and as third largest group the educational buildings with a 17% share in terms of total floor area. The remainder of the non-residential building stock comprises the following categories: hotels and restaurants (11%), hospitals (7%), sport facilities (4%), and other buildings (11%) (Laustsen et al., 2011, p. 8). The overall building stock of all EU27 countries, Norway, and Switzerland has been assessed as having c.25 billion m^2 of useful floor area, of which 25% are non-residential buildings and 75% residential buildings, used by more than 500 million people (Laustsen et al., 2011). Norway, the northernmost country in Europe, currently has a population of 5 million people. The country's existing building stock is estimated as having a gross floor area of 325 million m^2 divided between residential buildings (210 million m^2; 64%) and non-residential buildings (115 million m^2; 36%) (Haugen, 2008). Sartori et al. (2009, p. 1614) state: "Energy demand in the building stock in Norway represents about 40% of the final energy consumption, of which 22% goes to the residential sector and 18% to the non-residential sector." Norway has traditionally used a high amount of electrical energy for heating buildings. Due to the country's dependence on hydroelectricity, buildings in Norway have some of the lowest CO2 performances found in Europe (Laustsen et al., 2011). However, due to limited supplies of hydropower, the increasing demand for electricity causes problems, as stated by Halse (2005, p. 1) almost ten years ago: "consumption of electricity is reaching a level where additional growth will have to be covered by traditional non-renewable resources."

2 METHODOLOGY

The research is mainly based on the conduction of case studies. Case studies are considered as a most suitable approach to develop insights in a high level of complexity in its real-life context. The passive house school examples have been selected based on a thourogly conducted state of the art literature review. The development and implementation of passive house school design has been studied on international level (PHI., n.d., NS3710, 2012) and the management and usability with a special focus on Norway (THOMSEN, J., BERKER, T., HAUGE, Å. L., DENIZOU, K., WÅGØ, S., & JERKØ, S., 2013). The information utilized for the first case study, Åsveien School, is based on a project which has been conducted in cooperation with a public Real Estate and Facilities Management department. In autumn 2013 a group of master studends were involved in workshops, and the conduction of experts' interviews and site visits. The information about the second passive house school case study is based on published scientific conference papers (DOKKA, T. H., & ANDERSEN, G. (2012), JERKØ, S., MYSEN, M., HOMB, A., NERSVEEN, J., NILSEN, S., BLOM, P., & CHRISTOPHERSEN, J. (2006), research reports (THUNSHELLE, K., & LAPPEGARD HAUGE, Å. (2012) and interviews and site visits conducted by the author in 2014.

3 THE STATE OF THE ART

The passive house concept has been described earlier as "buildings, for which thermal comfort (ISO7730) can be achieved solely by post-heating or post-cooling of the fresh air mass, which is required to achieve sufficient indoor air quality conditions –without the need for additional recirculation of air" (PHI, n.d.). The basic principles of passive houses were summarized in five categories: (1) thermal insulation, (2) passive house windows, (3) ventilation with heat recovery, (4) airtightness, and (5) thermal bridge free design (Feist, 2013). This concept was mainly applied on passive houses, which were built as private homes, with the main objective of reducing the amount of energy used for heating. This was achieved through the construction of highly insulated, compact and airtight buildings with ventilation systems with heat recovery and special passive house windows.

In Norway, the passive house concept was further developed into a passive house standard for non-residential buildings (NS3701, 2012). Lexow and Dokka (2012, p. 5) state: “Standards Norway is the first member of the European Committee for Standardization (CEN) to have a national standard with criteria for Passive Houses covering all building categories defined in the national building code.” The standard specifies requirements for different non-residential building types, according to the Norwegian climate, building construction method, and architectural context. All buildings in Norway certified as energy-efficient conforming to either passive house or low-energy standards. The certification includes the minimum requirements for heat losses, cooling demand, heating demand, energy supply, and technical infrastructure as elements of a building’s design, components, and systems, as well as air tightness of the building envelope.

A conceptual structure for the description of passive houses can be summarized as follows: (1) General information providing some general information about the building (building type, gross floor area, location, and year of construction); (2) Winter heat insulation described by the compactness of the building form and quality of the thermal insulation of the building envelope (ground floor, outer walls, and roof), regarding the passive house requirement of reduced heat losses for transmission and infiltration; (3) Summer heat protection described by the quality of summer heat protection and how zero energy supply for cooling is achieved considering the orientation of rooms, heat storage, solar shading; (4) Energy supply considering the main energy sources and the technical systems of heating, domestic hot water, ventilation, lighting, technical equipment, and cooling; and (5) Windows described as such and as building parts, and with consideration of entrance doors.

4 PASSIVE HOUSE SCHOOLS IN NORWAY AND SELECTION OF CASE STUDIES

The passive house concept has been studied in Norway since the year 2000. In 2005, Norwegian researchers recognized a growing interest in the passive house concept in relation to low-energy housing. At that time mainly residential passive house buildings such as single-family houses were constructed. However, a growing interest in the passive house concept was identified. Halse (2005, p. 4) stated: “Passive houses and low-energy housing is on the verge of market breakthrough.” Five years later, in 2010, the first Norwegian passive house school building, Marienlyst School in Drammen, was taken into use (Dokka & Andersen, 2012; Thomsen et al., 2013; Thunshelle & Lappegard Hauge, 2012).

The number of high-energy efficient non-residential buildings is expected to increase continuously up to 2020 in Norway. (Enova, 2012, p. 15). The Norwegian Government is supporting municipalities in the development and construction of climate and environmentally friendly pilot projects under the programs “Framtidens by” (Cities of the Future) and “FutureBuilt.” As part of the program “Framtidens by”, city municipalities are encouraged to share ideas on climate-friendly city development in cooperation with the business sector, the regions, and the Government. “Framtidens by” is scheduled to run for six years (2008–2014) and the 13 largest cities in Norway involved in the program are: Bergen, Bærum, Drammen, Fredrikstad, Kristiansand, Oslo, Porsgrunn, Sandnes, Sarpsborg, Skien, Stavanger, Tromsø, and Trondheim (Government.no, 2011).

The “FutureBuilt” program is scheduled to run for ten years (2010–2020) and will support the realization of 50 projects contributing to the reduction of greenhouse gas emissions and a good city environment. Projects may also include urban areas or individual buildings. The cooperating partners in “FutureBuilt” are four municipal authorities (Oslo, Bærum, Asker, and Drammen), the Ministry of Local Government and Modernisation, the Norwegian State Housing Bank (Husbank), the Norwegian energy national fund (Enova), the national fund to reduce greenhouse gas (GHG) emissions from transport (Transnova), the National Office of Building Technology and Administration, the Green Building Alliance, and the National Association of Norwegian Architects (NAL). In 2014, the project documentation included six school projects (Table 1) within a total of 30 pilot projects: urban areas, schools, kindergartens, office buildings, cultural centers, and housing projects (futurebuilt.no, 2014).

Table 1. The development of passive house schools in Norway sorted by the year of construction (Newest, Oldest), (Source: futurebuilt.no, 2014, "Framtidens by"* and/or "FutureBuilt)

School building	School name (Norwegian name), location, year of construction	Energy-efficiency and FM relevant key figures	School type of use and user relevant key figures
	Åsveien skole,* Trondheim, 2013–2015	Gross floor area (GFA): 8836 m^2 Energy demand: 61 $kWh/m^2/year$	Primary school with 630 students, and autism center for 20 students
	Veitvet skole, Oslo, 2011–2015	GFA: 8789 m^2 Energy demand: 62 $kWh/m^2/year$	Primary and lower secondary school for Class 1 to 10, class with multiple-use hall, 840 students (school and multipurpose hall)
	Nye Gran skole, Oslo, 2010–2015	GFA: 6079 m^2 Energy demand: 61 $kWh/m^2/year$	Lower secondary school, 540 students, 65 man-labor years, 80 users
	Frydenhaug skole, Drammen, 2011–2014	GFA: 5795 $m^{2,}$ Energy demand data unavailable	Intermunicipal primary school and resource center for students with disabilities 100 students, 110 man-labor years
	Bjørnsletta skole, Oslo, 2010–2014	GFA: 9677 m^2 Energy demand: 64 $kWh/m^2/year$	Primary and lower secondary school, 790 students, special department for 12 students with autism
	Stasjonsfjellet skole, Oslo, 2010–2014	GFA: 3663 m^2 Energy demand: 74 $kWh/m^2/year$	Lower secondary school 390 students, 35 full-time equivalent (FTE) man-labor years
	Søreide primary school, Bergen,* 2011–2013	GFA: 7910 m^2 Energy demand: 43 kWh $m^2/year$	Primary school
	Heistad skole, Porsgrunn, 2008–2012	Energy demand (NS-3031): 37 $kWh/m^2/year$	Primary school, special department for 14 severely disabled students

	Marienlyst skole, Drammen, 2008–2010	6454 m^2 GFA Energy demand: 70 kWh/m^2/year	510 students, 95man-labor years c.12 m^2/student

5 SIMILARITIES AND CONTRASTS BETWEEN THE OLDEST AND NEWEST PASSIVE HOUSE SCHOOLS

Åsveien School in Trondheim is the newest passive house school in Norway. The building has been under construction since July 2013 and will be finished and taken into use in 2015, five years after the completion and start of operation of Norway’s first passive house school Marienlyst School in Drammen in 2010.

5.1 Comparison of the school buildings’ energy performance

In Trondheim, Åsveien School, which will be a passive house primary school has been under construction since 2013 and will be finished and taken into management and use in 2015. The project, including the main building of the primary school for 630 students and a department for 20 students with autism, has a total gross floor area of 8836 m^2. In addition, a multipurpose hall with a gross floor area of 2336 m^2 is under construction on the same site (Hasenmüller, 2013).

Marienlyst School, a lower secondary school is located in the centre of Drammen, a city c.40 km west of Oslo. The school is adjacent to a sports arena (Marienlyst idrettspark) and a public swimming pool (Drammensbad). The school has a heated floor area of c.6450 m^2. The school has a compact building form comprising three stories. Due to natural changes in the ground level on site, the first floor is partially buried and includes a large auditorium for the whole school, as well as locker rooms, rooms for special functions, and a library. The second floor has a community area with a café, workplaces for teachers, administration offices, and rooms for special functions. The third floor consists mainly of compact student areas and group rooms. The architectural design is characterized by a clear and simple building shape with much variation in architectural expression, form, and use of materials (Dokka & Andersen, 2012, Hahn, 2013).

Table 1 shows a comparison of the simulated energy demand of both Åsveien School and Marienlyst School, built according to Norwegian standards (NS3700, NS3701, and NS3031). The measured energy consumption of Marienlyst School for the academic year 2011–2012 is also shown.

Table 2. Building Energy Performance (kWh/m^2/year) of Two Passive House Schools in Norway (Dokka and Andersen, 2012, Hasenmüller, 2013)

Energy use categories	Åsveien School simulated energy budget	Marienlyst School simulated energy budget	Marienlyst School measured energy consumption
Room heating	9	12.8	13.7
Ventilation heating	4.4	0.6	4.1
Domestic hot water	10	10.1	3.1
Fans and pumps	12.7	10.8	12.8
Lighting	8.3	15.5	13.3
Technical equip.	8.8	13.3	13.9
Cooling	0.7	0	0
Total net energy demand	53.9	62.9	60.9

5.2 Effects on facilities management

The general understanding of facilities management in Norway is that it refers to the European standard, and it includes all traditional roles and methods related to the administration, operation, maintenance, and development of buildings, and service provision for building users. A triangular symbol is often used to visualize the interaction between the three key players, namely the building owner, building user, and building manager. However, in everyday practice many actors interact and thus there are also strategic, tactical, and operational levels in the functioning of buildings. For example, the school janitor may be described as an actor at an operational level (Haugen, 2003, p. 14). Some Norwegian public authorities are continuing with the traditional administration, operation, and maintenance (*forvaltning, drift, vedlikehold* (FDV)) focus, whereas others have adopted the FM approach in full. A variety of organizational models and service provision concepts exist, including the client-supplier-model, and different approaches to in-house service provision, outsourcing, or out-tasking (Haugen, 2003, 2008; Junghans & Olsson, 2014; Novakovic et al., 2012).

Marienlyst School is one of 21 school buildings that together account for 300,000 m^2 of public buildings owned by Drammen Municipality. Drammen Eiendom KF, the real estate and FM department of Drammen Municipality, represents the owner of the school building and is responsible for the buildings' management and operation as well as the management of facilities service provision. The general field of responsibility of the real estate and FM department includes operation, maintenance, modernization, new building development and realization, purchasing, selling, leasing, and renting.

Energy management is a subdomain of FM, and integrates all relevant facilities services to ensure that "Client demand for utilities (technical infrastructure) is satisfied by services resulting in a comfortable climate, lighting/shading, electrical power, water and gas" (EN 15221-1, 2007). The main area of responsibility is visible in the operational and utilization phase of a building. Regular monitoring of the power consumption, benchmark analyses, and identification of savings potentials and their implementation are essential working areas in energy management (Junghans, 2012).

The users of Marienlyst School experienced some problems with their school building that could be associated with the commissioning of the building and fine-tuning of automatic systems in the first year of occupation. The researchers highlighted the following issues (Thunshelle & Lappegard Hauge 2012):
(1) Temperature: Cold temperatures during the first winter, in 2010, especially in the mornings, were reported in interviews. A lack of supply from the district heating network was indicated as the main reason together with the fact that the winter of 2010 was particularly cold. One year later, the problems were not mentioned, but many of the interviewed students responded that some rooms could be cold or have varying temperatures. It was also pointed out in the interviews that some rooms could be hot and airless in summer months. The latter problem was connected with the use of sunscreens (see "Solar shading" below).
(2) Ventilation and air flow: The interviewees indicated that there were problems with air pressure conditions in the building. Doors were either slamming or were too heavy to open easily, or they remained open and emitted a peeping sound, probably due to the ventilation system. [Comment from the author: Probably the maintenance staff would have known why the doors made a peeping sound? Perhaps the doors were also fire doors that needed to be kept closed when not in use, and therefore emitted a warning sound if they were accidentally left open.] There were some complaints about the heavy and bad quality air in the small auditorium and small group rooms in core areas on the third floor, and thus the ventilation in these areas needed to be investigated further. The described problems indicated a need to examine the balancing and sizing of the ventilation units in the school.
(3) Solar shading: The interviews and responses to the researchers' questionnaire documented that the automatic shading and lighting did not work properly. Heat from the sun was also sometimes problematic. Teachers often wanted opportunities to override the solar shading systems in order to have more control over room temperatures. In addition, it appeared that the electric lighting that turned off automatically (controlled by light motion sensors) should have been fine-tuned so that it was more sensitive to movement than it was when the evaluation was conducted.

5.3 Effects on usability

Norwegian researchers have developed a systematic approach for the assessment of school learning environments. The main criteria evaluated are structured in the following three categories, with increasing degrees of complexity:

1. Evaluation of the Indoor climate with focus on five subcategories: thermal- (temperature quality), atmospheric- (air quality), acoustic- (sound quality), actinic- (light and radiation), and mechanical environment (vibrations)
2. Evaluation of the indoor environment, which includes: indoor climate, together with two subcategories, namely the aesthetic environment (visual impact) and the psychosocial environment (interpersonal relationships)
3. Evaluation of the physical environment, which includes the evaluation of the indoor environment (mentioned in point 2 above), together with four subcategories: the building's suitability for the use (operations and functionality), its suitability for the users (universal design), the user density (area efficiency, m^2/student, and volume/student), and usage time (duration of room usage, over time) (Jerkø et al., 2006).

Teachers, other employees, and students at Marienlyst School needed more information about how the building automation system worked and could be adjusted. Especially the solar shading, lighting, and temperature regulation needed to be better understood. Thus, there is a need for cooperation between the users and management staff of new schools when the final adjustments to all technical systems are being made according to user demand. The passive house building at Marienlyst School has improved awareness of the environmentally friendly profile of the school. Moreover, the teachers indicated that they would have liked more information about the passive house concept to communicate to their students (Thunshelle & Lappegard Hauge 2012).

6 CONCLUSION

In this paper, the complexity of energy-efficiency improvements in built environments has been studied with focus on passive house schools in Norway. The intention has been to improve the understanding of passive houses and how they are managed and used. A structure for the description of passive house examples has been developed based on the definition of the passive house concept and the Norwegian passive house standard (NS3701). Nine Norwegian passive house school projects have been identified through publically accessible sources. Marienlyst School in Drammen and Åsveien School in Trondheim, respectively the first and most recent passive house schools, were selected as study cases. The building energy performance of both schools has been compared on the basis of the simulated energy budgets, and the measured energy consumption of Marienlyst School has been reported. The definition of facilities management in Norway and an approach for usability evaluation have been shown to structure the effects of facilities management and usability. In the studied cases, the effects of FM referred to energy management and the janitor as a key actor at an operational level were indentified. The paper reveals that the main aspects of usability are related to the provision of a good indoor climate quality and communication with and feedback from the building user.

ABSTRACT

City regions and metropolitan areas form the scale on which the battle for will be won or lost, and the level at which cities can become resilient and even self-sufficient. A master plan for a sustainable energy system for city regions is not a luxury anymore.

An energy master plan will be based on incremental steps of transition. The approach needs to start with the charting of energy sources, sinks and unused potentials of a studied area. Herein the method of Energy Potential Mapping can play an essential role. The next step deals with the identification of demand reduction possibilities in the existing built environment – new construction can already be zero energy. Differences in simultaneous discrepancies between supply and demand can be bridged by synergetic systems, heat exchange, cascading and intermediate storage of energy. Finally the remaining demand needs to be solved with renewable energy, inside the city as well as in its environs, which become ever more indispensable to the modern metropolis.

In the energy master plan EPM deals with the identification of supply and demand, supports the finding - in place and time - of energy potentials from sun to magma, helps the discovery of simultaneous mismatches, surpluses and shortages, and helps determine the effect on the urban climate. Mapping is done in 3D, soon to be 4D, including the time factor (diurnal differences, seasonal differences, long-term developments).

Since 2005 Energy Potential Mapping has been developed at TU Delft. It has gained international scientific standing. The advanced 3D method has been used for sustainable energy plans and currently forms the basis for making Dutch regions energy-neutral, in cooperation with local stakeholders. The full paper will describe the Energy Master Plan approach and Energy Potential Mapping method, illustrated by cases executed so far.

1. INTRODUCTION

Sustainable development will become a question of climate adaptation and mitigation (IPCC, 2014) on the one hand and the lasting availability of resources on the other (Haas, 2013). Of these resources, after the basic needs for human survival – oxygen, drinking water and food – energy is the most quintessential element for human society. Without energy no element of civilization can be continued: buildings cannot be operated anymore, drinking water cannot be pumped around or poured into bottles, food cannot be transported from farms to cities and people will be limited again by travel distances they can cover by foot, bike or horse. Energy is the fuel of modern society – the end of energy will be the end of cities as we know them.

One might argue that present-day economy has built in sufficient safety and security for the continued provision of energy and all other needs, but over the past few decades various occurrences have demonstrated that cities are very vulnerable to hampering supplies. For instance, technical failures and black-outs have rendered power plants out of operation (e.g. New York City, USA, 2006), airplane accidents have cut major high-voltage lines supplying urbanized areas (e.g. the central river region, Netherlands, 2009), natural disasters have led to the destruction of power plants (e.g. Fukushima, Japan, 2010), politically driven decisions have blocked supplies (e.g. Russia versus Ukraine, 2009 and 2014), terrorist attacks have damaged energy infrastructure (e.g. Russia, 2010), and – more 'friendly' as we know it – market price mechanisms have influenced supplies in various ways (e.g. the Gulf War effects, late 1990s).

In the past most city regions used to be self-supporting entities: think of the Mesopotamian cities, Greek City states, yet also European mediaeval regional centres. Resource cycles used to be closed, meaning that all food, water, energy and materials came from the direct environs and waste products were reused in that same vicinity. Where this evolved out of balance, cities collapsed – think of the ancient Egyptian centres and Mayan cities on the Yucatán peninsula in Mexico. We are now in an era where none of the world's cities is self-sufficient. Globalisation has made cities strongly dependent on supplies from elsewhere, and wastes are also treated in places mostly not known to citizens. As described with the examples of hampering supplies of energy, this implies cities presently are very vulnerable to failures in the system.

The inevitable conclusion of the previous is that for a secure, sustainable future, cities need to become resilient. A greater extent of self-sufficiency will help to achieve this. Supported by historic examples, city regions and metropolitan areas are still the most suited level at which sources and sinks can be solved locally. Therefore these form the scale on which the battle for sustainability will be won or lost, and the level at which cities can become resilient and even self-sufficient. However, how are we going to transform existing cities or emerging and growing metropolitan areas, with their non-sustainable systems, to sustainable ones?

A master plan for a sustainable energy system for city regions is not a luxury anymore. There is not one single solution that will provide the answer; enforced by successful examples this paper discusses one approach that may help.

2. ENERGY MASTER PLAN

For the research presented the authors based themselves on existing urban regions. Handling an existing city must entail a stepped approach, since commencing with an integrated design from scratch is impossible. The proposed Energy Master Plan will therefore be based on incremental steps of transition.

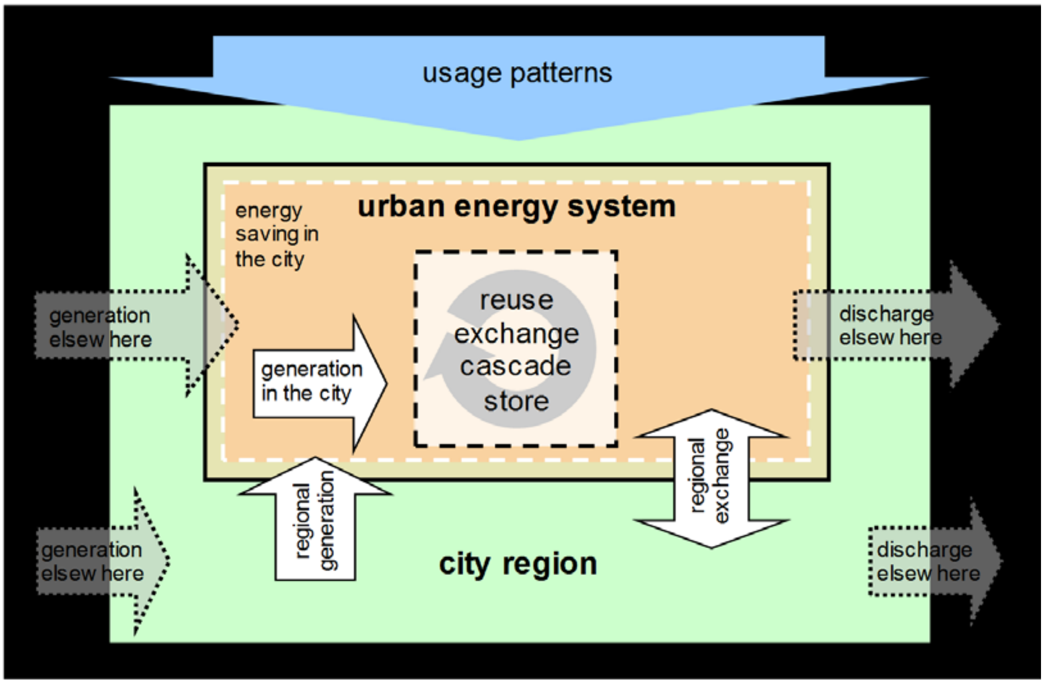

Figure 1 *Graphic depiction of the Energy Master Plan for self-sufficient cities (Dobbelsteen, 2012a)*

A quintessential basis for an effective approach to cities is formed by proper knowledge of the city's use patterns of energy: data are needed of energy consumption, production of energy and residual waste flows, to as much detail as possible. So the Energy Master Plan starts with the charting of energy consumption figures, sources, sinks and unused potentials of the studied area. Herein the method of Energy Potential Mapping discussed further on can play an essential role.

A first real step deals with the identification of demand reduction possibilities in the existing built environment. Every part of the energy demand you can reduce, means avoidance of required energy production; so it is a first step to self-sufficiency. New to be constructed buildings can already be net zero energy. Ambitious cities had better enforce that new development actually is energy-neutral, because all new non-sustainable developments add up to the already present problem. The greatest potential in most cities however lies in an improvement of the existing stock of real estate, so a meticulous analysis of the potential of energy saving in different districts and neighbourhoods, depending on the urban typology and architecture, will help make a leap forward.

A second step deals with the potential that lies within differences between supply and demand. In temperate climates with both heat and cold demands simultaneous discrepancies in demand and supply can be bridged by synergetic systems, heat exchange, cascading and intermediate storage of energy. Heat grids are already well-known in colder climates; these are usually based on high-caloric heat sources, often originating from fossil energy sources. There are however other options (as studied, for instance in the European FP7 projects CELSIUS and City-zen). Lower-temperature grids can also be deployed in order to optimize the exchange of heat (Dobbelsteen et al., 2012b), and cold grids can serve cities with a substantial demand for cooling. Energy can also be reaped from other resources' wastes, such as waste water or waste material. In these cases processing is most likely to be arranged outside the city borders. So inter-exchanging with the region becomes important here.

Finally, the remaining demand needs to be fulfilled with renewable energy, to be generated inside the city but in terms of quantity most logically outside the urbanised area, which has more space to allocate conversion techniques to produce electricity or heat. We should acknowledge that with the fossil reserves depleting, the world's energy supply needs to come from its surface ever more. This entails a competition with other forms of land use: agriculture, nature, recreation, building sites, etc. Therefore we need to become very considerate about the use of land around cities, for which Energy Potential Mapping (EPM) is a proven means to provide insight in the energy potentials locally available inside and outside the city. Taking into account the enormous quantity of energy a modern city consumes, every acre of urbanised area needs at least an acre of energy-productive land. The city's environs therefore become ever more indispensable to the modern metropolis.

3. ENERGY POTENTIAL MAPPING

As discussed, present-day urban energy systems largely rely on a controlled supply, capable of delivering high-exergy electricity and heat when and where required. Dimensioning of energy systems is mostly defined by peak demands. As the many renewable sources from sun to magma are fluctuating and/or take on a lower exergetic form (for example low-temperature heat), knowing both the spatial and temporal behaviour of urban energy demand and supply are paramount to shaping an Energy Master Plan.

The method of Energy Potential Mapping (Dobbelsteen et al., 2011; Broersma et al., 2013a), developed since 2005 at the chair of Climate Design & Sustainability at the Delft University of Technology and having gained international standing, aims to provide quantitative insight in the when and the where of these, visualising both mismatches, surpluses and shortages. The advanced 3D method (soon to be 4D, by detailed geospatial inclusion of the time factor) has been used for sustainable energy plans and forms the basis for making Dutch regions energy-neutral, in cooperation with local stakeholders, by providing them with a palet of possibilities with which they can choose and design appropriate, robust and long term sustainable measures.

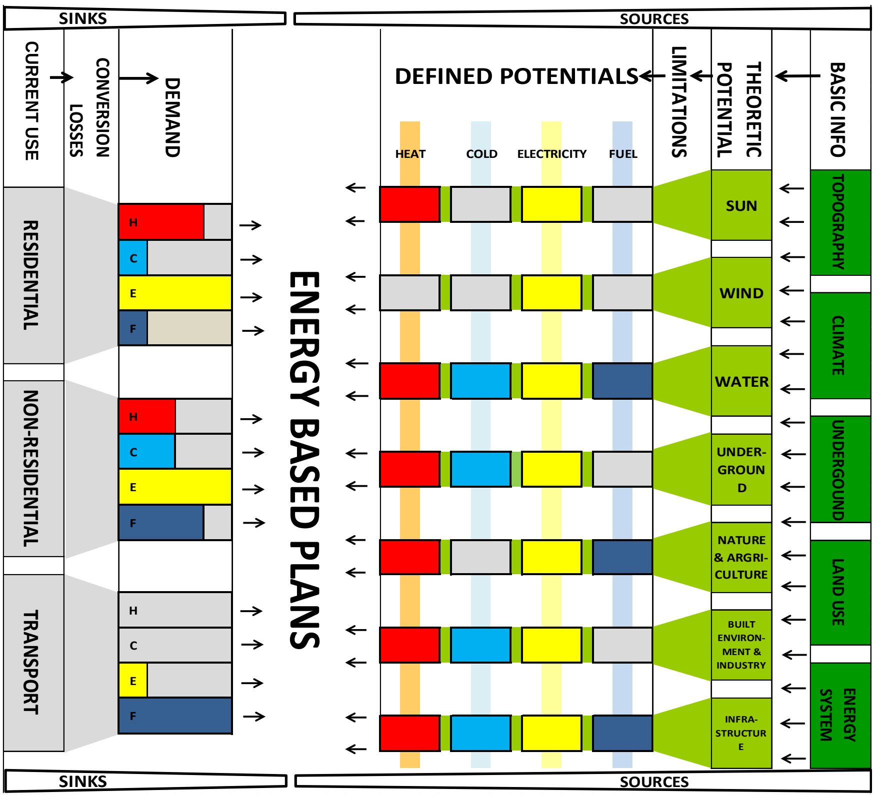

Figure 2 *Graphical explanation of the Energy Potential Mapping method, with consumers at left and potentials at right (Broersma et al., 2013)*

EPM takes into consideration conversion losses and various limitations on the demand side and theoretical renewable supply potentials in order to arrive at a more realistic potential for a chosen area, preferably while promoting multiple land use. An example would be the technical potential of photovoltaic panels on existing roofs, where the amount of solar radiation arriving at a given area is reduced by suitable roof area and orientation and expected long term PV panel performance. This can further be enhanced by structural suitability, glare issues, financial models and other local limitations and results in a detailed but realistic quantitative potential for photovoltaic electricity. Common themes on the demand side are assessing actual demand (thermal comfort, tap water heating, lighting and electricity use of appliances) from known metered figures and reduction potentials.

When combined, these form a stack of maps of many different demand and supply potential categories that provide both detailed quantified insight in and a policy-maker friendly overview of the available potentials, making it possible to arrive at a robust and realistic Energy Master Plan.

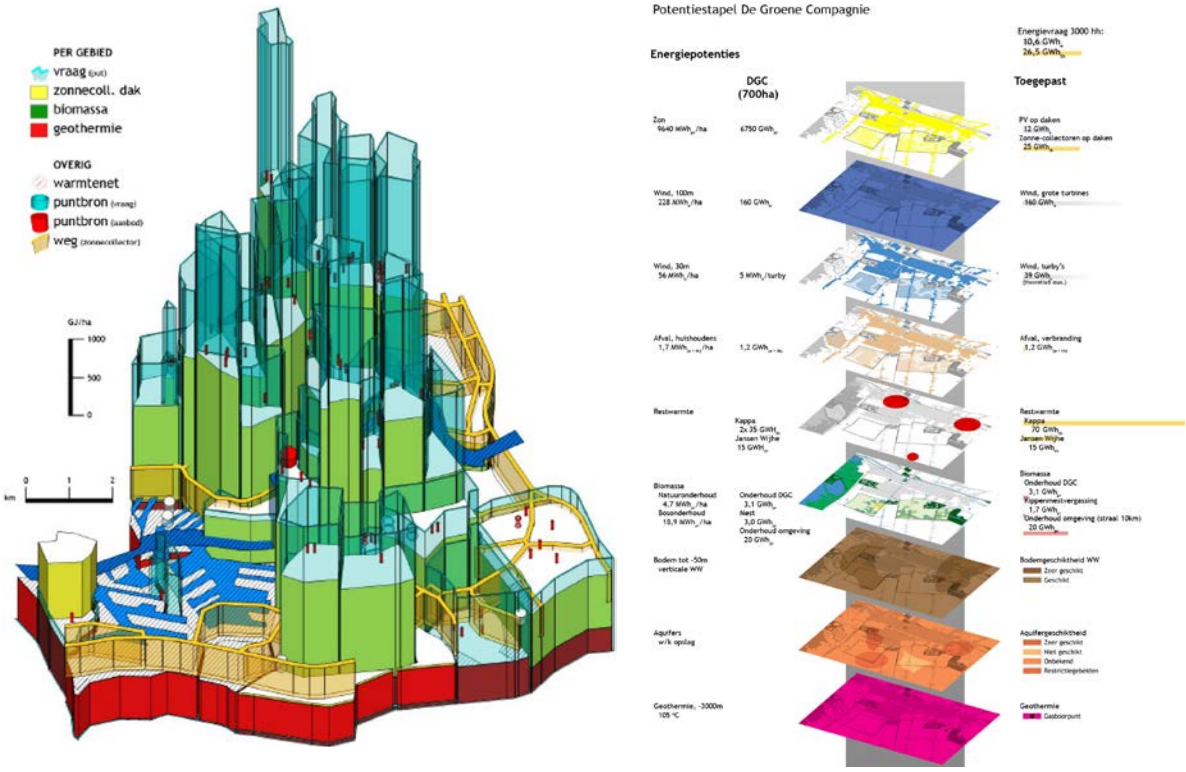

Figure 3 *(Left) Detailed 3D heat map of the central district of the city of Rotterdam: hollow cores indicate heat demands, full cores and layers are heat potentials, natural and anthropogenic (Broersma et al., 2011). (Right) Combined energy potential map stack for a neighbourhood in the Dutch town of Hoogezand-Sappemeer (Broersma et al., 2010).*

4. PRACTICAL APPLICATION IN CITY REGIONS

Rotterdam region

In the Netherlands, data are available for some 30 different housing typologies, for which average energy consumption and measures to improve energy efficiency are known. A step by step energy approach to integrate energy into spatial planning and making energy data easy accessible by EPM has proven to be a crucial part in preparing a stakeholder-based Energy Master Plan in the city.

A first step in building an Energy Master Plan was mapping the existing energy demand and reduction potentials per housing typology, which prioritised actions for policy-makers. Consequently, EPM en Heat Mapping presented the potential use of waste flows and the capacity for renewable energy generation of Rotterdam in a user-friendly format for a wide range of stakeholders as all maps were compatible to Geographical Information Systems (GIS). This meant that urban energy planning could finally be performed. Two cases will show the effect of EPM in GIS in the city. Since 2013 the Energy Atlas of Rotterdam is online. Using a 50 cm by 50 cm pixel grid, solar potentials are presented for the whole city of Rotterdam. This means that each square of 50 by 50 cm is presented with data of the feasibility of installing PV panels. The open data set is used by 2000 citizens and companies every month. Solar data are not only linked to weather data, roof angles, shading, cloud coverage etc. to get potentials as realistic as possible, but also to ownership of buildings. This way the Energy Master Plan can be translated directly into action plans. A second case is rolling out the district heating network in the city. Combining energy demand maps, heat maps, density maps and maps of existing pipelines made it possible to work with housing associations, energy companies and investors to work on a district heating master plan for the city. With threshold values agreed on by stakeholders a future district heating map could be drawn with new areas to connect, or areas to intensify, or areas where district heating was not feasible. This was a clear map for policy-makers, now translated into action plans for each area.

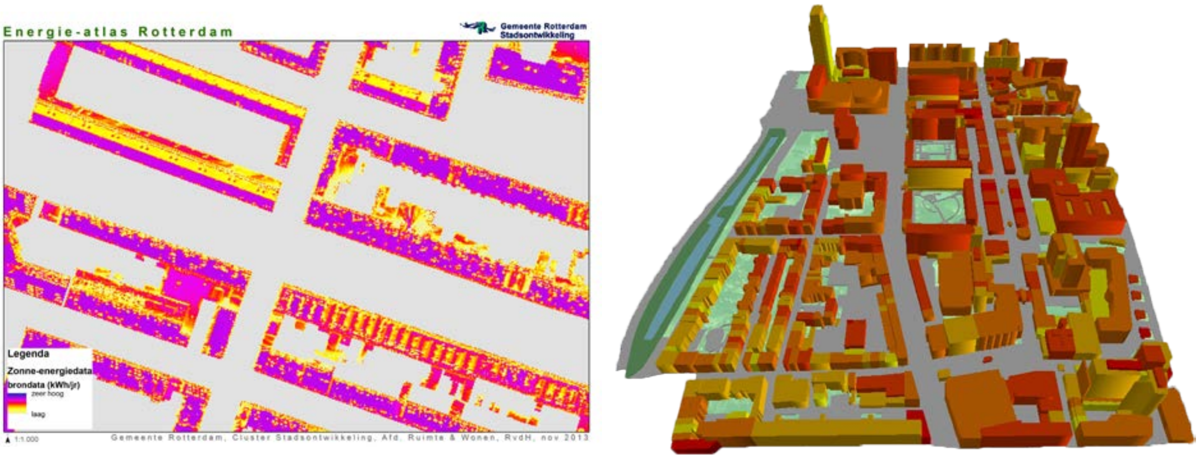

Figure 4 *(Left) 2D solar potential map in GIS of the Lijnbaan neighbourhood in Rotterdam, which can be combined with an ownership map as an example; yellow is low potential. (Right) 3D solar potential map for the same neighbourhood. Roof angles, orientation and shading are integrated in these maps; red is high potential (maps by Roland van der Heijden).*

One more important aspect of EPM is that it constituted the input for energy scenario planning methods such as GRIP, the Greenhouse Regional Inventory Protocol (Carney et al, 2009). A stakeholder-based energy scenario was the basis of the Energy Master Plan.

The energy scenario process can be run using bottom-up or top-down data. However, the internal consistency of the developed scenario pathways and their value for stakeholders will be much higher using local data as they can be directly translated into the Energy Master Plan and local actions. In short, one can state that EPM is an enabler of urban energy planning.

Oostland region

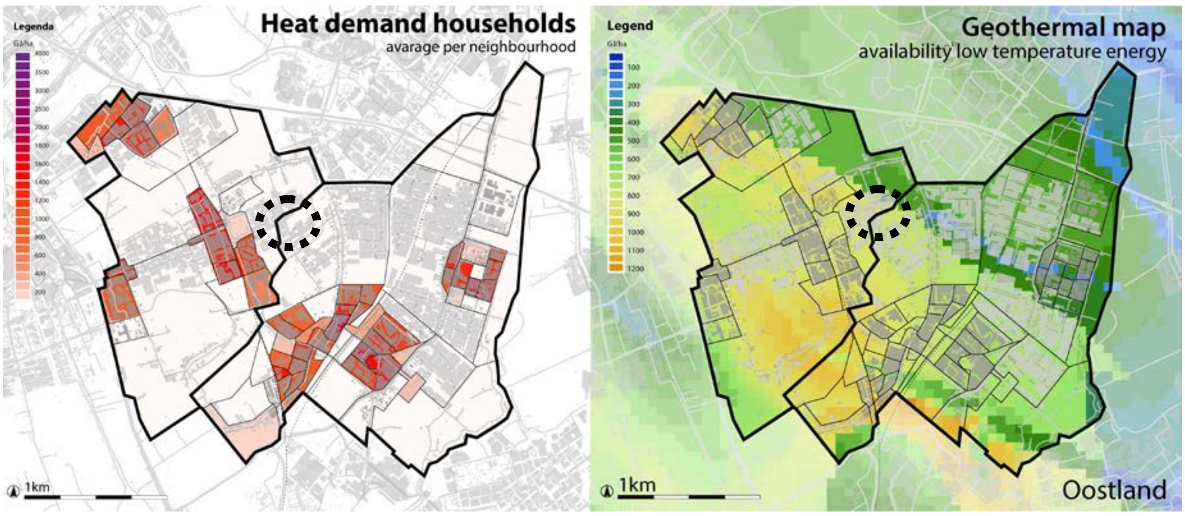

Figure 5: *Energy potential maps of heat demand of households in Oostland (left) and potentials of deep geothermal wells (right) (Broersma et al., 2013b)*

A recent regional energy study, in which the method of EPM was applied, was executed for the Dutch Oostland region (Broersma et al., 2013b). This 100 km^2 area is dominated by horticulture, spread between several smaller towns, including Pijnacker. The energy demand maps of different functions and origins as well as the various maps of sustainable potentials of the region (e.g. wind, solar, biomass, geothermal heat, thermal and electric potentials on roofs) served as the basis to expose and quantify sustainable interventions in the built environment. Figure 5 shows two examples of energy potential maps of Oostland, one of demand (left: heat demand of households) and one of supply (deep geothermal heat).

These two maps are shown here in order to explain an example of the application of EPM to a proposal of a geothermal energy cascade in the town centre of Pijnacker. The proposal is schematically shown in figure 6. The concept of a geothermal energy cascade comprises the maximised use of a geothermal energy source. This can be achieved by re-injecting the extracted hot water with the lowest possible temperature into the injection well. Different functions within the built environment can have different temperature trajectories used for heating (differences in inlet and outlet temperatures of the heating systems). If different areas, neighbourhoods or functions with consecutive temperature trajectories will be connected in series, a thermal cascade is created. Heat networks will distribute the hot water. The different districts need to have a similar heat demand too.

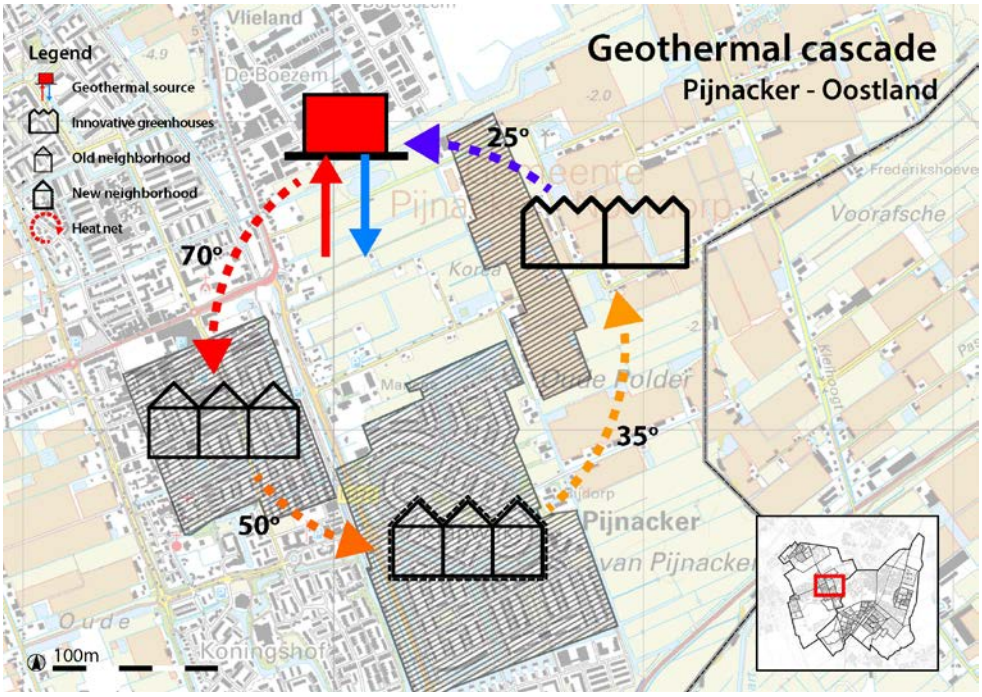

Figure 6: *Proposal of a geothermal cascade that consecutively supplies an older and newer residential area and a well-performing greenhouse area; this is based on and quantified by the energy potential maps of figure 2 (Broersma et al., 2013b).*

The centre of Pijnacker (encircled in the potential maps) has great geothermal potential. An old quarter here has a relatively high-temperature demand (~70°C inlet temperature); a significantly lower temperature could provide the adjacent newer area (~50°C inlet temperature). Adjacent to these two residential areas, a new greenhouse area is planned. If energy-efficient greenhouses are realised, very low temperatures (~35°C) will suffice. The two dashed residential areas in figure 6 have a similar heat demand. The new greenhouse area is finally dimensioned appropriately and connected by the heat supply of the cascade.

In this proposal, the present geothermal heat, at around 2000 m depth, provides a temperature of around 70°C and is re-injected at around 25°C. In the longer run, in an ideal situation, the geothermal well would be replenished by high-temperature heat in summertime, at present perhaps coming from fossil-fueled power plants, and in the future preferably from residual solar heat, won in collectors on roofs and in urban surfaces.

5. CONCLUSION

This paper discussed an approach to energetically resilient city regions, based on various energy studies that gradually led to the stepped approach, coined as the Energy Master Plan. The examples used in this paper were from the Netherlands, but the authors think the generic approach may be applied in various countries and climates, only leading to different outcomes than the relatively cool temperate climate of the Netherlands. Since this paper argued the importance of becoming energetically resilient in detail, cities anywhere across the world may profit from a generic approach that helps them to become more self-sufficient whilst maintaining the quality of life, or even increase it, when speaking of emerging or rapidly growing metropolitan areas.

The first self-sufficient city still needs to be developed, or rather: redeveloped. Many cities across the world have made vows to become climate-neutral, carbon-neutral or energy-neutral by a certain year in the nearby future, but only few of them have their energy administration up-to-date. The authors think that using the science-based approach of the Energy Master Plan, including the method of Energy Potential Mapping, will help to realise their ambitions better than using a less-rationalised approach.

By testing the approach in its full potential, flaws or specified deviations will inevitably emerge, but it is the only way to get ahead in times when old solutions do not provide an answer anymore to new challenges.

ACKNOWLEDGEMENTS

The authors would like to thank the organisations that have made possible the various energy studies this paper was based upon: Agentschap NL, the Province of Groningen, the Municipality of Hoogezand-Sappemeer, the City of Rotterdam, Rabobank Zuid-Holland-West, the municipalities of Pijnacker-Nootdorp and Lansingerland.

A Comparative Analysis of Household Energy Consumption in Jakarta and Bandung

Tetsu Kubota, Dr
Hiroshima University

Usep Surahman, Dr
Indonesia University of Education

Osamu Higashi, Dr
Hiroshima University

ABSTRACT

This paper aims to reveal the detailed household operational energy consumption patterns in major cities of Indonesia. A total of 297 households were surveyed in Jakarta, while 247 households were investigated in Bandung, focusing especially on unplanned landed houses. The detailed information about household appliances and gas consumption were investigated through face-to-face interviews. The households in the two cities were grouped into three clusters based on their 'wealth' and 'household size'. It was seen that the average household energy consumption and their CO_2 emissions increase with the increase in the above two factors, in particular the 'wealth'. The household energy consumption in major Indonesian cities was predicted to increase very sharply in line with the rise of middle class in the near future if proper energy-saving strategies are not implemented. We recommended the following potential energy-saving strategies for urban houses in Indonesia: (a) provision of more apartments rather than landed houses (from the viewpoint of energy), (b) natural lighting and use of LED lamps, (c) passive cooling techniques wherever possible, and (d) insulation for building envelope.

INTRODUCTION

Indonesia has been experiencing high economic growth in line with rapid urbanization and therefore sees large increase in urban energy consumption. The real GDP increased stably by approximately 6-7% over the last few decades, whereas the nationwide final energy demand rose by 14 times from 1970s to the present (Dewi et al., 2010). Energy-saving strategies are, therefore, essential to be introduced further to make the cities more sustainable. At present, Indonesia has a population of 240 million and the percentage of people living in urban areas reached approximately 50% as of 2010. It has been reported that approximately 60% of the total population are distributed in the relatively small island, Java, which accounts for only 6% of the total national land. As a consequence, major cities in the Java Island are densely populated, such as Jakarta, Bandung and Surabaya, etc.

In Indonesia, the household sector contributes to the nationwide final energy consumption by approximately 29% in 2011 (Indonesia, 2011) and the household energy consumption is expected to increase dramatically as the middle class in urban areas rises in the near future (JETRO, 2011). At present, most of the residential buildings in major cities are considered to be unplanned houses called '*Kampungs*'. These dwellings were settled in unplanned and overcrowded urban villages without being provided properly with basic urban infrastructure and services. These unplanned houses account for a large proportion in the existing housing stocks in the major cities: 74% in Jakarta, 89% in Bandung and 98% in Surabaya, etc.

The objective of this study is to reveal the detailed household operational energy consumption patterns in major cities of Indonesia. A total of 297 households were surveyed in Jakarta, while 247 households were investigated in Bandung, focusing especially on unplanned landed houses. Firstly, the samples of the two cities are classified into several groups based on household characteristics through a cluster analysis in order to analyze their household energy consumption patterns. Secondly, multiple regression analyses are carried out for respective cities to figure out the causal structures on the household energy consumption. Potential energy-saving strategies for urban houses in Indonesia are discussed based on the results of the above analyses.

METHODS

Jakarta, the capital city, has a population of 9.6 million in 2010 while that of Bandung is 3.3 million as of 2011. Both of the cities saw rapid population growth over the last few decades. The two cities are situated in the West Java and experience uniform hot-humid climates throughout the year. However, the average temperature in Bandung is not as high as other cities because of its relatively high altitude (700-800 m above the sea level). The monthly average temperature ranges from 22.9-23.9°C in Bandung, whereas that of Jakarta is 27.1-28.9°C. Due to the relatively cool climate, few houses use air-conditioning in Bandung.

As described before, the majority of urban houses are considered unplanned houses in Indonesia. The Indonesian government further classifies these unplanned houses into three categories based on construction cost and lot area, namely simple, medium and luxurious houses (Figure 1). Although the quality and size of houses differ among these three house categories, they are similarly constructed of brick-walled structure. Moreover, most of the building materials used and the construction methods of these houses are similar regardless of the house category (Surahman and Kubota, 2013).

A total of 14 typical residential neighborhoods were selected in Jakarta while six areas were chosen in Bandung for the surveys. The survey was conducted in Jakarta from September to November 2012, whereas it was carried out from September to October 2011 in Bandung. A total of 297 and 247 houses were investigated respectively (see Table 1). The detailed information about household appliances and gas consumption were obtained by means of face-to-face interviews using a questionnaire form. The content of the questionnaire covers the following items: (a) socio-economic profile, (b) building information, (c) monthly energy bills (electricity, water, gas (LPG), and kerosene), and (d) number and usage time of household appliances. Meanwhile, on-site measurements using watt meters (MWC01, OSAKI) were carried out to investigate the electric capacity of respective household appliances. Then, the monthly average household electricity consumption was estimated based on the data of (a) number of appliances, (b) usage time, and (c) measured electric capacities. These measured electricity consumption was validated by the data obtained through the electricity bills. The monthly gas (LPG) and kerosene consumption was estimated simply based on the data from their bills.

The annual average household energy consumption was then calculated in the form of secondary energy by combining electricity consumption for all the household appliances as well as gas and kerosene consumption. As explained before, the seasonal variation in climate conditions is not large in both Jakarta and Bandung. Therefore, the usage time of appliances was assumed to be constant

Figure 1 *Views of sample houses. (a) Simple house; (b) Medium house; (c) Luxurious house.*

throughout the year. Nevertheless, the small seasonal changes of air temperature and humidity were considered in the estimation of energy consumption caused by air-conditioners and refrigerators, though the resulting changes were found to be negligible.

The primary energy used for generating electricity in Indonesia comprised 42% of coal, 17% of oil, 28% of natural gas, 10% of hydro and 3% of geothermal as of 2010 (Indonesia, 2010; IEA, 2012a). Finally, the electricity consumption was converted into primary energy by considering the above energy mix, electric efficiencies and transmission losses in order to estimate the household CO_2 emissions.

Table 1. Socio-economic profile of respondents

	Jakarta	Bandung
Sample size	297	247
House category (%)		
Simple	42.1	48.6
Medium	38.7	40.1
Luxurious	19.2	11.3

Male	50.5	39.3
Female	49.5	60.7
Age (%)		
< 40 (years old)	21.9	17.0
40-49	33.7	27.9
50-60	32.3	32.0
> 60	12.1	23.1
Household size (persons)	4.5	4.8
Monthly household income (%)		
< 90 (US$)	3.0	4.5
90-450	58.9	61.5
450-900	26.6	28.7
> 900	11.5	5.3
Total floor area (%)		
< 50 (m^2)	33.7	25.9
50-99	28.3	32.4
100-300	34.0	37.7
> 300	4.0	4.0

RESULTS AND DISCUSSION

Profile of respondents

Table 1 shows the socio-economic profile of the respondents. The percentages of simple, medium and luxurious houses are approximately 42%, 38% and 20% in Jakarta, and 48%, 40% and 12% in Bandung. These percentages were determined to represent the approximate proportions among all houses of the cities, respectively. As shown in Table 1, the average household size of the respondents was approximately 4.5-5.0 persons in both of the cities. The luxurious houses tend to have slightly larger households of about 5.5 persons. The proportions of household income strata are almost the same between the two cities, although the average income in Jakarta is slightly higher than that of Bandung. In general, household income increases with the house category from simple to luxurious houses.

Classification of households: Factor analysis and cluster analysis

In order to figure out the socio-economic and demographic characteristics that affect their household energy consumption patterns, an exploratory factor analysis with principal axis factoring and a cluster analysis were carried out for the combined whole samples of the two cities (n=544). The orthogonal varimax rotation was employed and the factors were determined based on the eigenvalues (>1). As shown in Table 2, three factors were extracted from the combined samples. The variables with rotated factor loads of more than 0.4 were grouped into the same groups. These three factors were named as follows: 'Factor 1: Wealth', 'Factor 2: Building age', and 'Factor 3: Household size'.

It was found that both Factors 1 (wealth) and 3 (household size) have significant relationships with household energy consumption respectively. Then, cluster analyses were conducted by using factor scores of the selected two factors (i.e. 'wealth' and 'household size') for the combined samples (Figure 2). Since sample sizes were relatively large, the *K*-means nonhierarchical clustering technique was adopted. By considering the resulting average household energy consumption values, three clusters were determined for the combined samples (Figure 2). In both cities, the factor score of Factor 1 (wealth) consisting of total floor area, house category, household income, lot area, and educational attainment, increases from Cluster 1 to 3. However, the wealth levels are almost the same between Cluster 1 and 2 in both cities. Instead, the households in Cluster 2 have larger household size than those of Cluster 1 as shown in Figure 2.

Household energy consumption by clusters

Figure 3 presents the ownership levels of major household electric appliances in respective case

Table 2. Rotated factor matrix (Jakarta and Bandung)

Variable	Factor 1	Factor 2	Factor 3
Total floor area	0.822	0.003	0.079
House category	0.820	-0.093	0.074
Household income	0.673	-0.081	0.262
Lot area	0.659	0.004	-0.024
Educational attainment	0.582	-0.061	-0.057
No. of building story	0.338	0.065	0.150

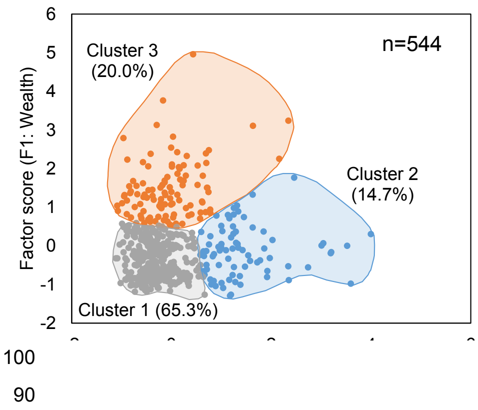
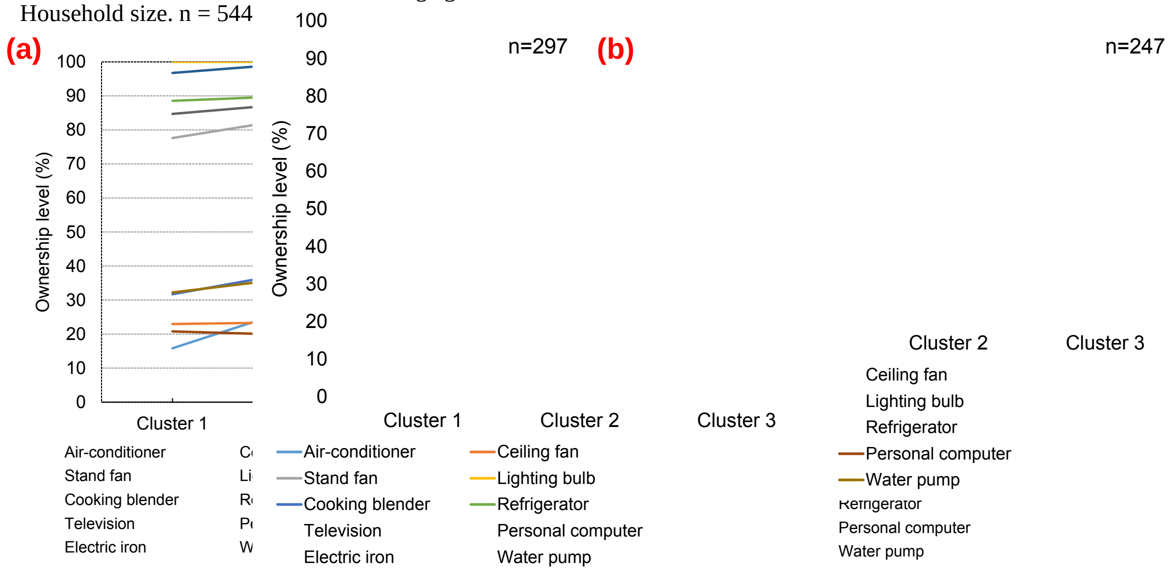
Living duration	-0.021	0.910	0.099
Household size	0.182	0.090	0.658
No. of household	-0.013	0.019	0.607
% of variance	27.24	17.22	9.18

Note: Factor 1, Wealth; Factor 2, Building age; Factor 3, Household size. n = 544





studies. As shown, lighting bulb (100%), television (95-100%) and refrigerator (79-100%) recorded high ownership levels similarly in the two cities among three clusters. In the case of Jakarta (Figure 3a), the stand fan also recorded high ownership levels of 78-84%, reflecting its severe hot climatic conditions. In general, the ownership levels of other appliances increase from Cluster 1 to 3 respectively, except for a few appliances such as water pump in Bandung. The ownership levels of air-conditioners significantly differ between the two cities: they are 16-79% in Jakarta and 0-17% in Bandung.

In both cities, compact fluorescent lamps are well penetrated among households regardless of the clusters (Figure 4). It has been reported that the Indonesian government highly promoted fluorescent lamps for replacing incandescent lamps from 2007 (BUMN, 2007). The national power company (i.e. *Perusahaan Listrik Negara*) exchanged one incandescent bulb by three compact fluorescent bulbs for free for their customers all over Indonesia with the aim of reducing the nationwide electricity consumption and the government's subsidies for electricity tariffs.

Figures 5 and 6 show the annual household energy consumption (secondary energy) averaged in respective clusters. Figures 5a and 6a indicate the energy consumption by different energy sources and Figures 5b and 6b show those by different end-use categories. Overall, the average annual energy consumption in Jakarta is approximately 5,726 kWh, which is 1,402 kWh larger than that of Bandung. The difference is mainly attributed to the use of air-conditioning between the two cities. As shown in Figure 5b, the energy consumption for cooling accounts for 22% in Jakarta on average, whereas the corresponding percentage is only 1.3% in Bandung. Hence, in the case of Jakarta, basically, the average household energy consumption of clusters increases with the increase in ownership and use of air-conditioning (Figures 3a and 5b). In the case of Bandung, the energy consumption for cooking, lighting, entertainment and power, etc. largely influence the increase in the overall energy consumption (Figure 5b). As described before, Clusters 1 and 2 have similar wealth levels on average, while Cluster 2 has larger household size than Cluster 1 in both of the cities (see Figure 2). As shown in Figure 5b, the

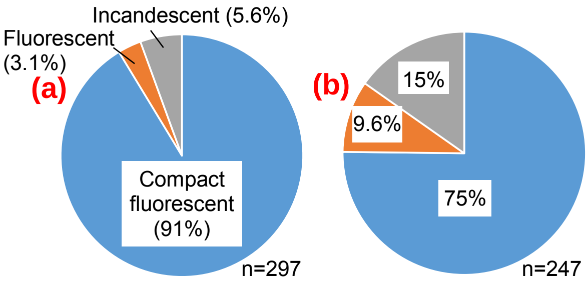


Figure 4 *Percentage of lighting bulbs used in their houses. (a) Jakarta; (b) Bandung.*

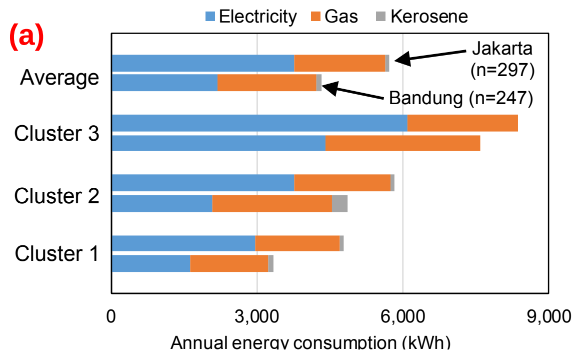
Table 3. CO_2 emission factors

Energy source	CO_2 emission factor (kg CO_2-eq/GJ)	Source
Electricity	196.9	IEA, 2012b
LPG	66.7	Kurdi, 2006
Kerosene	72.5	Kurdi, 2006



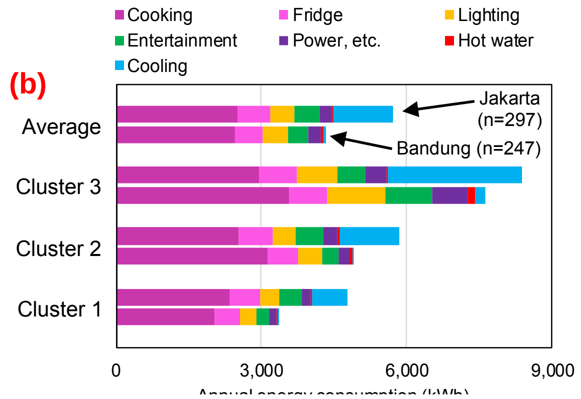


Figure 5 *Annual household energy consumption by clusters (Secondary energy). (a) by energy source; (b) by end-use.*

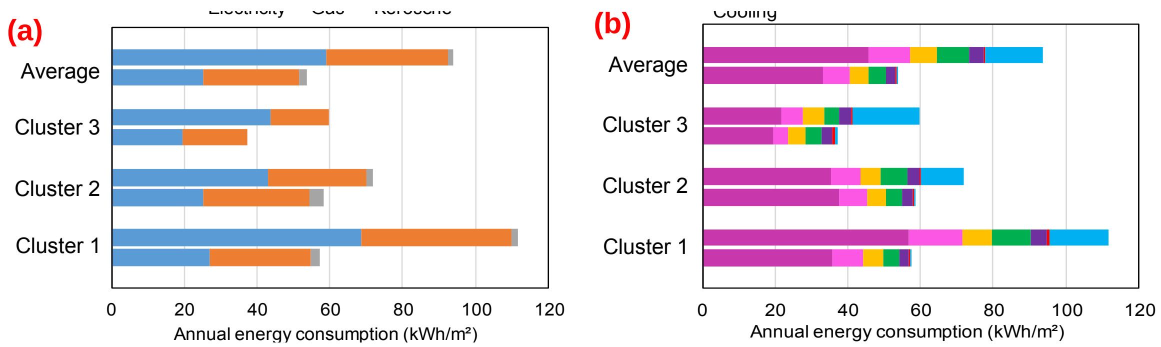

Figure 6 *Annual household energy consumption per square meter by clusters (Secondary energy). (a) by energy source; (b) by end-use.*

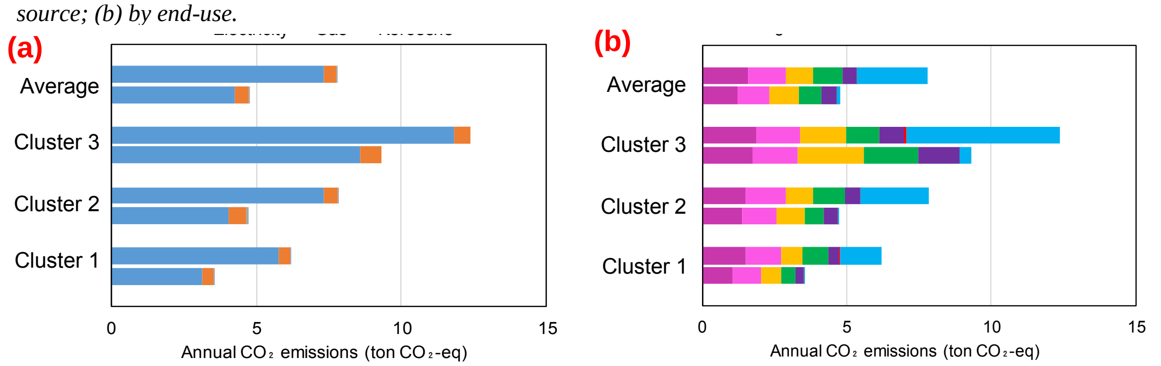

Figure 7 *Annual household CO_2 emissions by clusters (Primary energy). (a) by energy source; (b) by end-use.*

difference of household size between Cluster 1 and 2 cause a significant difference in energy consumption for cooking in the case of Bandung. In both of the cities, electricity consumption is larger than that of LPG and kerosene except for Clusters 1 and 2 of Bandung, even when they are assessed based on secondary energy: 62-73% in Jakarta and 43-58% in Bandung (Figure 5a).

Figure 6 shows the corresponding annual energy consumption per square meter. Interestingly, the averaged energy consumption decreases from Cluster 1 to 3, except for Clusters 1 and 2 of Bandung. This is mainly because the occupant density declines from Cluster 1 to 3 accordingly. In particular, the average total floor area of houses in Cluster 1 of Jakarta is so small (64 m^2) that the corresponding energy consumption per square meter is larger than the others.

The annual household CO_2 emissions were estimated through multiplying the energy consumption

(primary energy) for each fuel type by its corresponding CO_2 emission factor (Nansai et al., 2002; Surahman and Kubota, 2013). Table 3 presents the CO_2 emission factors used for this analysis. As indicated in Figure 7, the average annual CO_2 emission in Jakarta is estimated at 7.8 ton CO_2-equivalent, while that of Bandung is 4.8 ton CO_2-equivalent. The major contributors in Jakarta are cooling (2.4 ton (31%)), cooking (1.6 ton (20%)) and refrigerator (1.3 ton (17%)), while those in Bandung are cooking (1.2 ton (26%)), refrigerator (1.1 ton (23%)) and lighting (1.0 ton (21%)). If the amount of CO_2 emissions caused by cooling are excluded, then the difference of total CO_2 emissions between the two cities would be insignificant (5.4 ton in Jakarta and 4.7 ton in Bandung). This clearly indicates that the increase in use of air-conditioning in the future would dramatically increase the household energy consumption and therefore their CO_2 emissions.

Causal structures on household energy consumption: Multiple regression analyses

Multiple regression analyses were carried out to further analyze the causal structure on household energy consumption in the two cities (Table 4). Since electricity and LPG were found to account for almost all the energy consumption in the two cities (see Figure 5a), firstly, we examined the major factors explaining consumption of these two energy sources (Table 4ab). In this analysis, the new variables (electricity consumption caused by respective appliances) were created for each of the household electric appliances by multiplying its electric capacity by the number of the appliance and its usage time. Secondly, further determinants for respective electric appliances were analyzed in the two cities respectively (Table 4c).

As shown in Table 4a, the major appliances contributing the electricity consumption largely differ between the two cities. In the case of Jakarta, air-conditioner (β=0.71) is found to be the major determinant for the electricity consumption in this model, followed by television (0.21), stand fan (0.20), ceiling fan (0.16), and refrigerator (0.14), etc. As seen in Figures 5b, 6b and 7b, this result confirms that energy consumption for cooling appliances, in particular air-conditioners, is significant and large in the case of hot-humid climate of Jakarta. In contrast, in the case of Bandung, water pump (β=0.35) is found to be the most influential contributor for the electricity consumption in this model, followed by television (0.29), lighting bulb (0.26), and refrigerator (0.24), etc. Both of the regression models obtain high R^2-values of 0.93 and 0.87, respectively. The determinants for LPG consumption are similar in the two models for respective cities, although both of the R^2-values record low values of 0.08 and 0.13 respectively (Table 4b). In the two cities, both household size and building size may be able to explain weakly the LPG consumption.

As shown in Table 4c, in Jakarta, the energy consumption caused by air-conditioning, which is the main contributor to the electricity consumption, can be explained by the total floor area, the household income and the age of husband with a coefficient of determinant of 0.47. Other major appliances (i.e. television and stand fan) are weakly explained by the total floor area and the number of children, respectively. On the other hand, in Bandung, water pump is weakly explained by the household income. Other major appliances (i.e. television and lighting bulb) can be determined by the lot area and the household income, and total floor area, respectively.

It is seen that overall, the increase in household income and building size, such as total floor area and lot area, increase the electricity consumption caused by the major appliances. In both of the cities, it was found that the increase in household income increase their building size such as the total floor area (r = 0.38** in Jakarta and r = 0.72** in Bandung) and the lot area (r = 0.39** in Jakarta and r = 0.60** in Bandung). Hence, it is anticipated that the further increase in household income would increase the building size, thus the energy consumption caused by major household appliances. As a consequence, the increase in household income would increase the total household energy consumption significantly in the near future in Indonesian cities. It has been reported that the household income in Indonesia is predicted to rise dramatically in the near future in line with the rise of middle class as described before (JETRO, 2011). The household energy consumption in major Indonesian cities is predicted to increase very sharply if proper energy-saving strategies are not implemented.

It is important to avoid the tendency that building size increases straightforwardly with the increase in household income. From the viewpoint of energy, one of the possible solutions is to recommend more apartments rather than landed houses that generally increase total floor area. It should be noted that most of the incandescent bulbs were already replaced by compact fluorescent bulbs in Indonesian cities. This means that further energy-saving should be made for lighting by utilizing more natural lighting or using LED lamps. The increase in air-conditioning would be a major concern in terms of the energy-saving strategies in Indonesia (the relatively cool climate of Bandung is not typical of other major cities). Even in Jakarta, the ownership level of air-conditioner was only 32% on average at the moment in this survey. It is important to reduce the use of air-conditioning in the future despite the expected increase in household income. Passive cooling techniques should be adopted wherever possible. Insulation for building envelope should also be considered.

On the other hand, the current energy efficiency in electricity generation in Indonesia is not as good as other developed nations. The total loss due to electric efficiency and transmission losses results in the increase in primary energy consumption by approximately 2.7 times than the end-use electricity consumption. This exceeds the scope of this paper but this should also be considered in the future energy-saving strategies in Indonesia.

CONCLUSIONS

Key findings are summarized as follows:

1. The households in Jakarta and Bandung can be grouped into three clusters based on their ‘wealth’ and ‘household size’. It was seen that the average household energy consumption and CO_2 emissions increase with the increase in the above two factors, in particular the ‘wealth’. Overall, the average annual energy consumption in Jakarta was approximately 5,726 kWh, which was 1,402 kWh larger than that of Bandung. Accordingly, the average annual CO_2 emission in Jakarta was estimated at 7.8 ton CO_2-equivalent, while that of Bandung was 4.8 ton CO_2-equivalent.
2. The difference of household energy consumption and CO_2 emission between the two cities was mainly attributed to the use of air-conditioning. The ownership levels of air-conditioners significantly differed between the two cities: they are 16-79% in Jakarta and 0-17% in Bandung. It was predicted that the increase in use of air-conditioning in the future would dramatically increase the household energy consumption and therefore their CO_2 emissions.
3. It was anticipated that the further increase in household income would increase the building size, thus the energy consumption caused by major household appliances. As a consequence, the increase in household income would increase the total household energy consumption significantly in line with the rise of middle class in the near future in Indonesian cities if proper energy-saving strategies are not implemented.
4. It is important to avoid the tendency that building size increases straightforwardly with the increase in household income. We recommended the following potential energy-saving strategies for urban houses in Indonesia: (a) provision of more apartments rather than landed houses (from the viewpoint of energy), (b) natural lighting and use of LED lamps, (c) passive cooling techniques wherever possible, and (d) insulation for building envelope.

ABSTRACT

*The city of São Paulo is the richest city in Brazil, accounting for more than 12% of the national GDP, offering employment opportunities for the countries' middle class as well as for the poor (*IBGE, 2012*). As a result, approximate 2 million people live in slums with deficient urban infrastructure (*FRANÇA, COSTA, 2012*). In the last decade, the increase buying power of the low income families in the big cities of the country has caused a dramatic raise on electricity demand due to the acquisition of domestic appliances, which have proved to become comparable to those of middle class, based on the data gathering in the fieldwork research presented in this paper. Hence, the growth of urban slums in Sao Paulo is associated with the increase of its population density accompanied by an increase of electricity demand, adding pressure on the precarious infrastructure and impoverishing even more the living conditions, due to the accumulation of heat gains in compact irregular and overcrowded housing, agglomerated in informal settlements of poor quality open spaces. In this context, this work examines the environmental challenges of slums in the city of São Paulo, the so called "favelas", drawing from two cases: "favela Morro da USP", covering 18.500m² and housing 515 families, and "favela Paraisopolis", the second biggest in São Paulo, with almost 60.000 inhabitants living over 100 hectares. Field work has shown energy consumption of the slums' households of around 220kwh/month, the equivalent to the typical figures from the local middle class homes. In addition, the environmental research has identified the potencial of improving internal conditions with bigger openings to higher ventilation rates and shading of roof components.*

INTRODUCTION

Being the 10th richest city in the world, São Paulo entered the new century accounting for 12.26% of the national GDP and 36% of the total output of goods and services of the State of São Paulo (IBGE, 2012). Associated with its economic development, the city of São Paulo is seen as a place of employment opportunities, availability of infrastructure and assess to education, health, leisure and culture in the country. On the other hand, economic and urban growth has also reflected in a series of socio-economic, urban and environmental negative impacts, compromising the quality of life of various neighbourhoods in the city, formal and informal. In this context, the housing deficit is one of the most critical issues in the city. According to the census of 2010 (IBGE, 2010), 1.16 million people were counted

Joana Gonçalves and Roberta Mulfarth are Professors of the Faculty of Architecture and Urbanism of the University of São Paulo, FAUUSP. Eduardo Pizarro is MSc Architect and PhD candidate of the graduate programme of FAUUSP and Claudia Ferrara Caruncho is undergraduate student and junior researcher of FAUUSP.

in the slums, 1.8 million inhabitants in irregular settlements, and about 9,000 homeless in the city of São Paulo. The phenomena of the *favelas* in São Paulo, which started in the 70s, became visible and distinguished in the urban fabric of the city (figure 1).

Covering an area of almost 2 hectares (18.500m²) and housing 515 families, *Favela Morro da USP* is a small informal settlement where 50% of residents live in units smaller than 30m^2 (Pizarro, 2014). On the other end, *Favela Paraisopolis* is the second biggest slum in São Paulo, with almost 60.000 inhabitants living over 100 hectares (França, Costa, 2012). Whilst the first case has the population and a total area equivalent to a couple of typical urban blocks, *Paraisopolis* covers a territory of a medium size city in the country. Despite these differences, both case studies have similar social and physical structure, typical of the consolidated urban slums in the city. The consolidated slum in São Paulo has a basic infrastructure in place (roads, water, sewage and energy utilities), the permanent character of the buildings and the identification of a coherent social organization. Problems for the quality of life are found in the lack of open spaces and in the environmental conditions of the residences.

CLIMATE

The city of São Paulo is located in the latitude 23º24'south, with a tropical climate subjected to the effects of altitude (approximately 800 metres above sea level) where thermal comfort is likely to be achieved for approximately 70% of the year (ASHRAE, 2009). The climate offers sunny winter days, when direct solar radiation is a key factor for thermal comfort, especially in outdoor spaces, and partially cloudy days in summer, when the main strategy for thermal comfort is solar protection combined with natural ventilation.The mean air temperature in the summer months stays around 23^{o}C, whilst humidity can easily reach 80 per cent (figure 2). However, it is worth highlighting that in the hot periods of the year, thermal comfort indoors and outdoors is highly dependent on shading strategies and proper ventilation rates. Winters are mild, with mean air temperatures between 16^{o}C and 18^{o}C, though even in winter relative humidity stays high. Heating demand is identified for short periods of the year, being easily solved passively with solar gains and internal gains from dense ocuppantion patterns.

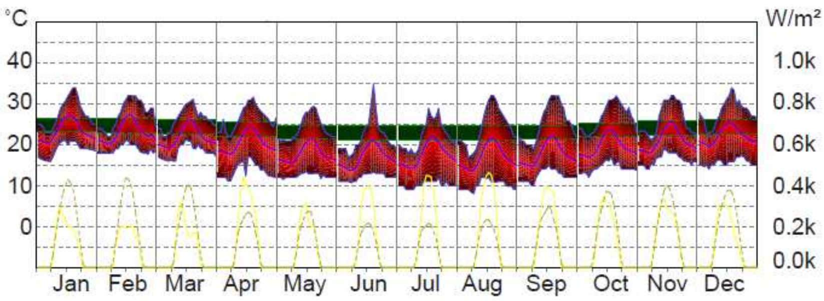

Figure 2 Monthly average temperatures of the climate of Sao Paulo with incident radiation. Source: Pizarro, 2014.

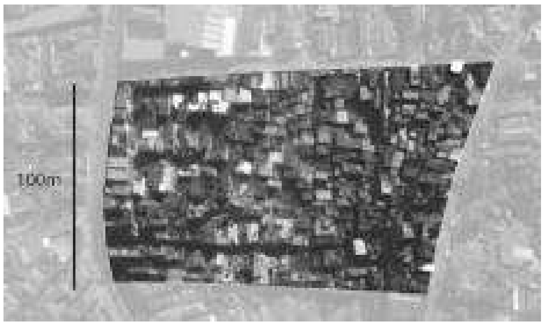
In addition to the characteristics of the natural climate, the city presents a huge variety of urban microclimates, influenced by the multiple aspects of the urban form and human activities and characterized by problems with air quality, urban heat islands, poor urban ventilation, urban noise, among others, which affect the quality of both open spaces and buildings, typical in the slums (CETESB, 1990, Silva, Ribeiro, 2006). Moreover, it is important to consider that, in the residential units, high occupation density coupled with insufficient air changes (due to small windows), compromise the internal environmental conditions in the warm days of the year, as shown bellow.

THE BUILT ENVIRONMENT OF SLUMS

Urban fabric

Originally, the urban fabric of both case studies (as in the majority of slums in Sao Paulo) developed on top of a formal parceling of the territory (figures 3 and 4). As a consequence, main roads were kept within their original size (10 meters long), whilst a complex grid of alleys grew within the urban blocks to give access by foot to the internal and smaller residential units (figures 5 to 8). As a result, the built environment is characterized by a diveristy of circulation spaces with constrasting environmental conditions in need of improvement. The compactness of the urban blocks leads to lack of vegetation and space to the accommodation of urban and living activities, which are either castigated by solar radiation or deprived of daylight and air flow between buildings due to the rather narrow canyons (figures 5 and 6).



Figures 3 and 4 On the left, the urban fabric of *Favela Paraisopolis*, over 100 hectares. On the right, the site planning of *Favela Morro da USP*, covering the small area of 2 hectares. Despite the difference in size, both cases have a similar parttern of urban fabric. Source: Pizarro, 2014.

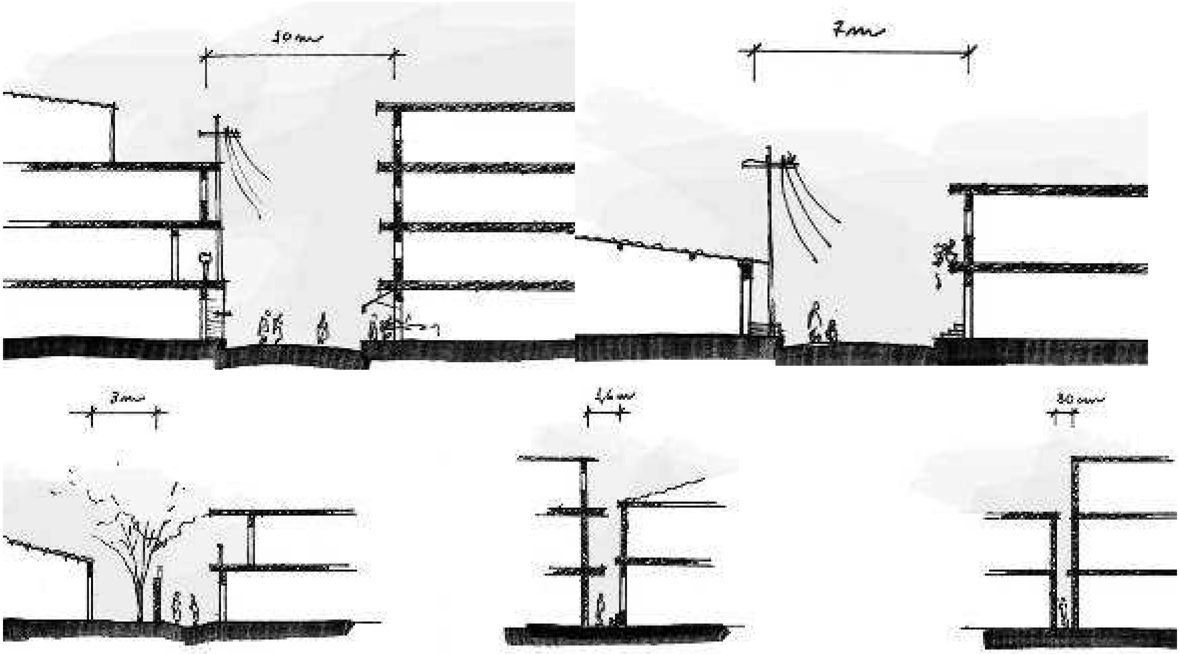

Figures 7 and 8 Sections of the typical canyons in the slums of *Morro da USP* and *Paraisópolis*. Above two of the main streets shared by pedestrians and cars. Below the pedestrians´ alley. Source: Pizarro, 2014.

The building

The buildings in the slums of Sao Paulo vary from one to four storeys, supported by concrete columns and beams and brick walls. The area of the residential unit (one per floor), vary from 30 to 50m^2, for an average family size of four people. Typically, each residence has one façade to the exterior. As identified in Samora and Vosgueritchian (2006), the limited exposure to the outside combined with the compatness of the urban fabric incurs to internal spaces characterized by lack of solar access, daylight and ventilation. On the other hand, the thermal capacity of the buildings, in addition to the self shading of the urban fabric and external shading strategies, protects internal and external spaces from the harsh impact of solar radiation.

Figures 9 and 10 On the left, view of a typical street within the fabric of *Favela Morro da USP*. On the right, view of multistorey buildings supported by concrete columns and beams with brick walls.

ENVIRONMENTAL CONDITIONS AND CHALLENGES

Outdoor environment: walking through the streets of *Paraisopolis*

Measuraments of environmental variables in the streets of *Paraisopolis* included air temperatures, surface temperatures, relative humidity and air movement. Comparing the results found in the streets with those from the alleys, the fieldwork showed the significant positive impact of the shading and shaded mass in reducing surface and air temperatures in hot days. The unshaded street presented surface temperatures as high as 50^{o}C and air temperature around 36^{o}C (figure 11). In contrast to that, within a short period of time, the protected space of alley had higher air temperatures around 36 ^{o}C but significantly lower surface temperatures, showing figures around 28 ^{o}C, which have a major favourable impact on pedestrians' comfort and on the thermal conditions within the rooms facing the alleys (figure 12). Air movement also varied from higher than 2 m/s in the main street to around 1.5 m/s in the alley, in the best scenario. Nevertheless, insufficient daylighting in the alleys is obvious.

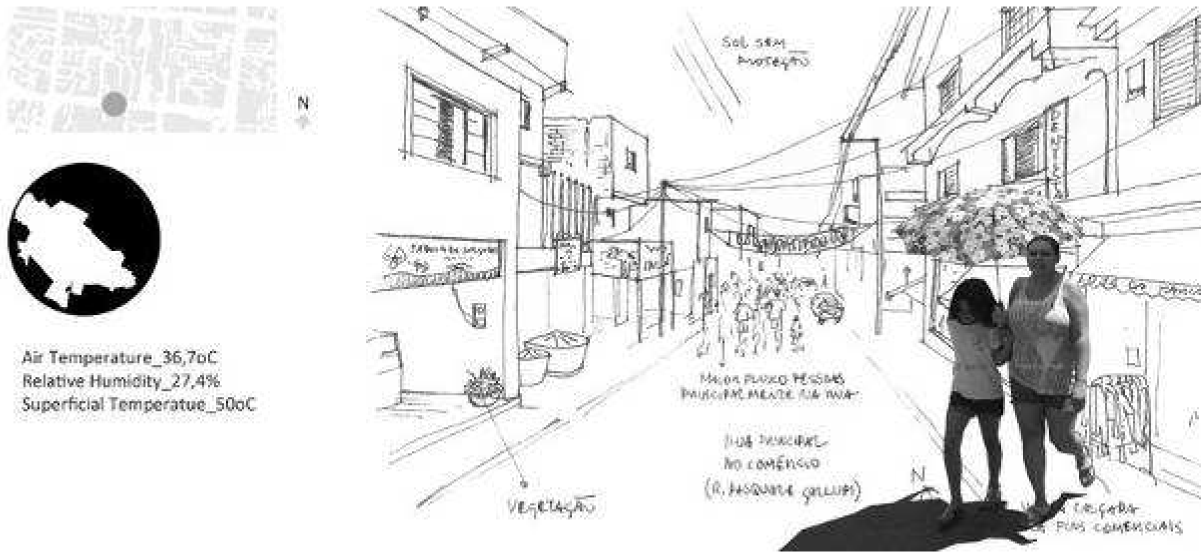

Figure 11 Sinthesis of thermal conditions in one of the main streets of *Paraisopolis,* showing air temperature, surface temperature, relative humidty and air movement taken on a hot day at 4 pm. Source: Pizarro, 2014.

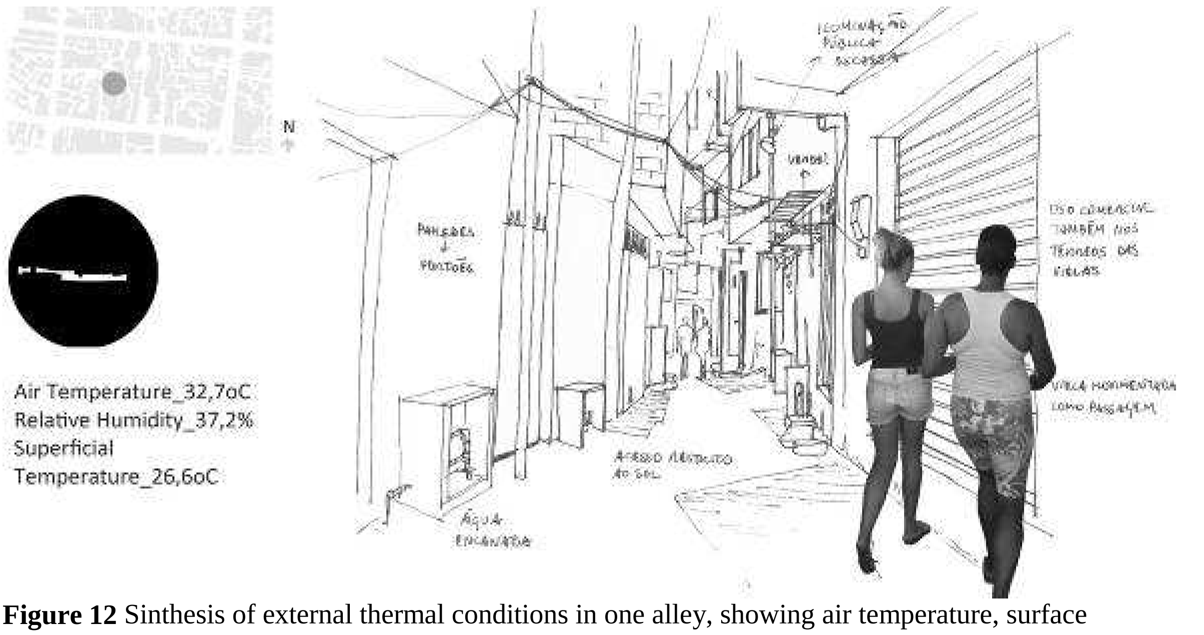

Figure 12 Sinthesis of external thermal conditions in one alley, showing air temperature, surface temperature, relative humidty and air movement on a hot summer day at 4:15 pm. Source: Pizarro, 2014.

Thermal environment in internal spaces

Measuraments of thermal conditions of an internal space were taken in one of the houses facing a main street. The exposure to solar radiation coupled with the concentration of internal gains and insufficient ventilation rates resulted in air temperatures as high as 40^{o}C in the living space (bringing together living and kitchen in one area) at 4 pm of a week day, when outdoor temperatures oscilated around 33 ^{o}C (figure 13). The way windows are design, protection against solar gains would inevitably block the already limited air ventilation rates, so as a common practice, windows are kept open by the occupants during the day in order to provide some air movement, however, inefficient to control the rise of internal temperatures. At nitgh, internal temperatures drop up to 10 ^{o}C. It is known that windows are kept open during the night allowing for nitgh time cooling of the internal spaces and the building fabric of brick walls and concrete block ceilings. However, during the internal temperatures quickly go up to 35^{o}C and than 40^{o}C degrees during the 1st half of the day. In principle, solar protection and higher ventilation rates would improve such conditions.

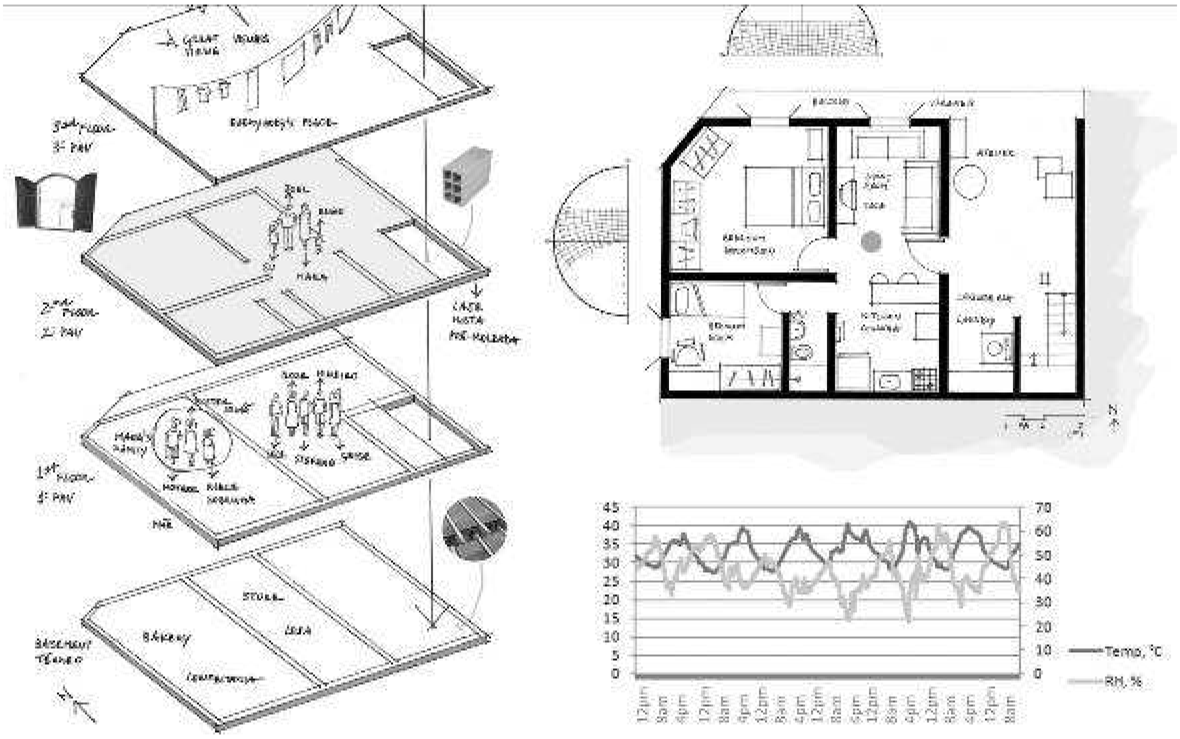

Figure 13 Measuraments of air temperature in a residencial unit with a multistory building, facing a main street in *Paraisopolis*. Source: Pizarro, 2014.

ENERGY DEMAND: THE CASE STUDY OF *FAVELA MORRO DA USP*

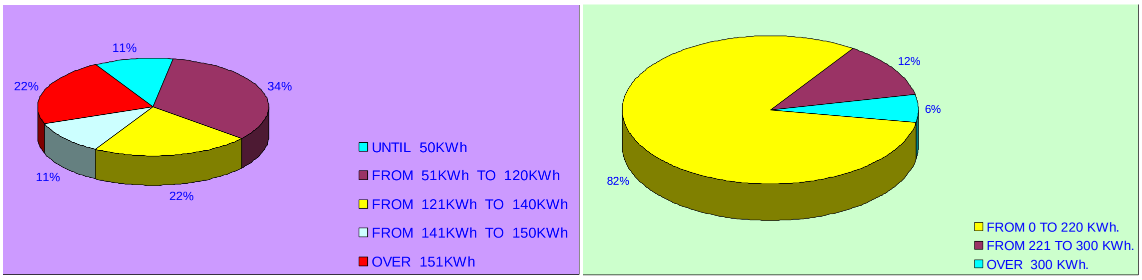
The main type of energy consumed in the building sector in Brazil is electrical. The electricity consumption in the Brazilian residential sector represented 20% of the total in 1991, whilst in 2000 it grew to 27% (CCPE, 2004). In the group of cities of the South-East region of the country, where São Paulo is located, the main energy consumer is the fridge with approximately 30%, followed by the electric shower with approximately 26% and the artificial lighting with approximately 10% (Guisi *at al*, 2007). Looking at the electricity consumption in a typical middle class residence in São Paulo, this trend results in a average of 117Kwh/ m^2 month, in a residence of around 70m^2 (BESP, 2009). Compared with data from the National Energy Balance (BEN, 2010), the numbers relating to residential energy consumption in São Paulo are very close to the national average, being 113kWh/m^2. It is worth noticing that almost 40% of the residential energy consumption range from 100 to 160kWh/m2, with an average of 3.2 people per family (BEN, 2010).

Looking at the case of *Favela Morro da USP*, although almost 70% of its population have an monthly income below five minimum wages (between U$545,00 and U$1.818,00), proving the hypothesis that the consumption of electricity in consolidated favelas has a similar pattern to that from the local middle class homes in Brazil (Pizarro, 2014). This is due to the increasing acccess to affordable appliances. As the enegy demand grows in consolidated slums, as in *Morro da USP*, the provision of electricity becomes problematic for two reasons: the difficult access to the residential units, due to the informal use of land and compact nature of the built envionemnt, and the dynamic changes of the slums' social and physical structures. The precarious nature of living combined with great expansion of self-built units and subdivisions of one residence in multiple ones (figures 14 e 15), imposes a fundamental challenge to the task of checking and monitoring the consumption of the different buildings and families.

In *Favela Morro da USP* it is common to observe a single residencial unit housing two or more families, which would demand different electricity meters. In a number of cases, the informal sharing of the spaces and domestic appliances between families makes the division in electricity consumption of different families not clearly distinguishable and difficult to be priced.

Figures 14 e 15 On the left, the precarious electricity grid running in front of windows in favela *Morro da USP*.On the right, the multiple electricity meters installed in one residential building.

In this context, the total monthly energy consumption by household cannot be translated into kWh/m^2, once the area occupied by each household is a constant changing factor and cannot be simply identified by the plot ratio of the building. In order to present a clear energy consumption profile, the figures chosen to illustrate the electricity consumption in the case study of Favela *Morro de São Paulo* refer to only one month, corresponding to the biggest number of households being registered in the year of the fieldwork, May 2013 (Pizarro, 2014). The fieldwork showed that for 82% of households the threshold of electricity consumption is 200kwh per month, thus achieving the Social Discount Rate Low Income, created by the Federal Government in January 2010 (figure 16 e 17). The new social tariff of electricity consumption promoted discounts for social housing, varying between 10% a 65% in cases which the monthly family income per capita is equal or less than half of the national minimum wage. The degree of discount is associated with the household consumption, varying from the minimum of 30kWh per month for the maximum discount of 65%, to 202kWh per month for the minimum discount of 10%.



Figures 16 e 17 Energy consumption in the residential buildings of Favela *Morro da USP* in May 2013. On the left, the percentage of households below 50kWh and above, including demands over 151kWh. On the right, a detail assessment of consumption above 1501kWh, with 82% up to 220kWh, the threshold of the Social Discount Rate Low Income, and percentage of units above.

With respects to life-style, it is important to note that the population of consolidated favelas such as Morro de São Paulo, where addresses have been established based on to energy and sewage bills, has led residents to have access to bank credit and, therefore, to domestic appliances existing in a typical middle-class residence in Brazil (TV, microwaves, stereos, computers, irons, electric shower, washing machine, etc.). The gradual increase in the buying power of the low income sector in Brazil, which is visible and practiced in the city of Sao Paulo is among the factors that justify the levels of energy consumption shown in figures 16 and 17. In order words, the oficialization of energy consumption has become an efficient way of socioeconomic inclusion. Nevertheless, the challenges to access all residential units, provide electricity with a safe grid and measure the consumption of individual households remain. Furthermore, the compact urban fabric of the favela results in a highly-concentrated energy demand. In this scenario, to avoid risks of power supply for electricity, implementation of conventional infrastructure facilities could be planned with the introduction of the so called alternative or ”green” technologies, such as solar collectors for water heating and photovoltaic cells for electriccity.

FINAL CONSIDERATIONS

Access to electricity became an effective means of social inclusion. In that sense, since the energy bill is associated with a formal address, within an informal urban settlement, the households have the minimum requirements to take part in the formalozed market of goods and appliances, including the access to financial credits. In addition to that, contrary to the misconception that low income families inherit inefficient domestic appliances (or have none at all), the reality in consolidated *favelas* is that there is a trend of energy consumption similar to those of the overall residential sector in the region. On the other hand, different from the formal part of the residential sector, the energy supply in *favelas* faces the challenges brought by the constant growth and changing of the physical environment, including the horizontal and vertical expansion and multiple subdivisions of one building in several households.

From the point of view of broader environmental issues, whilst energy consumption shows the increasing buying power of low income families living in *favelas* in São Paulo, the comfort of the inhabitants inside the buildings and the environmental conditions of open public spaces do not offer good quality. In this respect, the performance of the local built environment of the *favela* with the principles of environmental design for the specific climate of São Paulo needs to be further improved both for indoor and outdoor spaces, if quality of life is to be provided beyond access to energy.

ABSTRACT

Water management model in cities is based upon large-scale systems which take water form external watersheds located dozens to hundred kilometers to the municipalities they supply. Water is treated to drinking standards despite the intended use, leading to wastewater which is discharged back to the environment through sewer systems, often without previous treatment, being an important source of environmental pollution and public health hazards. Meanwhile rainwater is considered a problem, being collected from roofs and streets to be also disposed in sewers as other kind of wastewater. Although water technologies have evolved, this model has virtually remained the same since the ancient Rome, twenty centuries ago. A paradigm shift is urgently required and buildings must be in the center of this transformation. Terra Bio-hotel, a 41 room hotel located in Medellín is a project designed and being built with sustainable water systems, integrating low consumption devices, rainwater harvesting, greywater recycling and groundwater catchment. Although the building is connected to the municipal service, altogether these strategies allow the project to function as net-zero as for water is concerned. As expected, the water management scheme of this project is considerably more expensive than a conventional one. Nevertheless, when operation costs are compared to conventional water fares, it appears that investment costs are returned in five years, demonstrating eco-efficiency to be an economically sustainable choice at this scale.

INTRODUCTION

As world urbanization increases so does the pressure upon water resources. This is particularly true for Latin America and the Caribbean, where 80% of population lives in cities which are dependent on external water sources to supply, where wastewater treatment is low and vulnerability to urban floods from storm water is high (Howe, Butterworth, Smouth, Duffy, & Vairavamoorthy, 2012; World Bank, 2013)

This unsustainable condition is related to sectorial water frameworks where local governments, environmental agencies and water companies work for contrasting agendas and measure their challenges and achievements by divergent indicators, whereas citizens, private sector and public institutions remain as passive users, with no say on water governance (Domenech, 2011; Bedoya, 2011)

Since urban water is mainly used and polluted through building operations; water-efficient buildings are a reasonable starting point to give users a more meaningful role on water governance. This paper describes and discusses the water management model implemented on Terra Bio-Hotel Building in Medellin – Colombia, as a study case, whose comprehensive adoption on other building projects in Latin America and other regions may make a significant contribution for cities to become less dependent, more efficient, healthier, less contaminant, more resilient and more sustainable with regards to water (Howe, Butterworth, Smouth, Duffy, & Vairavamoorthy, 2012).

OBJECTIVE

The aim of this applied research was to conceptualize, develop and implement a model for water efficiency on a real scale building in Medellín – Colombia and to forecast the expected environmental and financial cost-benefit ratio in order to provide governs, planners, designers and constructors a framework to make informed decisions on sustainable water management schemes.

PROCESS APPROACH

Case study

Terra Bio-Hotel is a medium size hotel building with 41 rooms and 2400 m^2 built area, looking to be distinguished for its environmental standards at both construction and operation phases, giving host a differential factor concerning architecture and technical facilities.The project is set in Medellín, biggest of ten municipalities assembling a metropolitan area called the Aburrá Valley, inhabited by 3.5 million people.

Water management data for Aburrá Valley

Information concerning water management for Aburra Valley was collected and analyzed from local land and water plans, publications by local environmental authorities and local Water Service Company, as well as from technical relevant literature.

Water management systems for the case of study

Prior to hydraulic design, two water system schemes were pre-designed, analyzed and compared. System 1 is conventional, whereas System 2 is an alternative system proposed to lower the environmental impacts related to water demand and wastewater disposal along operation phase of the building (see figure 1).

Figure 1. Water treatment systems installed at Terra Bio Hotel

Water treatment plants for System 2

In order to fulfill the principles for System 2, two treatment plants are required: one plant to treat grey water to be reused on activities that do not require drinking-quality water, such as toilet flushing, general maintenance and irrigation of green areas; the other plant is to treat rain water and groundwater up to drinking-quality standards, to be used for showers and faucets. Both rainwater and groundwater were previously sampled and tested for compliance to water quality regulations set for water sources intended for domestic supply (data not shown).

Cost-benefit analysis

Financial investment costs for pre-designs of each hydraulic system scheme were calculated. Water demand is estimated as established for hosting facilities by Colombian regulations.

Environmental costs-benefit analysis is based on the following indicators:

- Total water consumption (m^3/year)
- Dependency on water sources external to the watershed (m^3/year)
- Wastewater discharge (m^3/year)
- Storm water discharge (m^3/year)

RESULTS

Water in the local context: Water management model in the Aburrá Valley

Table 1 provides main data concerning water management in the Aburrá Valley, which is highly dependent on external water sources despite of its high water yield. Most urban population has access to water supply, but unaccounted for water is high. Most population also has access to basic sanitation trough connection to a sewer network, although the level of wastewater treatment remains low. New wastewater treatment facilities are under construction and will be fully operating by 2015 though. Due to such investments, sanitation is charged higher than supply. Groundwater is an abundant source and it is used, mainly by industry, but total withdraw is unknown. For building sector, such abundance becomes a problem since parking lots and basements get below the water table, thus water has to be pumped out and discharged into the sewer system which is charged at sanitation fares, this would also be the case for Terra Bio Hotel project (see table 1) (Municipio de Medellín, 2014; URBAM, Área Metropolitana del Valle de Aburrá, & Municipio de Medellín, 2011)

Table 1. Main Data Describing the Current Model for Water Management in the Aburrá Valley

Parameter	Value
Water cycle balance	
Valley Area (km)	1250
Average precipitation (mm/year)	1672
Average evaporation (mm/year)	1172
Water yield (mm/year)	500
Water yield (million m^3/year)	625
Water supply	
Total water consumption from water supply (million m^3/year)	192
Dependency on external water sources –watersheds located outside Aburrá Valley- (%)	90
Unaccounted for water (%)	40
Volume extracted from external sources, considering unaccounted for water (million m^3/year)	288
Population served (% of total urban population)	99
Wastewater	

Combined sewer network (%)	60
Sewage currently being treated (%)	20
Water reuse	0
Population served (% of total urban population)	99
Rainwater	
Rainwater use (%)	0
Conventional drainage (%)	100
Groundwater	
Recharge (million m^3/year)	400
Water table depth on the alluvial plain (m)	4 - 8
Groundwater extraction (million m^3/year)	unknown

Environmental costs comparison

Figures 2 and 3 show a water balance conceptual model for System 1 and 2

System 1 consists of:

- 100% of water needs supplied by the local water company
- drinking-quality water is used for all purposes
- no reuse is considered
- rainwater is directed to sewer without use
- since parking lot base is below water table, groundwater is pumped in order to prevent floods and discharged into sewer with no prior use

Principles for System 2 are:

- water needs supplied from diverse sources
- water source defined according to required quality by use
- reuse is considered
- rainwater as well as groundwater are caught, treated and used

As shown in figures, System 1 produces more environmental impacts than System 2. Water demand for the two systems is the same, but system 1 requires 40% more water, since it fully depends on external sources (table 1). System 1 also produces more pollution since groundwater and rainwater are not harvested but just discharged on sewers and grey water is not reused.

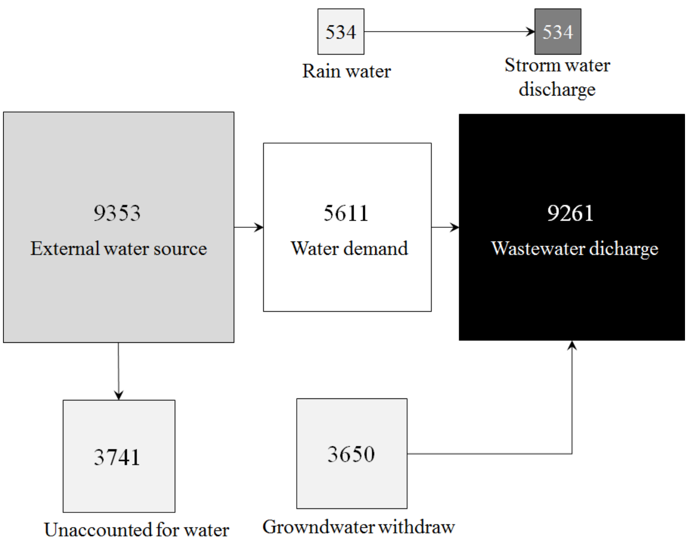

Figure 2. Water balance conceptual model for conventional water management system, System 1. Numbers are expected volumes expressed as m3/year. Frame fill colors are related to water quality: white = high quality, black = low quality.

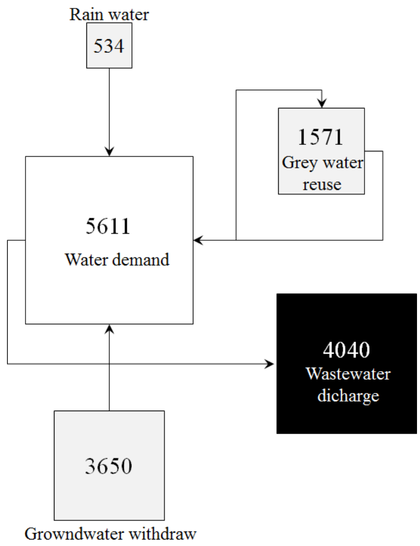

Figure 3. Water balance conceptual model for alternative water management system, System 2. Numbers are expected volumes expressed as m3/year. Frame fill colors are related to water quality: white = high quality, black = low quality.

Due to the use of groundwater and rain water as well as the reuse of grey water, implementation of System 2 not just significantly reduces pollutant discharges from the project but also would eventually allow it to be fully independent from external water sources (see figure 2), in fact, volume balances for System 2 shows that the project may produce more water than it actually needs (see table 3)

Cost-benefit analysis

Investment cost

Table 2 lists the investments required for hydraulic installations under Systems 1 and 2 schemes. Implementation of the efficient water management option costs as much as 38% more than implementation of the conventional system.

Table 2. Investment cost comparison between System 1 and System 2

Item	Cost for System 1	Cost for System 2	Description
Water pumps	$ 28.947	$ 32.632	On System 2 an additional pumping system for grey water supply is required, but the pumping capacity required for drinking water supply gets reduced
Storage tanks	$ 10.526	$ 12.632	On System 2 an additional storage tank is required for grey water supply, but the storage capacity for drinking water supply tank gets reduced
Drinking water network	$ 9.944	$ 5.966	Drinking water supply network gets shorten on System 2, since part of it is replaced by the grey water supply network
Grey water supply network	$ -	$ 6.526	It only applies for System 2
Wastewater network	$ 13.158	$ 11.053	It gets reduced on System 2 since part of it becomes greywater supply network
Rainwater network	$ 6.642	$ 8.105	Rainwater network becomes longer on System 2 in order to reach treatment system
Treatment systems	$ -	$ 18.421	Only applies to System 2

Sum	$ 69.217	$ 95.334	
Difference	$ 26.117		

Operational costs

Table 3 compares both financial and environmental operation costs for the two systems, water treatment per cubic meter under System 2 costs just 10% of the fare charged on water supply and 6% of the fare charged on sanitation. Hence the cost of using rainwater is 10% of conventional supply. Groundwater use and grey water reuse have a further benefit since these volumes do not get charged for sanitation. Altogether operational cost for System 2 is 40% of operational cost for System 1, allowing full return of the additional investment costs by year 3 of operation. On a 30 year lifecycle basis System 2 leaves the project a US $ 261000 net benefit over System 1 (see figure 4).

Table 3. Operation cost comparison between System 1 and System 2

Item	**Symbol**	**Metric**	**Value**	
Number of romos	R		41	
Water demand (m3/room/day) According to Colombian regulation	wd		0,5	
Occupation index for hotels in Medellín (%)	oi		75%	
Daily water demand (m3/day)	dd	r*wd*oi	15,4	
Total water demand (m3/year)	WD	dd*365	5611,9	
Total rainwater (m3/year)	RW	Average precipitation from table 1 * On ground building area	534,4	
Total groundwater withdraw (m3/year)	GW	From case study description	3650,0	
Grey water reuse (m3/year)	GyW	Estimated as 28% of water demand	0,0	1571,3
Dependency on water sources external to the watershed (m3/year)	DEW	System 1 = WD/(1-Unaccounted for water from table 1) System 2 = WD - GW - RW - GyW	9353,1	-143,8
Total wastewater discharge (m3/year)	WW	System 1 = WD + GW System 2 = WD - GyW	9261,9	4040,6
Supply water costs (US $/m3)	wc	Sytem 1 = supply charges from table 1 System 2 = by treatment plant providers	0,86	0,08
Supply anuual costs (US $/year)	SWC	WD*wc	4.826	443
Sanitation charge (US $/m3)	sch	From table 1	1,3	
Sanitation annual costs (US $/year)	SnWC	System 1 = (WD+GW)*sch Sytem 2 = (WD-GyW)*sch	12.040	5.253
Total water system operation costs (US $/year)	WOC	SWC + SnWC	16.867	5.696
Difference				(11.171)

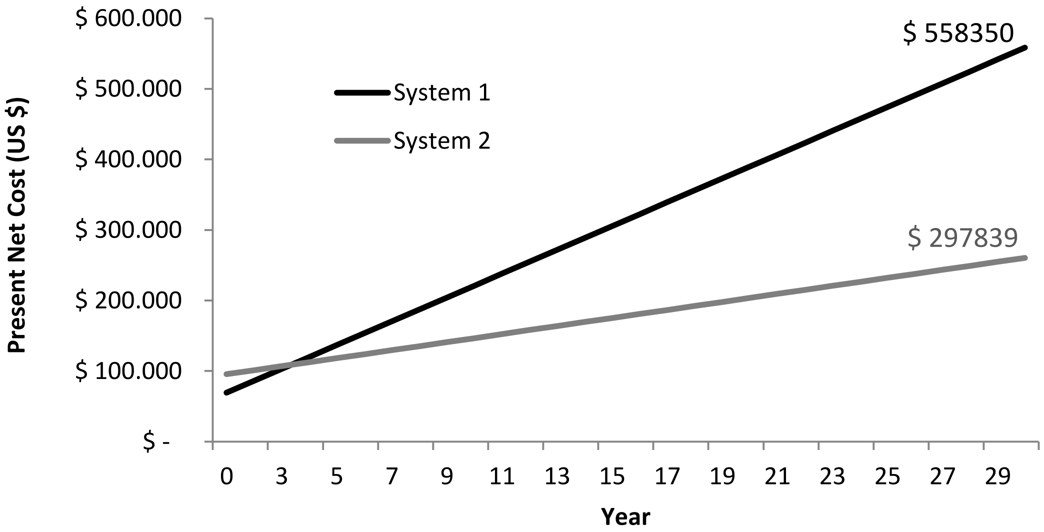

Figure 4. Comparison of net present costs for the two systems

In spite of requiring higher investment costs, an alternative ecoefficient water management system shows to be the best choice in order to reduce both economic and environmental costs for this case of study. Dependency on external water sources and storm water discharge might get down to zero, as total water demand and wastewater discharge might reduce down to 45% at a financial present net cost of 53% as compared to a conventional water management system.

DISCUSSION

Aburrá Valley urban water management is characterized by a high dependency on external water sources, a high unaccounted for water index, a non-regulated groundwater withdraw, a low level of wastewater treatment and no policies on storm water discharges, leading to a vulnerable, inefficient, pollutant system. Most Colombian and Latin-American cities might be described likewise (Howe, Butterworth, Smouth, Duffy, & Vairavamoorthy, 2012; Domenech, 2011)

These concerns are being addressed from centralized approaches such as upgrading supply systems and building new wastewater treatment facilities, but the role of end users is not yet being considered a key issue. This paper shows that buildings, as end water users, would significantly improve the whole system performance by reducing dependency, inefficiency and pollution, while significantly reducing operational costs, leaving in fact economic benefits on a lifecycle basis (Penagos, 2007; Bedoya, 2011)

The model described here may be adopted by building projects along the Aburrá Valley, similar approaches might be analyzed, developed and implemented in other Colombian and Latin-American Cities, which will continue expanding in coming years under uncertain scenarios concerning incidence of climate change on water availability, which is already a critical threat to human development in the region. This study would be also a useful base for governments in order to promote policies and regulations encouraging sustainable water management for healthier cities (Howe, Butterworth, Smouth, Duffy, & Vairavamoorthy, 2012; Penagos, 2010)

Energy certification process in Chile: steps to dynamic simulation of buildings' energy performance.

Massimo Palme, PhD
Catholic University of the North
Email mpalme@ucn.cl

ABSTRACT

This paper presents comparative studies among dynamic simulation and steady-state evaluation (degrees – day) for residential building certification in Chile. Energy certification is still young in the country, but its impact in reduction of thermal demand could be very high. The main problem seems to be the use of simplified methods, which have not been tested for all the country's climates. Chile has a lot of very different scenarios, from the Atacama Desert to the extreme south Patagonia, which are not always well represented by daily average temperatures. The Chilean National Energy Certification System started in 2013 to qualify residential buildings, most of them by using steady-state evaluation. However, in the northern deserts of the country, dynamic simulation is needed to permit a quality work of certification. This paper presents 21 dwellings located in the city of Antofagasta, simulated by using normative software CCTE and also evaluated by using the simplified normative method developed by the Government. Results shows important differences in the final results, both in terms of estimated thermal demand and final etiquette obtained. Steady-state evaluation definitively seems to be not very useful for the desert climate, even in the coast region, were thermal oscillation is relatively low because of the Ocean's effect.

INTRODUCTION

In 2013, The Chilean Government introduced the National Energy Certification System for Dwellings. The system is voluntary but the Ministry of Housing has the intention to make it mandatory by 2015. The system assigns two different energy classes: one relates to architectural parameters (envelope, form, orientation) and the other relates to systems efficiency (heating system, solar energy use for hot water, and photovoltaic panels for electric generation to be used in electricity). The first group of accredited evaluators started to certify social and private projects in order to test the results of system implementation. Two options are managed to estimate heating energy demand: simplified steady state option that uses degree-day concept and fully dynamic simulation by using CCTE software (MINVU, 2012).

Chile is a country that extends from a latitude of 18 South (Arica) to 56 South (extreme south Patagonia). For this reason, in Chile all kind of climates can be detected, from arid to cold, from mountain to tropical. However, the national certification system only considers heating needs of the central and southern zones. The climate classification developed to use the degree-day concept divides the country in seven zones, plus two sub-zones (extreme south and north), not considering day-night thermal oscillations to distinguish locations with the same average temperature but very different maximum and minimum temperatures (MINVU, 2008b).

Massimo Palme is a professor in the School of Architecture, Catholic University of the North, Av. Angamos 610, 1240000 Antofagasta, Chile.

Thermal zones defined by Ministry of Housing are different with respect to climate zones defined by norm NCh 1079 (2008) that consider longitude and altitude as well as latitude defining Chile's climates. This contradiction has been mentioned in the country as one of the most important limitations of the National Energy Certification System; see for example Bustamante (2009).

In northern regions of the Country, the system does not appear to be completely useful, because of a lack of consideration in regards to cooling demand and because of the simplified options, which don't consider thermal inertia of construction. To reach a good energy class (starting from "D"), in the north zones dwellings have to have less than 75% of the thermal demand and less than 80% of total energy consumption in respect to the reference building. The reference building has the same size and form of the analyzed building, but mandatory compliance in materials and average orientation.

In addition, low heating demand in the North leads to poor energy labeling, because of the limitation in reference building demand (if reference building has an estimated heating demand lower than 30 kWh/m2, thermal performance is not calculated and only hot water and electricity are considered to assign the energy class). To investigate discrepancies between the simplified method and dynamic full simulation, a social dwelling project was selected as a case study.

METHODOLOGY

In this research, 21 dwellings are evaluated by using steady-state method and also simulated by using dynamical software CCTE. Then, a comparison of results is done, searching for differences in heating demand and in the final energy class assigned to each dwelling.

Case study "Tres Marías"

Dwellings located in the city of Antofagasta, 23° south and 70° west, at Sea level. Figure 1 shows project emplacement and dwelling orientation (courtesy of SERVIU). Site has a little slope, resulting in shadows on the east side and solar access on the west. Moreover, on the east the first line of mountains protects houses from solar access in the morning. On the south and north other buildings generate shadows at specific hours of the day in summer and winter, respectively.

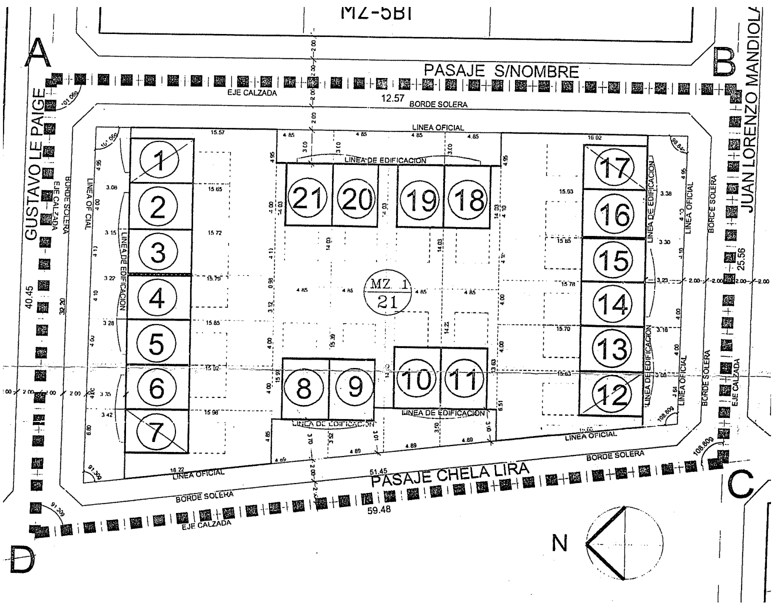

Figure 1 House's emplacement and orientation

Figure 2 shows architectural distribution on two floors. Houses have a floor surface of 45 m2 (22 m2 on each floor). Figure 3 shows the facade.

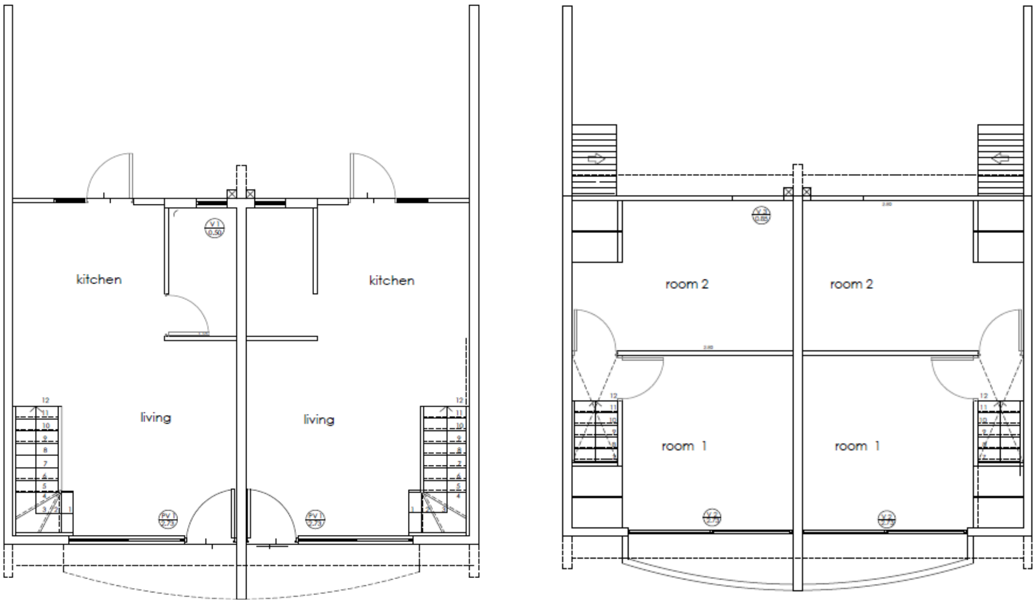

Figure 2 Ground and first floor plan

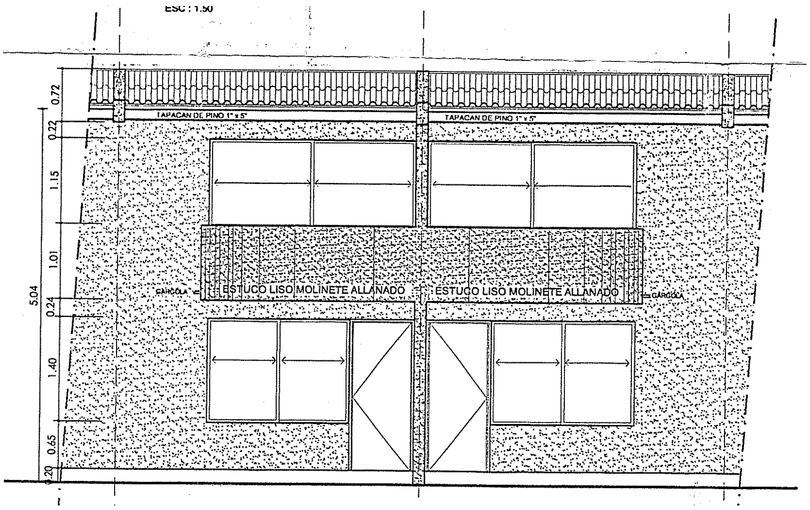

Figure 3 Facade of the dwelling

Materials and equipment

Construction uses two kind of vertical walls: block walls and external board walls. Block walls are composed by 150 mm of concrete plus 20 mm of insulation (polystyrene) and 10 mm of ceramic finishes. Thermal transmittance is 1.32 W/m^{2}K. External board walls are composed by OSB (11 mm) plus 40 mm of insulation (rock wool) between steel profiles, plus another 20 mm of insulation (polystyrene) and 10 mm of ceramic fihishes. Thermal transmittance is 0.88 W/m^{2}K. Roof is made of block work (130 mm) plus 100 mm of insulation (rock wool). Thermal transmittance is 0.38 W/m^{2}K. Floor is composed by blockwork. Door is made of pressed wood, thermal transmittance 3.7 W/m^{2}K. Windows are single glazed, with thermal transmittance of 5.3 W/m^{2}K and solar factor 0.87. Table 1 resumes transmittance values of construction elements. Transmittances have been calculated as indicated in Chilean norm NCh 851 (2008), NCh 853 (2008) and Thermal Norm of MINVU (2008a).

Table 1. Walls and windows properties

Wall	Transmittance (W/m^2K)	Thickness (mm)	Solar factor (%)
Blockwork wall	1.32	180	0
Board wall	0.88	81	0
Roof	0.38	230	0
Floor	3	230	0
Door	3.7	50	0
Window	5.3	6	87

Dwellings do not have heating systems. Hot water system is electric boiler with 150 dm^3 deposit. No solar panels are considered for hot water or electricity production. Electricity is considered in certification as standard system. No other appliances are considered.

RESULTS AND DISCUSSION

Steady state evaluation

21 dwellings were evaluated, first by steady state method. The system considers a reference building that has the same form of the project, compliance materials and average orientation. Reference building has in most cases a heating demand of less than 30 kWh/m^2 year. As a result, most dwellings facing south or north are not evaluated in terms of heating demand. Only the dwelling numbers 1, 7, 12 and 17 are evaluated. East and west dwellings are also evaluated, because of the higher exposed surface. All dwellings are evaluated in terms of hot water production (electric system).

In the Chilean system, the architectural energy class assigned to a dwelling depends on the thermal zone where the dwelling is placed. In northern deserts, to attain an “E” label, the dwelling must have a thermal demand between 75 and 110% of the reference dwelling. Reference dwelling has the same form, average orientation and minimum standard compliance for materials. To reach a “D” class, the dwelling must have a thermal demand between 55 and 75% of the reference. To obtain a “C”, thermal demand has to be between 40 and 55%; to obtain a “B”, between 30 and 40% and to earn an “A”, between 0 and 30%.

System energy class depends on the primary energy consumption; therefore electrical systems for hot water are normally evaluated as “G”. To obtain an “E” label, primary energy consumption has to be between 80 and 110% of the reference; to obtain a “D” has to be between 60 and 80%; to obtain a “C” 45 to 60%; “B” 30 to 45% and “A” less than 30%. This indicator is not dependent on the thermal zone as the heating demand. Table 2 resumes the label correspondence for thermal zone 1 (northern coast deserts of Chile).

Table 2.

	Energy percentage respect to reference building				
	Label A	**Label B**	**Label C**	**Label D**	**Label E**
Demand	0-30	30-40	40-55	55-75	75-110
Consumption	0-30	30-45	45-60	60-80	80-110

Results are resumed in table 3: most of the dwellings have class energy “G” or “F”. The main reason of this result is the impossibility of evaluating dwellings if reference has less than 30 kWh/m^2 year heating demand. However, the result is illogical, because the dwelling has better values of transmittances than reference building, then a better class is expected (if dwelling has the same demand of the reference, class “E” is assigned).

Table 3. **Steady state evaluation results**

Dwelling	Orientation	Architecture	Systems	Heating demand (kWh/m^2 year)	Heating reduction (%)
1	N	D	E	22.0	42
2	N	/	G	/	/
3	N	/	G	/	/
4	N	/	G	/	/
5	N	/	G	/	/
6	N	/	G	/	/
7	N	D	E	22.2	40
8	W	E	F	39.4	15
9	W	E	F	40.2	12
10	W	E	F	38.2	19
11	W	E	F	41.1	10
12	S	E	F	41.7	2
13	S	/	G	/	/
14	S	/	G	/	/
15	S	/	G	/	/
16	S	/	G	/	/
17	S	E	F	39.7	5
18	E	E	F	40.1	8
19	E	E	F	36.4	17
20	E	E	F	30.1	21
21	E	E	F	32.6	19

CCTE simulation

CCTE evaluation uses dynamical simulation of the real and the reference buildings. Because in this case the reference building has the same orientation of the analyzed one, four simulations have been done and reference building results are the average of the four orientations considered (N, S, E and W). Figure 4 shows the CCTE model of East/West dwellings.

All dwellings are analyzed because in this case the reference building has a heating demand higher than 30 kWh/m^2 per year. In general, analyzed dwellings are better than the reference in terms of heating demand (between 20% and 30%) and very close to the reference in terms of energy consumption, because of the low efficiency of the electric boiler.

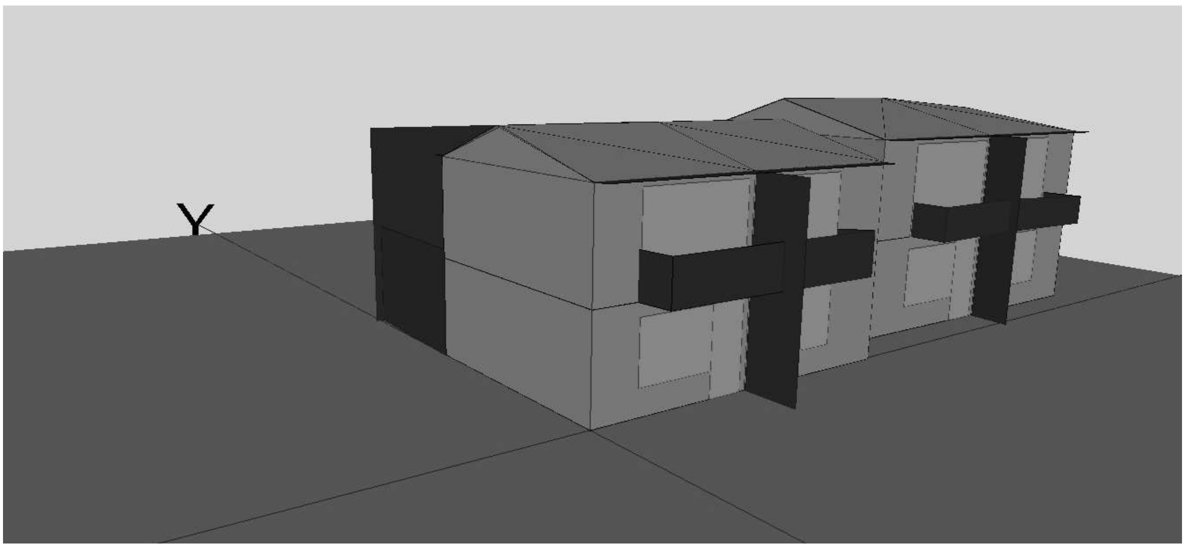

Figure 4 CCTE model used in simulations

Results in this case are more consistent, because all dwellings have a better or at least the same energy class of the reference building. The reason is that dynamic simulation leads to more than 30 kWh/m^2 year of heating demand, which permits the obtainment of the architecture class. Table 4 summarizes the results.

Table 4. CCTE evaluation results

Dwelling	**Orientation**	**Architecture**	**Systems**	**Heating demand (kWh/m^2 year)**	**Heating reduction (%)**
1	N	D	E	34.1	37
2	N	D	E	25.4	31
3	N	D	E	24.8	33
4	N	D	E	23.6	37
5	N	D	E	25.8	34
6	N	E	E	32.2	26
7	N	E	E	36.1	22
8	W	D	E	35.3	36
9	W	E	E	36.1	24
10	W	E	E	34.9	19
11	W	E	E	34.2	27
12	S	E	E	35.9	19
13	S	E	E	27.9	19
14	S	D	E	26.3	28
15	S	E	E	26.3	20
16	S	D	E	25.5	30
17	S	E	E	31.9	23
18	E	E	E	40.1	26
19	E	D	E	32.2	34
20	E	D	E	30.1	32
21	E	E	E	35.5	26

North-facing dwellings have “D” class assigned (most of them), because of better solar access in winter. Some south-facing dwellings also have “D” class because they reach 25% of demand reduction.

Steady-state evaluation leads to unreliable results in most considered cases: because of low heating demand of the climate zone, architecture is not evaluated and only electrical system for hot water production is considersd. Dwellings that have better performance than the reference building (between 20% and 30% considering heating demand) are classified as “G” or “F” because of the low efficiency of electric boilers for hot water production. Only two of the north-oriented dwellings are evaluated and classified as “D” in architecture and “E” in energy consumption. On the other hand, CCTE dynamic simulation lead to more realistic results and all the 21 dwellings are evaluated, obtaining architectural class “D” or “E” (depending on energy saving: to obtain “D” class energy saving has to be more than 30%). In this case, all consumption classes are “E”.

CONCLUSION

The energy certification process in Chile is focused on heating demand reduction, the most important problem in southern regions of the country. Northern regions are considered to be temperate, and building overheating is nowadays resolved by natural ventilation. However, some considerations have to be made. First, the energy certification system has two options, simplified evaluation and dynamic simulation. In the South of Chile, both methods lead to the same energy class in most cases, but in the North many cases have different classes, as discussed in this paper. Thermal mass effect and especially 30 kWh/m^2 limitations in reference building to evaluate architecture thermal demand are problems in the current system.

Second, natural ventilation is supposed to be sufficient to cool buildings, but in the future some urban climate changes could modify this situation. Global warming in northern Chile will probably be very high (up to 5 degree increase of temperature in the middle of the century), heat island effect will be present in cities of middle size, tall buildings construction in the first coast line will act as a blockage to sea wind. All these factors are clearly indicated as a danger for overheating in built environment; see works of Chilean Government (2013), Palme (2014), Valenzuela (2013).

Finally, economic development of the country, especially of the northern mining zones, will have the consecuence that people will search for better comfort standards, and install air conditioners to avoid overheating in residences. This could be very dangerous, because it will add to an increase in global warming. In this conclusion, it appears very important to recommend the introduction of a dynamic system of energy certification, taking into account heating and cooling demand, as well as the removal of the 30 kWh/m^2 limitation in reference building heating demand.

ABSTRACT

Building Assessment Tools (BATs) are widely used to estimate the performance of building and to assist designers in making decisions. As building codes and rating systems move from prescriptive to performance-based metrics, BATs are increasingly used to show compliance. BATs use computational methods and the results are mostly in a single annualised metric. However, the scientific community has shown that aleatory factors such as occupant behaviour and weather make the potential energy use of a building far from being a single deterministic value. Also, it is known that there is a significant deviation between predicted (at design stage) and actual energy use in buildings. These variations reduce the credibility of the predictions, questioning the acceptance of BATs results without considering underlying errors. This problem is amplified in developing nations because of under-policed construction sector. To address this, our work analyses uncertainty in a typical air-conditioned multi-storey residential building's performance in Delhi and shows implications of variable inputs in the results.

The paper first reviews the use of BATs and existing studies on simulation uncertainty. Then uncertainty is evaluated in energy simulation of a sample building, including effects of inconsistent and construction practices. EnergyPlus is then fed values sampled (by Monte-Carlo method) from probability distribution functions of inputs (building fabric and operational parameters). Further sensitivity and uncertainty analysis of the results is performed. From the 3500 simulations, the most sensitive inputs found were internal gains; cooling setpoints and infiltration. The variation in cooling demand and discomfort hours is more than double between the best and worst case.

INTRODUCTION

Anthropogenic activities in the last decades have altered climatic stability, water cycles and natural habitats. At the time of writing, atmospheric CO_2 concentration is 399 ppm (Tans & Keeling, 2014) (Mauna Loa Observatory); 37% more than the highest concentrations in 8,00,000 years (EPICA DATA) (Lüthi, D., et al., 2008). The annual mean surface temperatures are rising due to greenhouse gasses

Nishesh Jain is a consultant and research fellow at PSI Energy, New Delhi, India and a MSc. Graduate (now doctoral applicant) at University of Bath, UK. Dr Alfonso P Ramallo-González is a postdoctoral researcher at University of Bath, UK. Dr Sukumar Natarajan is a Assistant Professor(Lecturer) and Director of Studies, Environmental Design in the Architecture and Civil Engineering Department, University of Bath, UK

(GHG) concentration increase. It is estimated to rise by 0.3 to 4.8 in next 100 years (IPCC, 2013).

Governments around the world are evaluating the impacts of climate change on their economies. The Indian economy could be considered as climate sensitive as many sectors are wholly or partially dependent on seasonal weather cycles. Indian meteorological data shows a 0.4°C increase in the mean annual air temperature in the past 50 years (INCCA, 2010). Also, intensity and frequency of extreme weathers like heat waves, dry spells and heavy rainfall have increased (INCCA, 2010). Data assessments indicate warmer climates in India, with temperatures rising by 2-4^{o}C by 2050 (INCCA, 2010).

Buildings have a significant impact on the environment. Infrastructural development of cities leads to rapid growths in construction, causing 25% of India's current carbon emissions (Parikha, et al., 2009). Buildings are responsible for 40% of energy use and 33% of GHG emissions globally (UNEP, 2009). The energy use in buildings includes operational and embodied energy and 80% of building's life cycle energy is by the former (Gregory A. Keoleian, 2008) (Chris Scheuer, 2003). Also, the building sector has the highest and most cost-effective potential for providing long-term, energy and GHG emission savings globally (IPCC, 2014). This has also been observed at a national level in India (PC : IEP, 2006). Building assessment tools (BATs) are widely used for detail assessment of energy use in buildings.

Buildings are complex systems and their energy use assessments dependent on many parameters. However, in most cases, these parameters are variable and not certain (Pettersen, 1994). These uncertainties arise due to lack of knowledge in simulation inputs, improper construction methods, approximate weather data and unpredictable occupant behaviour. Statistical analysis of energy simulations has been seen as a powerful tool in predicting this variability (MacDonald, et al., 1999) (Blight & Coley, 2013). In this paper, we assess the effect in outputs by the variation of some building design input parameters, which are regulated by energy saving related polices.

This paper begins with a background section reviewing: (1) the use of BATs for design decision making; and (2) existing studies that analyse uncertainty in simulation results. This is followed by assessing variations in input parameters in energy simulations of a residential building in Delhi, including the effects of construction processes used. The paper focuses on uncertainties in the fabric (i.e. thermal properties) and operational parameters. It concludes by performing uncertainty and sensitivity analysis of the input variables for the output of cooling and heating energy use and discomfort hours.

BACKGROUND

Use of Building Assessment Tools (BATs) for code compliance to reduce energy use in buildings

BATs are widely used to estimate energy performance of building designs. These tools assist designers in the decision making process by providing comparative and detailed assessments of building performance under various design conditions and strategies. Due to their capabilities to model building systems and physical phenomena in detail, they are used make predictions about the performance of a building under a wide range of scenarios. But, in most cases, these tools rely on input parameters that are either assumed or averaged to provide deterministic outputs, i.e. predict future scenarios that are known to be uncertain (Haldia & Robinson, 2011) (de Wilde & Tian, 2009) (Blight & Coley, 2013) (Ramallo-Gonzáleza, et al., 2013). This results in simulations that are fundamentally unrealistic and have shown to have errors exceeding 100% (Brohus, et al., 2009) (Demanuele, et al., 2010).

In the context of the move from prescriptive to performance-based building regulations (e.g. US building energy performance assessments (BECP:US DoE, 1991); and Energy Performance of Buildings Directive in Europe (The European Parliament and The Council of European Union, 2003)), deterministic outputs seem to be ill-suited to provide realistic estimates of future performance due to the well demonstrated stochastic nature of energy use in buildings (Page, Robinson, & Scartezzini, 2007) (Blight & Coley, 2013). Similarly, India's Energy Conservation Building Code (ECBC) (BEE, 2009) has a performance based compliance criterion (BEE, 2009). ECBC is partly mandatory and does not include residential buildings. Experience in other countries suggests that voluntary codes eventually make the transition to mandatory codes (National Action Plan for Energy Efficiency, 2009) (Liu, et al., 2010).

Apart from the issues of uncertain results due to deterministic nature BATs' results, construction techniques that are widely used in India might result in underperforming fabrics even when conforming to ECBC specifications. Uncertainty analysis (with the inclusion of construction process deficiencies) could provide a contextual picture, with a more robust understanding of the likely outcomes of measures in the ECBC.

Uncertainty and applicability of BATs

Most BATs use deterministic algorithms to predict a single value for the building performance. Actual prediction is more complex. Uncertainty in building simulations arise due simplifications in computation process and building complexity to reduce computing time; or because of unknown and erroneous input parameters (Clarke, 2001). Simplification generally occurs in inputs like weather data, material properties (like U-values), geometry etc. There, only the mean or most probabilistic values are used. This provides an unrealistic picture as value of each input can vary within a range of data. This theoretical simplification gives a range for the value calculated but not a credible result (especially when results depend on many such inputs). Adapted from Ramallo-González's PhD thesis (Ramallo-González, 2013) and other similar works, we classify the types of uncertainty into three groups:

1. Environmental: Uncertainty in weather data because of use of nearest weather station's synthetic weather file and uncertainty in prediction of changing climate.
2. Workmanship and quality of building elements: Differences amid the design and the real building: Conductivity of insulation and thermal bridges, infiltration amount or U-values of walls and windows.
3. Behavioural: Actual building occupant behaviour and usage patterns.

Additionally there is divergence in computation i.e. the approximation and uncertainty in computational formulas in the simulation tools. Above groups, describe the broad areas of uncertainty. Based on the reasons of existence they can also be divided in two types, aleatory and epistemic. Aleatory uncertainties represent the randomness nature of some variables. Epistemic uncertainties are due to lack of knowledge (Sandia Lab, n.d.). Uncertainties make it impossible to find, for some inputs, a value that is actually true; observed by Newton when building energy simulations were in their infancy (Newton, et al., 1988):

"…the choices of climatological data and occupancy patterns are not easy and, in many cases, there is no single correct value."

Assessment of uncertainties at all levels is required to get results with confidence intervals. It is the only way to have realistic assessments and a better understanding of energy simulation results. In this study, aleatory and epistemic uncertainties in groups 2 and 3 would only be considered.

Areas where consideration of uncertainty can play a major role are in energy-savings performance contracts and in certification and code compliance for green and ultra-energy efficient buildings (e.g. LEED Ratings, or codes like EPBD in Europe or ECBC in India.). Since BATs are used to inform and evaluate designs, there is a significant risk (could be financial or of occupant comfort) if the real and predicted performance vary. Additional information about the uncertainty (like confidence intervals) would facilitate a more informed decision by the designer. Therefore, the argument of this paper is to prove how BATs should not be relied upon in a deterministic manner but in a probabilistic way, to provide the designers with stochastic indicators of the future performance or demand of the building. In this paper, we have used these indicators to verify the impact of uncertainties in workmanship and operations in the final energy performance of buildings.

Most of the studies discussed in the next section take the variation in input parameters as a normal distribution. These variations when seen practically do not necessary apply. E.g. actual measurements of accumulated electricity use in the UK (Carbon Trust, 2011) show a non-normal distribution. For that reason, in this paper, probability distributions that are more representative have been used. They represent more closely what seen in reality. This point will be further developed in later sections.

Existing studies on uncertainty in building energy design

There have been many studies in the last two decades vis-à-vis uncertainties influencing the results of BATs. However, the studies are mainly theoretical and have not been applied in real world problems. Pettersen's work is one of the first studies that looked at the effects of climate variability, building characteristics and occupants (Pettersen, 1994). Using a statistical simulation method based on Monte Carlo Analysis (MCA), Pettersen studies the variation of energy use in dwellings, which was about 15%.

There is little literature showing the impact of uncertainties in specific inputs. De Wit studies the effect of uncertainty as well as relative importance of non-linear effects and parameter interactions on thermal comfort, using factorial sampling (de Wit, 1997) (de Wit & Augenbroe, 2002). He also explores effect of assumptions in measurement and simplification in calculations. Domínguez-Munoz studies the impact of uncertainties on the peak-cooling loads using MCA with a global sensitivity analysis to identify the most important uncertainties (Domínguez-Munoz, et al., 2010).

Hopfe et al. have also worked on uncertainty and sensitivity analysis for thermal comfort prediction to help in design decision making and optimisation (Hopfe, et al., 2007). Another paper written by Hopfe and Hensen (Hopfe & Hensen, 2011), covers the implication of uncertainties on energy consumption and thermal comfort using a theoretical case study and studying various building performance parameters using as inputs physical, design based, and scenario variables with their standard deviation.

Several works of MacDonald have focused on quantifications and application of uncertainty on the predictions of demand using building simulation software (MacDonald, et al., 1999), (Macdonald & Strachan, 2001), (MacDonald, 2002).His thesis (MacDonald, 2002) shows two ways of achieving this: The first way altered the input variables, requiring multiple simulations of systematically altered models and the subsequent analysis of the changes, with differential, factorial and Monte Carlo sampling; The second way altered the algorithm of BAT to include uncertainty at all computational stages. Applying these changes, the predicted uncertainty in thermo-physical properties, casual heat gains and infiltration rates was quantified and was compared with MCA and differential analysis. Further, the issue of non-convergence building simulations was discussed (MacDonald & Clarke, 2007). The non-convergence was caused by introduction of new uncertainty terms that were uncorrelated to existing terms.

In other recent works, Wang examines uncertainties in energy consumption due to annual weather variation and building operations using MCA (Wang, et al., 2012). Eisenhower enlarged uncertainty and sensitivity analysis to take into account the influence of 1000+ parameters (Eisenhower, et al., n.d.).

Uncertainties in India Context

The uncertainties in building input parameters are particularly relevant in the Indian context because of the techniques of construction used. Indian standards, codes and practices for construction allow significant tolerances and deviations in the fabric (IS: 2212: 2005 (BIS, 1991)), (IS4021: 1995 (BIS, 1995)), (IS: 4913-1968 (BIS, 2001)), (IS: 1948: 1961 (BIS, 2006)). General construction practice shows that most of the construction procedures are not consistent. From mixing of concrete by rough estimation to fabrication of wood framed doors and windows, all the work is done on-site. The quality is mainly dependent on the skills of the professionals. The doors and windows, constructed on site have gaps created at the time of installation which are filled with plaster (IS: 4913-1968 (BIS, 2001)) (IS: 3935: 1966 (BIS, 1986)). This technique compromises the U-value of the construction and airtightness and it might lead to thermal bridging because of the improper sealing and frame effects.

The bricks used for construction also have variation in their properties due to the variation in the composition of clay used and non-consistency of the firing process (Sarangapani, Reddy, & Jagadish, 2002). Small ducts for building services (plumbing pipes and electric conduits) are also embedded in the walls (SP20 (BIS, 1991)), (IS: 2212: 2005 (BIS, 1991)). This reduces the wall's thermal effective thickness, affecting the overall U-value. These inconsistencies in the fabric can create variation in the actual energy use. We show here a method to quantify this effect. We think it is a powerful tool for policymakers, as it will enable them to understand the fruitless and somewhat detrimental impact of stringent energy policies on an un-prepared industry. In other words the building sector, at present, is not prepared for incorporating energy policies unless the functioning of the whole sector is modified. The building components used should be quality controlled, ensuring consistency in performance then only the energy polices can be implemented. Such recommendations are incorporated in ECBC, e.g. supply-chain improvements to ensure availability of certified products, but are not exercised in practice.

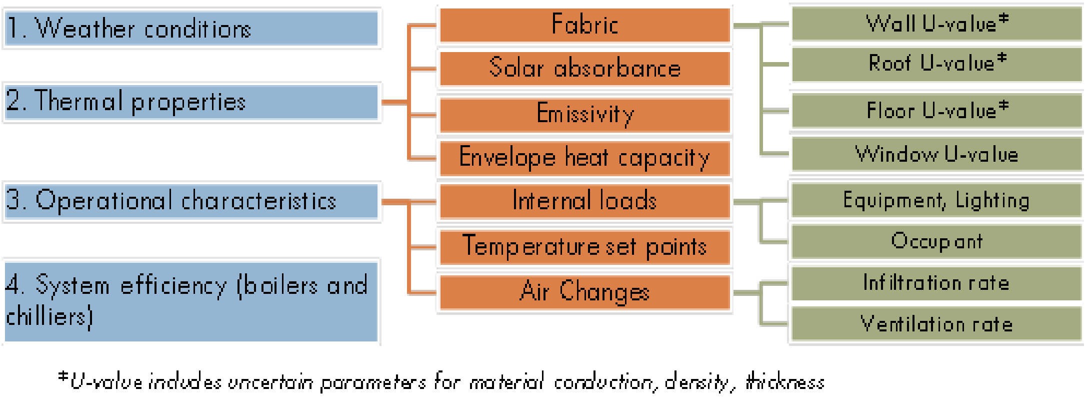

Figure 1 Uncertanity Parameters included in existing studies

In order to estimate the overall effect, uncertainties due to variation in inputs, discussed earlier, have to be combined with the impact of construction procedures in India on the building fabric. Studies exploring the latter issue were not found. Based on past studies (Heo, et al., 2012), (de Wilde & Tian, 2009), (Hopfe, et al., 2007), (MacDonald, 2002), (Wang, et al., 2012), (Pettersen, 1994) on uncertainty (Figure 1) and assuming the uncertainties because of local factors, uncertainties in various parameters are estimated. A more accurate finding of the distributions is suggested for further work. For this paper, we have used generic distributions that could be changed for each region to obtain more accurate results.

In this paper, a methodology for uncertainties related to thermal properties, temperature set points, internal loads and ventilation is presented. Weather, system efficiencies and other operation parameters have not been considered in this study, but the method can be extrapolated to include these too.

METHODOLOGY

Uncertainty propagation, sensitivity analysis (SA) and uncertainty analysis (UA) has been carried out in this paper in the following manner (*It has been assumed in this study that the input variables are not dependent*):

1. A baseline building with fabric based on ECBC specifications was created as refernce point.
2. Based on existing studies, six major uncertainty factors were selected and the calculations of their variability with probabilistic distributions defined.[1]
3. The deviation in conditioning loads and occupant comfort in relation to the input variables was explored. Random MCA sampling is used for input variables based on their determined probability distributions. Those samples are used for multiple EnergyPlus runs for Propogation of uncertainty.
4. Multiple Linear Regression (MLR) is done to asess the sensitivity of variables - sensitivity analysis (SA).
5. A mean and peak variation for each output is calculated to assess the uncertainty - uncertainty analysis (UA).

[1] It has to be calculated as there was no data found that could provide with the variations of these factors.

SIMULATION

Building Plan

The reference building is a three story residential building in New Delhi based on normal practice. The floor area is 75 m^2 (total built up area of 225 m^2). The floor-to-floor height is 3 meters. The building has longer axis along E-W direction. The Living (4.275m*4.8m – with toilet)/Dining (2.915m*2.8m) room is in North and the bedrooms are located on in SE (3.915m*4.21m) and SW (3.235m*4.21m – with toilet) corner; the kitchen faces West (2.8m*1.885m). Each room is taken as a separate zone.

Construction and operation

The building has a mixed mode running system with natural ventilation happening between heating and cooling setpoints. Table 1 below shows the input parameters for the initial base case.

Table 1 Table showing the input parameters taken for the baseline building model

Criteria	Remarks
Structure	RCC and brick infill panel walls
Walls	0.44 W/m2K ; Insulated brick cavity walls
Windows	3.3 W/m2K; Openable, and air filled clear double glazed (6-12-6)
Roofs	0.40 W/m2K; Insulation covered RCC slabs
Setpoints	Heating -19°C; Cooling - 24°C

Room type	Occupancy schedule		Internal gains
Bedroom	Weekdays	2200-0600	2 people, 1 TV, 1 tube light, 1 fan
	Weekends	2200-0600; 1400-1600	
Kitchen	Daily	0600-0800; 1200-1400; 1900-2100	1 person, 1 tube light, 1 fan, 1frige
Living/dining room	Weekdays	0600-1000	4 people, 1 TV, 8 tube lights, 4 fans
	Weekends	0600-0200; 1600-2200	

Outputs considered

Two outputs were obtained from the simulations: (1) the total heating and cooling energy use; and (2) the number of non-comfortable hours of the occupied spaces. The standard ASHRAE 55-2004 Predicted Mean Vote (PMV) was used to define non-comfortable hours (integrated in EnergyPlus).

Variable inputs and their distributions

As described earlier, based on existing research, the uncertain factors taken are fabric thermal properties, temperature set points, and ventilation. The section below describes the input variables and Table 2 shows the base case, upper and lower values distributions selected and their variation graphs.

Internal loads

Internal loads are one of the most significant aspects governing the building performance. Internal loads cannot be negative, thus, a normal distribution is not ideal to represent the variation in internal loads. In previous studies (Schnieders & Hermelink, 2006) internal loads have been assumed to vary in a symmetric distribution. However, in actual measurements done on accumulated electricity use in the UK (Carbon Trust, 2011) it has been seen that the electricity use has been an asymmetric distribution.

Infiltration rate

Infiltration is primarily due to construction defects, gaps and cracks. Onsite fabrication of windows and high tolerances in construction of fenestration increase infiltration drastically.

Temperature set points

Set points depend on personal preferences. Variation in heating and cooling set points is assumed to follow a normal distribution as these variables are far from zero, therefore could be assume symmetric. During sampling, if the heating set point is less than 2 degrees below the cooling set point, the sample is rejected and another one calculated as this is considered the width of comfort (ASHRAE, 2009).

Wall U-value

Wall U-Value has a large impact on energy calculations. Standard deviation in U-values because of measurement techniques is 5 % (MacDonald, 2002). Moreover, due to construction techniques, detailing and material manufacturing processes, the variation is more. It is more likely that errors in manufacturing processes and workmanship lead to a larger U-Value (lower quality).

Window U-value

The in-situ construction of windows will affect the overall U-Values. The variation in the overall U-Values is mimicked by changing in thickness of the cavity as we consider it is the parameter of the window more likely to vary in a production process with poor quality control.

Table 2 Uncertain parameters chosen and their distributions

Parameter	**Element changed**	**Units**	**Base**	**LB**	**UB**	**Distribution Name**	**Distribution details**	**Graph**
Internal Loads	Equipment Loads	W/m^2	20	10	50	Scaled inverse chi-squared	μ = 20 ; τ^2 = 2	Infiltration Rate	Space Infiltration Design Flow Rate	Ach/h	0.75	0.25	2	Log Normal Distribution	σ= 0.45; μ=0	Cooling Set points	Thermostat	°C	24	22	26	normal	μ= 24; σ^2= 1	Heating Set points	Thermostat	°C	19	17	21	normal	μ= 19; σ^2= 1	Wall U-Value	Insulation Cond.	W/mK	0.03	0.02	0.11	inverse gaussian	μ= 0.5 ; λ= 4	Window U-Value	Air Gap	mm	0.013	0.010	0.016	normal	λ= 0.013; σ^2=0.0015	
LB=lower boundry; UB=upper boundary; μ=mean, σ^2=standard deviation; λ=shape parameter; ν=degrees of freedom and τ^2=scale parameter

SIMULATION RESULTS ANALYSIS

Based on the values ranges and the PDFs, values between the upper and lower bounds are selected by random monte-carlo sampling for multiple simulation runs. Results of all 3427-simulation runs are analysed to propagate the uncertainty and to perform a SA and UA.

Uncertainty propagation

The histograms in Figure 2 show variation in heating and cooling energy use and non-comfortable hours (minimum, average and maximum of all zones). Being a cooling dominated climate the cooling energy use is in GJ and heating energy use is in MJ. The cooling energy use in the building varies between 150 GJ and 385 GJ with the peak frequency at 225 GJ. Heating energy use shows a very large variation with values ranging from zero to 17GJ. The peak frequency is at 100 MJ of energy with the average use of 446 MJ. The graph is presented in logarithmic scale. For the non-comfortable hours the values vary from 0 to 2180, 0 to 3110 and 0 to 4960 for minimum, average and maximum for all the rooms respectively.

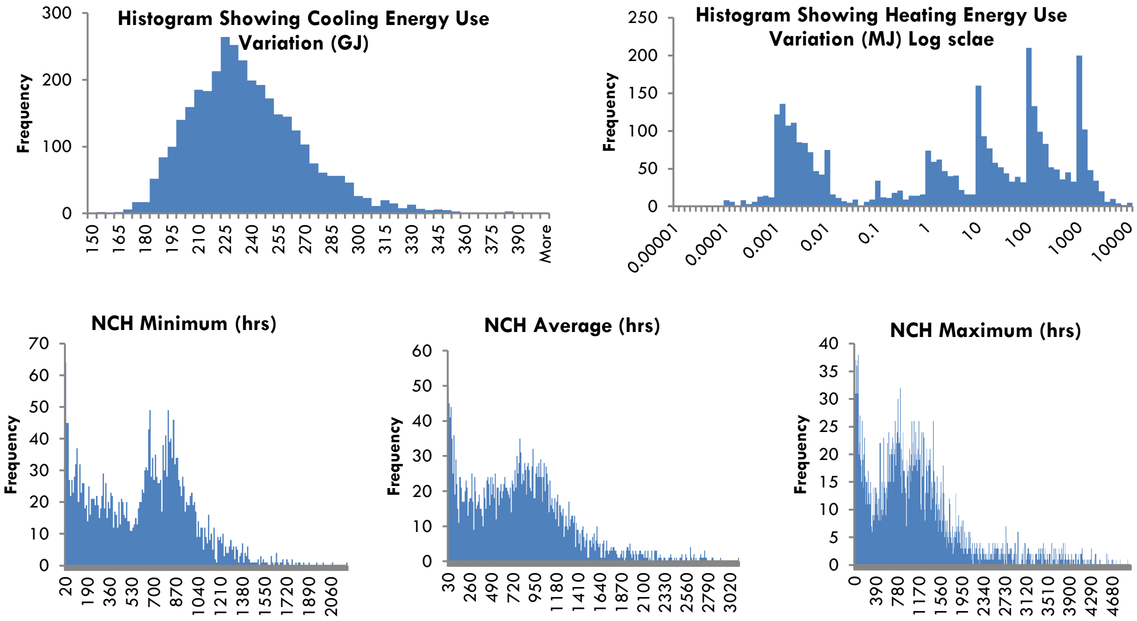

Figure 2 Histograms showing spread of output results

Sensitivity Analysis (SA)

Sensitivity of each input, for the outputs is gauged through regression. The analysis is similar to one in (Blight & Coley, 2013). Table 3 shows adjusted R Square value and Significance F for regression.

Table 3 Results of regression analysis showing adjuster R square value and significance F

Output Variable	adjusted R square	Significance F	Remarks
Cooling Energy Use	0.9869	0	Regression model fits the outputs very well. Coefficient values are significant.
Heating Energy Use	0.5460	0	There are more factors which affect the output. Coefficient values are significant
Non Comfortable Hours Min	0.8635	0	Regression model fits the outputs very well. Coefficient values are significant.
Non Comfortable Hours Avg	0.8183	0	Regression model fits the outputs very well. Coefficient values are significant.
Non Comfortable Hours Max	0.7213	0	There are some factors more affecting the output. Coefficient values are significant

It can be seen that adjusted R square values are high (except heating energy use) showing high accuracy of the data. Significance F value is 0. This shows that the variables are still important and relevant enough and that the results are not by chance. The regression analysis is done at 95% confidence interval and P-value <0.05 in Table 4 shows that those input variables are significant for the output. Green means significant and red means insignificant.

Table 4 P-value (significance) of inputs for the different outputs

	Insulation Conductivity	Window Air Gap	Internal Loads	Cooling Set points	Heating Set points	Infilteration Rate
Cooling Energy	0	0.79	0	0	0.13	0
Heating Energy	0.00003	0.48	0.000001	0.0001	0	0
NCH Min	0.0003	0.59	0	0	0.34	0
NCH Avg	0.023	0.29	0	0	0.29	0
NCH Max	0.23	0.21	0	0	0.33	0

Residuals for each output also show randomness and equal distribution about the x-axis thus showing homogeneity and linearity and verifying the credibility of the regression.

The standardised coefficients are found by dividing the 'distance from the mean' by the standard deviation of each variable, and can be used to directly compare the relative contributions from independent factors. The taller the bar, more influential is the input on the output. Positive means a direct relation between the change and vice-versa.

The most influential variables for cooling energy use are internal loads and cooling set points with infiltration and wall U-value next. Window air gap does not have any big impact on the output but does change is a little. Similarly, for heating energy use infiltration and heating set points are factors that are more dominant. For the NCH hours Infiltration, internal loads and cooling set point affect the outputs the most.

It can be seen that occupant behaviour is the most important aspect as in most cases; they determine the internal loads and cooling set points. A conservative approach in estimating the internal loads can be quite detrimental when calculating building's cooling energy needs and comfort. Infiltration and U-value of the fabric also show that construction and proper airtightness is required.

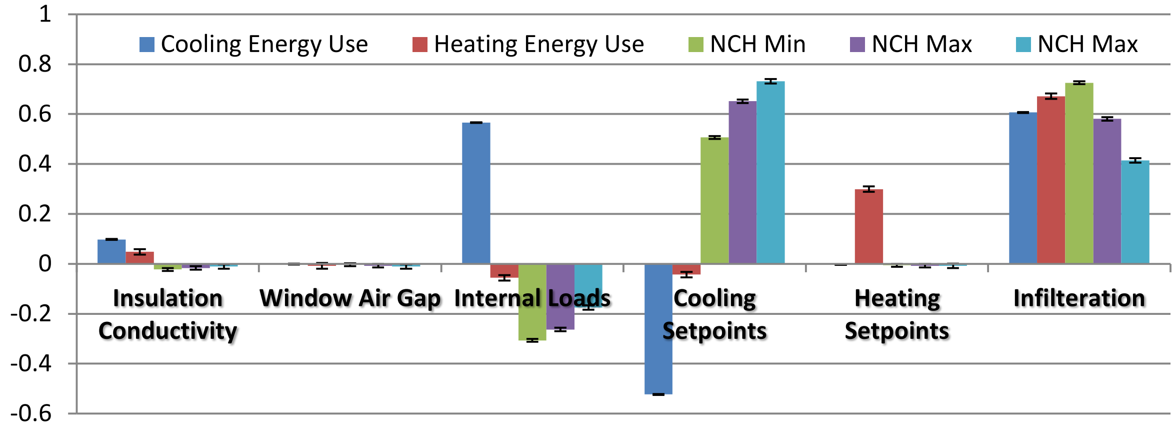

Figure 3 Standardized regression coefficient comparing the relative influence of the explanatory variables on the dependent variables

Uncertainty Analysis

The values in all outputs show substantial variation. Table 5 below shows the upper value, lower value, mean value, and standard deviation of the various outputs.

Table 5 Spread of the outputs because of variations in the input values

Outputs	Maximum Value	Minimum Value	Mean	Std. Dev.
Cooling Energy (GJ)	384.97	152.36	234.94	31.76 (13%)
Heating Energy (MJ)	17305.56	0.00	441.30	1150.85 (260%)
NCH Min (hrs.)	2177.75	0.00	495.17	411.92 (83%)
NCH Avg (hrs.)	3107.14	0.00	711.02	454.58 (63%)
NCH Max (hrs.)	4955.50	0.00	1108.89	888.76 (80%)

It can be seen from the results that the variation is very big and outputs have very high percentage of uncertainty. Through the results, it can be seen that occupant behaviour is the most important aspect as in most cases; the occupants determine the internal loads and cooling set points. A conservative approach in estimating the internal loads can be quite detrimental in assuming building's cooling energy needs. Infiltration and U-value of the fabric also show that construction and proper airtightness is also required.

CONCLUSION

Through this study, it has been shown that there could be a significant variation in the simulation result output because of the variation in the inputs. Cooling energy use because of occupant usage and construction quality alone could produce variations over the mean of about 13% with the variation in maximum and minimum values of more than 150%. Similarly, non-comfortable hours in the year could have a variation of whole year comfortable to more than half a year uncomfortable. While, the sensitivity analysis it is seen that the most influential variables in regarding the increase the cooling loads and decrease in comfort are internal gains and cooling set points, both factors primarily governed by occupants. Infiltration and U-value of the walls are similar on importance; both are primarily governed by quality of construction. Therefore, owing to these persistent uncertainties, simulation results should be taken in a more probabilistic manner to ensure that the risk associated with the uncertainties in the inputs is also calculated when making the assessment.

Another important issue that needs to be addressed when performing uncertainty analysis is that the type probability distribution of input variables should be based on realistic factors and measured data. The use of normal distributions might not represent the actual variation in some cases as it has been shown here. Fail to use the right distribution could render the methodology misleading.

It is of prime importance that the uncertainty on input variables is considered when performing energy assessment. Obtaining stochastic results encourage constructor and designers to take the adequate measurements to minimise this variation when it has a large impact in the final energy use of the building. This has even more importance in buildings in which low-demands are the aim.

ABSTRACT

The study introduces G-SEED (Green Standard for Energy and Environmental Design), with particular reference to the importance of the government's role in the dissemination and diffusion of Green Architecture through the certification system, incentive schemes and certification records. In addition, the need for improvement of the current environmental performance has been discussed through green building diffusion in Korea, by introducing the revised G-SEED and further directions for improvement.

1. INTRODUCTION

Background and Purpose of Research

The Korean G-SEED (Green Standard for Energy and Environmental Design) was initiated in 2002 for efficient building energy consumption and reduction of greenhouse gas. G-SEED is quite different from LEED (US) and BREEAM (UK) in terms of government-developed certification systems. The Korean government fulfilled critical policies as an obligation of the public building certification for diffusion, expansion and dissemination of green architecture, introduction of different incentives to induce the private sector's building certification in short-term plans. Also, in the private sector there was different voluntary participation in this certification process for business and value improvement in the building industry through reduction of energy consumption and promotion of a healthy indoor environment. Thus, the green building certification system in Korea was successfully developed within a decade thanks to strong government policies and positive support from the private sector. Therefore, both the public and private sectors have contributed to the environmental performance improvement and energy saving. Particularly given the poor political and industrial infrastructure and the scant realization of the importance of green architecture in the private sector, Korea's successful rapid implementation of a green building policy might provide a good model for developing countries planning to introduce green architecture.

Scope and Method of the Research

The purpose of this research is to examine the changes in private building construction records according to the certification incentive system in Korea and the expansion of certification records through obligation of certification. In addition, the research aims to examine the changes in factors such as building energy reduction and environmental performance improvement within the green building certification-assessment standards. Finally, we will analyze the development of Korea's green building certification system to analyze what made the certification system successful.

2. GREEN BUILDING CERTIFICATION SYSTEM IN KOREA

Author A is a Vice President, Author B, C is a Director, Author D is a Head Manager at KRIEA(Korea Research Institute of Eco Environment Architecture), Seoul, Korea

The research for green building certification in Korea began in 1996, promoted by the Ministry of Construction and Transportation. First the certification was applied to apartment buildings but eventually it was expanded to education facilities, offices, and currently all buildings are included in its certification scope and from 2013 all buildings 3,000㎡ or over were obliged to be certified. In particular, the ministries established the Green Architecture Support Act to legally implement the policies such as economic-institutional support for green architecture, establishment of information system and education of relevant professionals, etc.

Operating Body and Certification Procedure

The operating bodies of the green building certification system are classified into management organization and certification organization. The management decides and establishes the diverse economic and institutional incentives as certification assessment standard, certification procedure, designation of entity for certification, inspection of certification records, etc. and the initial management organization was the Ministry of Land, Infrastructure and Transportation and the Ministry of Environment, which alternately managed with terms of 2 years.

Green Building Certification Records

In the green building certification records, the standard for apartment building was established in 2002 and in 2006 the certification records were increased to 142 cases. In addition, the office buildings standard was prepared in 2003 and in 2010 the certification records were increased to 110 cases. Meanwhile, the education facilities standard was prepared in 2005, and in 2007 the records increased to 120 cases. For other buildings, the standard generally was established in 2010 and in 2013 the records increased to 100 cases.

Related Regulations

Green Architecture Support Act. The Korean Government established and enforced the Green Architecture Support Act in February 2013, aiming to reduce greenhouse production by 26.9% until 2020 through a general and systematic green architecture promotion and progress plan considering that the building industry in Korea is producing 1/4 of all greenhouse gas production.

Local Government Ordinances related to Green Architecture. The City of Seoul established the Seoul City Green Architecture Support Ordinance in January 2014 according to the enforcement of Green Architecture Support Act in February 2013, to expand green architecture and reduce the greenhouse gas generated by buildings.

3. INCENTIVE FOR CERTIFICATION

The economic-institutional support consisted of exemption of acquisition-registration tax, property tax, relaxation of architecture regulation, environmental improvement charges, additional charges for design services and obligation of public buildings.

Incentives related to acquisition-registration tax. The period in which the acquisition-registration taxes were reduced over 5~15% for green building certified buildings to promote green building was May 2009.

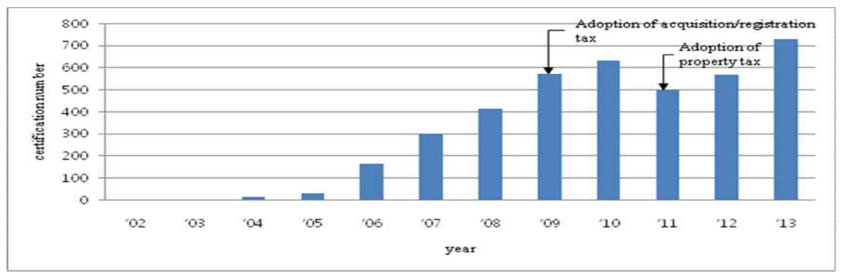

Figure 1 Current status of certification cases (March, 2014)

The number of certified buildings in 2010 increased to 570, which is 156 more than the 414 certified buildings in 2008. Also, the property tax the exemption period is December 2011, it was found that compared to 500 cases in 2011, certification number is increased by 567 in 2012.

Additional Price Incentive. The incentive system for apartment buildings was revised in March 2005 to add 3% of the basic construction cost when the green building certification was acquired according to the regulations of the Calculation of Parcel Price (Article 13-2) for Housing price ceiling system[1] applied to apartment buildings. Therefore the certification records of apartment buildings rapidly increased, from 33 cases in 2005 to 163 cases in 2006

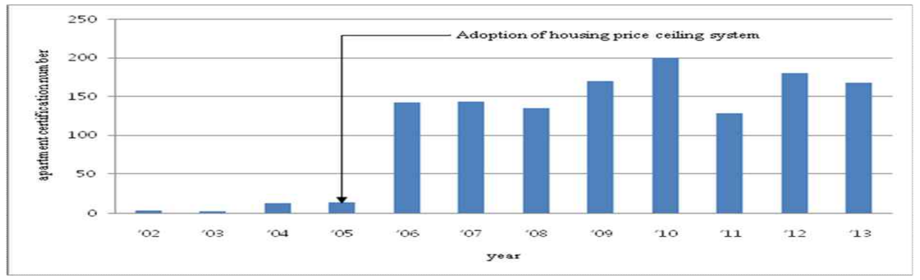

Figure 2 Current status of certification of apartment buildings (March, 2014)

Obligation of public buildings and Green Building certification records. The regulation on the obligation of green building on public buildings was revised in March 2010 according to the energy usage rationalization guideline. There were 64 public buildings with certification, 19 more than in 2009. Furthermore, in December 2011 the standard was revised to apply at least Excellent level for public office buildings.

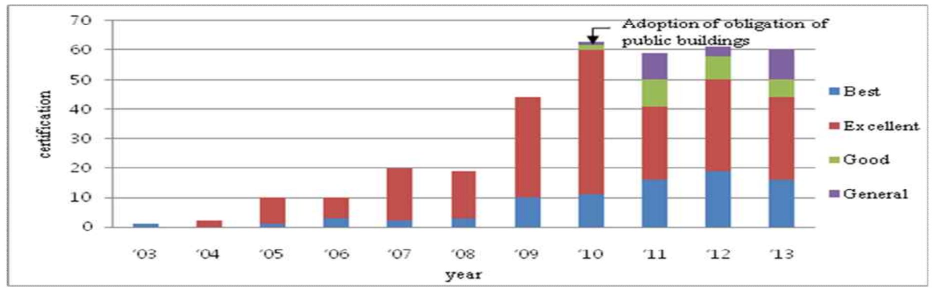

Figure 3 Current status of certification of public office building/facilities (March, 2014)

4. CHANGE OF BUILDING ENERGY-REDUCTION AND ENVIRONMENTAL IMPROVEMENT FACTORS IN G-SEED

ENERGY-SAVING EFFECT OF THE BUILDING

Building Energy-saving. The building energy-saving sector was assessed as an EPI item from 2002 to assess the energy consumption. There were only 12 energy consumption points among all other items of energy sector, but in 2010 the system was modified by applying the weighting, and therefore it was increased to 15 points. Thus, the importance of the energy-saving sector (energy consumption) is increasing daily.

Obligation of use of Renewable Energy: In 2002, renewable energy such as sunlight, bio-energy, wind power to reduce the use of fossil fuel and increase renewable energy facilities was only applied to the apartment buildings and the hot water supply, but from 2003 it was modified to produce 1~5% of the total electric design load, air-conditioning and heating by renewable energy facilities.

[1] Parcel Price Ceiling System: System which designates the parcel price of the house calculated based on the site price, construction costs and the proper rate of constructor's income, which limits the price according to this calculation (Ref: Doosan Encyclopedia)

Table 1. Assessment standards of Energy-saving sector

Classification	Assessment standard
Energy consumption (2002)	Energy consumption assessment according to Energy Performance Index (EPI) points. Y = 12 × (EPIpts-60) ÷ 25
Energy consumption (2003)	Energy consumption assessment according to Energy Performance Index (EPI) points. Y = 15 × (EPIpts-60) ÷ 25
Energy efficiency improvement (2010)	Applied as energy performance index review

Improvement of Ventilation Performance

Material and Resources. The carbon emission of the material is an assessment item that was adopted in 2010 to assess the inherent carbon emission assessment and indication of the material information for the materials and resources used in the construction, and products that acquired the carbon certification were classified into 1~5 types. In 2013, the assessment was classified/divided into apartments and other type of buildings. Significantly, the greenhouse gases emission was indicated in the product for customers' information to contribute to the low-carbon consumption culture, and it is estimated that these carbon-related items will increase further.

Water resources. Rainwater reduction measures were adopted to reduce flood and maintain soil ecosystem in urban area in case of localized heavy rain. The assessment standard in 2002 was a 15~30% permeable paving ratio to reduce efflux of rain water by applying permeable paving, but the 2010 standard was modified to the ratio of rain water treatment facility installation compared to connected area within the total plottage to induce rainwater into the treatment facility. This means reducing efflux of rainwater to the plottage by inducing it to treatment (rainwater efflux reduction) facilities.

Ecological environment. The ecological area ratio is an item to induce the underlying resolution of the urban ecosystem through quantitative assessment of ecological function of the land (soil circulation, rain water circulation, air and climate control, habitat function, etc.) introduced in 2010 to assess by classifying the space type of the land and multiplying it by the weighting of each space type and comparing it with the plottage ratio.

Indoor ventilation. The natural ventilation was assessed in terms of availability for users, with an open-able windows area for each use to provide proper fresh external air, but currently it is assessed to procure natural ventilation by installing additional ventilation equipment for a complementary ventilation system.

Table 2. Natural ventilation performance assessment standard

Classification	Assessment standard
Natural ventilation (2002)	10~15% open-able windows area
Natural ventilation (2013)	2nd degree+natural and mechanical ventilation equipment composes 1 system, and when necessary one component can function in a mutual-complementary manner = combined ventilation system, installed.

5. CASE STUDY BUILDINGS

S Chemical BLDG. The S Chemical BLGD is located in Gyeonggi-do. The total architectural area of the building is 47,541.88㎡, with 5 basement floors and 9 floors above ground. The building acquired the Best G-SEED certification level and LEED (Platinum) certifications. The main application parts are: energy saving sector (energy performance index (EPI) 96 points), renewable energy (installed sunlight and geothermal heat pump system), BIVP installation, ecological material, rainwater and graywater, permeable paving rainwater load reduction plan, etc. In addition, using the temperature difference between the upper and lower atrium, an air control system, the S Chemical BLDG was planning to reduce the air-conditioning load and natural ventilation.

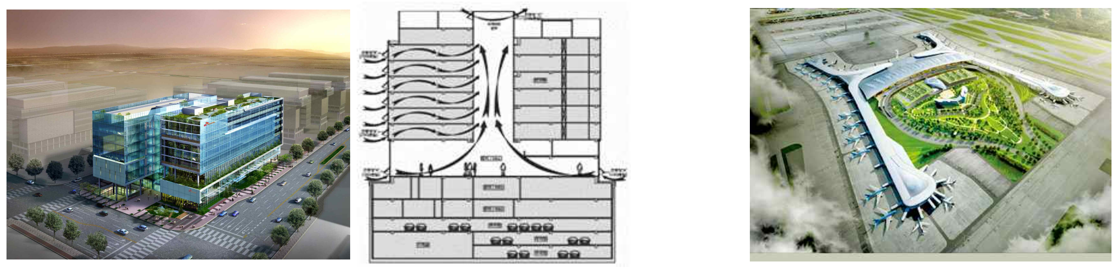

Figure 4 (a)Aerial view-Layout and main section of S Chemical BLDG. (b)Aerial view of New Terminal of International Airport

New Terminal of International Airport. New Terminal of International Airport project is in progress, with the total architectural area of the building as 384,000㎡, including 2 basement floors and 5 floors above ground. The building is estimated to acquire the Best G-SEED certification level. The main application parts are: considering energy saving sector according to energy performance index (EPI), application of carbon emission material, renewable energy (installed sunlight (BIPV) and geothermal heat), and ecological sector of interior garden and outdoor garden, etc. In addition, New Terminal of International Airport is designed to take advantage of the flow of outside air into the thermal tunnel, to improve the energy savings.

The FKI Building. The FKI building is located in Seoul. The total architectural area of the building is 168,629㎡, with 6 basement floors and 50 floors above ground. The building acquired the Best G-SEED certification level. The main application parts are: energy saving sector (energy performance index (EPI) 80 points), renewable energy (installed sunlight and geothermal heat), and ecological sector of rooftop greening, roadside plantation and bio-top, etc. In addition, The FKI building was planned, which will include solar panels on the roof and elevation to maximize the use of solar power. (The production of 4% electricity to 728,971 kw solar power generation amount)

Figure 5 (a) Perspective and elevation detail view of The FKI Building (b) Aerial view of W New City, Apartment building.

W New City. The apartment complex of W New city is located in Seoul. The building consists of 2 basement floors and 11~19 floors above ground for 1493 households. In the green building certification the building is implementing the development for acquisition of G-SEED excellent level certification. The main applications are energy-saving sector (application of 1st degree of energy efficiency), new regeneration energy (sunlight and geothermal heat), and in the ecological part an artificial ground green belt and green wall curtain were applied, while in the interior a mechanical-device for excellent ventilation function was featured. In addition, the W New City apartment complex was planned to introduce a geothermal heat pump system, which will be responsible for generating the equivalent of 3.49% of the total energy.

6. DISCUSSION

The green building certification system in Korea, which was adopted in 2002, had been applied to over 4000 cases of certification records in a short period of about 10 years, contributing to the spread of green architecture in Korea. By increasing the energy efficiency it also played an important role in the reduction of greenhouse gases. This was thanks to strong government support to respond to the private sector's demand. The successful case studies shall be an exemplary reference for further green architecture introduction, diffusion and dissemination for other countries.

The Green architecture support act, which was established in 2013, consolidated all the scattered green construction related regulations and standards and encapsulates the generalized and comprehensive green building policy and promotion plan. By enforcing diverse and effective ecological and energy-saving green architecture dissemination policies such as the establishment of a certification system, establishment and disclosure of an information system, designation of a professional organization, education and training of professional operators, etc., it became a strong legal basis for the dissemination and expansion of green architecture by the government and local governments.

Green architecture suffered various difficulties in its initial phase of voluntary diffusion due to increased investment costs, though it assured the improvement of environmental performance of buildings. These were surmounted through diverse economic and institutional incentives provided by the government, and certifications increased explosively after the enforcement of the certification incentives. The public sector led the private sector by requiring certification and established a paradigm in which long-term innovative design took precedence over short-term economic profit.

The building industry in Korea also developed rapidly. As skyscrapers and diverse complex buildings increased, issues such as global warming showed the problematic nature of the curtain wall method, leading to a general change and improvement in the construction industry. Korea's green building assessment and certification system, initiated in 2000 and implemented in 2002, have improved and developed assessment standards for the most optimal assesssment, and led the construction industry by responding to the demands of the private sector through measures such as departmentalization of certification levels, diversification of buildings for certification, etc.

The development of professional bodies to support the government policy is critical to the success of the certification system. The green building certification is based on fairness, objectivity, consistency, and the subsidiary roles such as education and consulting for the constructor, designer and operators also guarantee the greater effectiveness of this certification system. In addition, its role as a medium that delivers the industry's demands to the government and reflects them in policies is also a critical function of the certification institutes. Also, its role as a professional certification institute that performs education of professionals and accumulation of relevant technologies is a critical factor affecting the general sector of certification system. If the certification body is not reliable, the entire certification system loses credit and fails.

7. CONCLUSION

As mentioned previously, for the dissemination and diffusion of green buildings, a certification system based on relevant regulations is essential, and therefore a fair and professional certification institute must be developed. By reflecting these features of a certification body the institute needs a strategy to survive within a system of autonomic competition. Furthermore, though the obligation of public areas it must take an initiating role and grant diverse and effective incentives to the private sector to promote the rapid proliferation of the certification system. To continue and maintain this, the certification system must be steadily improved and developed to provide actual benefits to prevent dismissals. The greening of architecture that results will have great results, including the reduction of greenhouse gases, saving of resources and efficiency of energy consumption, which are critical problems in architecture from an economic-environmental point of view, as well as improving the residential environment, and thus promote global sustainability.

Meanwhile, from 726 cases certified as green architecture in 2013 by G-SEED, only 118 cases were certified by the Korea Research Institute of Eco-Environmental Architecture (KRIEA), which corresponds to 16.3% of the total records and 2nd place in the entire certification records scope.

Developing Free-running Prototypes for different Climates of Chile

Gabriel Felmer, BArch

gefelmer@gmail.com

Simos Yannas, DiplArchEng AAGradDipl(Hons) PhD
[Architectural Association, London UK]

ABSTRACT

This paper presents results from thermal simulations conducted for a terrace house in Santiago (33˚S). Previous findings from field studies concluded that despite the use of polluting space heaters social housing households were unable to heat their homes to an adequate level of warmth, being exposed to noxious pollutant gases and also forced to live in fuel poverty. The studies presented here investigate whether adequate thermal comfort conditions can be provided in free-running buildings, i.e. neither heated nor cooled mechanically, within the economic limitations posed by social housing standards. Results from thermal simulations have evidenced that, through passive heating and cooling design techniques, thermal comfort can be achieved at low costs without any additional energy inputs all year-round. These results will be further used to develop a modular housing prototype for the varied climates of Chile.

INTRODUCTION

Over the last five decades, the development of social housing policies has led most Chilean cities to a scenario of social and environmental exclusion. Driven by a large housing shortage the proliferation of hundreds of thousands of apartment blocks spread around suburban areas created high poverty ghettos, characterised by low quality housing, raised levels of air pollution and degraded thermal environments. The combination of thermally inefficient housing stock and the use of fossil-fuels for space-heating have long been threatening public health and well-being in poor suburban areas. Although studies have revealed high levels of indoor air pollution attributed to the use of unvented space heaters low-income households have been unable to heat their homes to an adequate level of warmth (CENMA, 2011; Ruiz et al., 2010). Moreover, high fuel costs exacerbate vulnerability and forces inhabitants to live in fuel poverty.

With a deepening energy crisis and the prospect of fuel price increases looming large on the horizon, fuel poverty has become a progressively more urgent social issue in Chile. Although the negative impacts of thermally inefficient housing have been largely acknowledged, as well as their adverse effect on poverty, the supply of polluting fuels for residential space heating has remained unquestioned politically. This highlights the question as to whether polluting fossil-fuels are necessary to provide affordable warmth. Previous studies have proved that more thermally efficient housing could reduce space-heating demand without incurring significant extra capital costs (Bustamante et al., 2006; Méndez, 2008), but is it possible to do so under free-running conditions?

THERMAL SIMULATION STUDIES

In order to test whether thermal comfort can be provided without additional energy inputs, parametric simulations were carried out using as a case study a building in Santiago. The aims of this research is to investigate the thermal performance of housing and develop passive heating and cooling design techniques for different climates of Chile. The study here outlines a criteria to evaluate thermal comfort in residential buildings, as well as present results from a series of thermal simulation tests conducted to find the appropriate combination of passive designs to achieve thermal comfort at low costs. The results from this will be used to inform the design of a prefab modular prototype, *Prototype Zero*, proposed to test the research objectives through further thermal simulations for the cities of Antofagasta (23˚S) and Puerto Montt (41˚S). The final outcome of the project will be the design proposal of a net-zero apartment district located in inner-city Santiago.

The building case study was selected from a sample of buildings studied under the present research framework. This provides a reliable base case supported by monitored temperature results and field study observations. The selected scheme corresponds to a three storey intermediate terraced house with a total habitable floor area of $55m^2$, taken from *Olga Leiva* social housing development. **As shown in Figure 1**, since the house has a low level of exposure and the insulation of its exterior walls are below minimum standards, this is a U-value of 1.9 W/m^2K, the overall heat loss coefficient results to be significantly below an average detached house for the same location.

In order to evaluate the thermal performance of the house in relation to occupants' preferences, a thermal comfort index is proposed. This provides a weighted indicator of the effective thermal comfort contribution made by each design strategy as well as allowing comparisons to be drawn against final construction costs. **As shown in Equation 1**, the thermal comfort index expressed here as ΔT_c sums the hourly difference between resultant operative temperatures and monthly comfort temperatures estimated from an adaptive model of thermal comfort. In order to simplify results, the index is assumed to equal zero when temperatures are outside thermal comfort thresholds.

$$\Delta T_c = | T_{op} - T_c | \qquad \textbf{(1)}$$

Where : T_{op} = Operative temperature
T_c = Monthly comfort temperature

To keep track of the impact of each design parameter over final construction costs, a marginal cost index ΔMC was proposed. As shown in **Equation 2**, the index, which is the simple difference between initial construction costs and final construction costs of a given building when incurring any design modification, allowed thermal performance to be optimized against construction costs allocated by current housing programs. This was accomplished through a series of simulation tests conducted after the completion of the parametric studies, by further testing the sensitivity of the building to the combination of the lowest resulting comfort indexes. In order to find the appropriate combination of passive design techniques, the simulation results were computed using an analysis matrix, containing both, comfort and marginal costs indexes for each variant tested.

Figure 1. Building case study, plans and construction specifications

The criteria adopted for the cost-benefit analysis is based on subsidy schemes granted by social housing programs. According to government sources (MINVU, 2013), the total construction costs granted for the poorest income quintiles, corresponding to the first title of the *Integrated Housing Subsidy System*, varies from nearly 22,700 to 52,000 USD. Although for the purpose of this research it was decided to adopt the minimum cost, in order to allow further improvements to the performance of buildings, the budget scheme adopted considered the addition of a thermal conditioning subsidy which in total reaches up a budget of 27,000 USD.

$$\Delta MC = C_f - C_i \qquad \textbf{(2)}$$

Where : C_f = Final construction cost
C_i = Initial construction cost

ADAPTIVE THERMAL COMFORT

The criteria by which thermal performance was evaluated was based on the assumption that thermal comfort is not a commodity, but an imperative constituent of an individual's right to overcome poverty. Therefore is crucial to distinguish first the subtle threshold between the notion of thermal comfort and health, the former being a condition of mind associated with an individual's perception, and the latter being a basic biological need for human survival. Under these terms, thermal comfort is stated here as an adaptable necessity subject to buildings' inherent capacity to provide shelter from outdoors, whereas looking beyond human thermal regulation capacity, an adequate level of warmth or coolness is a minimum condition required for the maintenance of health. The assumption that space heating is required if any of these limits are exceeded has undermined the responsibility of housing authorities to provide adequate thermal environments, creating a burden for the income of poor households.

Field studies conducted under this research study, during the winter of 2011 in Santiago, evidenced that none of the above definitions were actually met in social housing. Findings drawn from interviews conducted in *Olga Leiva* and *El Estanque* housing developments, unveiled the paradox of the 'cure being worse than the disease' as occupants claimed that, despite raised levels of air pollution and space heating fuel costs during winter, estimated at an average around 40USD for a monthly heating load of 100kWh, above the 10% of the poorest quintile income average, the level of heat provided by common kerosene and gas space heaters was not sufficient to cover their thermal needs, where surprisingly in order to ensure health and safety many interviewees stated that they operated their houses under free-running conditions. So why are space heating fuels used at all?

The above observations were consistent with monitoring data and comfort survey results. Whereas building monitoring showed that indoor daily temperature averages around 14˚C, the outcomes of a survey conducted on a sample of 100 households showed that indoor temperature patterns tended to follow outdoor patterns, exhibiting mean comfort votes of 15.9˚C and 17.3˚C, in *Olga Leiva* and *El Estanque*, respectively (Felmer, 2014). The evidence suggests that a more open connection to the outdoors widens the scope of temperature ranges into which occupants express thermal satisfaction. Providing that people's health is ensured through limiting building temperature extremes, an adaptive approach to thermal comfort is advocated here through the integration of adaptive thermal controls aimed at reducing space-heating, and to providing thermal comfort all year-round.

$$Tn = 17.8 + 0.31\,Tm; \quad Tc = Tn \pm 3.0 \qquad \textbf{(3)}$$

Where : Tn = Neutral temperature
Tm = Mean monthly temperature
Tc = Comfort temperature

In order to widen the study across other seasons and climates, comfort temperature ranges were estimated from a database of field studies by de Dear & Brager (2001). The model adopted was developed over a linear regression obtained from the revision of 22,000 sets of raw data compiled around different climates world-wide. **As can be observed in Equation 3,** thermal comfort limits were taken as ± 3K from thermal neutralities estimated for each month. In order to parallel with studies in social housing, the algorithm was estimated for the same period (August; Tm= 9.8 ˚C), resulting in a lower limit of 17.8˚C, higher than the comfort votes showed above, the equivalent of a monthly heating load of 500kWh. Although this is low, fuel expenses are unaffordable for low income households.

OCCUPANCY HEAT GAINS

Heat gains from occupants and appliances were estimated from field study observations in *Olga Leiva*. Although there is no empirical research on the matter previous assumptions estimated an average daily heat load for standard residential buildings of around 5.0 W/m^2 (Hatt et al., 2012; Müller, 2003). Whereas, the average daily heat load adopted for the studies presented here was estimated at 7.0 W/m^2, by considering that 4.0 W/m^2 comes from occupants; 2.0 W/m^2 from appliances and 1.0 W/m^2 from lighting. This results in a total daily heat load of 9 kWh, resulting at a similar rate to previous studies conducted for social housing (Bustamante, 2009). The house was assumed to be occupied by four occupants, two adults and two children, considering continuous occupation by one member of the household, while one working adult and the children out for most of the day. In order to cover energy end-uses other than space heating, only electric efficient equipment was considered, obtaining lower energy consumption rates than an average household in Santiago.

INFILTRATION AND VENTILATION

Air infiltration rates were taken from recent empirical studies conducted to set a baseline for residential buildings. Previous simulation studies by Bustamante (2009) assumed a value of 1.0 ach as the maximum acceptable limit for thermal efficiency in social housing. However, recent evidence gathered from studies around different climates has proven that higher air tightness can be achieved with simple economic measures (Cortes & Ridley, 2012). Results from pressurization tests conducted to set a baseline standard by Figueroa et al. (2013), exhibited values ranging from 0.12 to 2.5 ach under normal pressure conditions, for both brick and timber constructions. The air change rate adopted here was then 1.2 ach, corresponding to the average value of the sample. Minimum fresh air supply rates were taken as 7.5 l/s per person for each room, when occupants were in at any given time (ASHRAE 62, 2005).

THERMAL PERFORMANCE

As can be observed in **Table 1**, preliminary simulation results showed that indoor temperatures were below thermal comfort limits during most of the heating season. This means the conjecture that current standards do not aim to target thermal comfort is borne out, as temperatures can drop significantly below mean comfort votes, or even further below recommended limits for healthy thermal environments. Results plotted for a typical winter's day, as shown in **Figure 2a**, were consistent with space heaters patterns of use, which was around an average of four hours a day between 6.00-10.00pm, and occasionally for a few hours during the morning. Thermal comfort conditions are only achieved during the hours around midday, and from there on temperatures steadily decrease reaching below 15˚C and reducing further to 10˚C during early mornings. On the other hand, results from a typical day in summer in **Figure 2b** showed that thermal comfort was only achieved in the living area, whereas in the bedroom resultant temperatures exceed the upper limit during most occupancy hours in the evening.

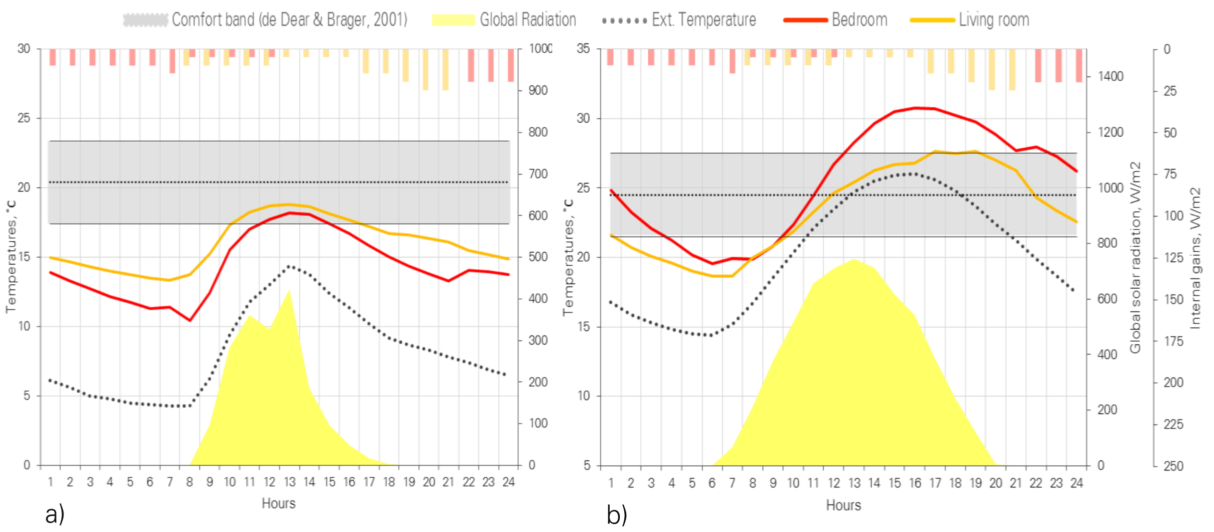

Figure 2. (a) Case study performance on a typical day in winter and (b) on a typical summer's day.

Table 1. Comfort Indices for the Building Case Study					
		ΔTc (Degree-hours)	ΔTc (%)	To min (˚C)	To avg. (˚C)

	Living room	8,943	71	7.9	15.6
Summer	Bedroom	3,228	49	36.3	26.3
	Living room	785	36	33.1	23.8

PARAMETRIC SIMULATION STUDIES

Since thermal comfort was not achieved, parametric simulations were carried out to test the influence of different design techniques. The aim was to select the parameters to be tested in further studies with a free-running prototype around the country's varied climates. Based on a review of previous studies by Bustamante (2009) and Müller (2003), the parametric variants proposed were based on four distinctive design principles: *heat loss control*, *passive solar design*, *thermal mass* and *natural ventilation*. These were considered as a conceptual basis to move from one climate to another. However the design approach adopted for each location might be subjected to the nature of each climatic problem, rooted in the interaction between occupants' thermal needs and outdoors. As the predominant problem found in Santiago was underheating and, as the sole choice, the use of polluting space heaters, the analyses were structured to provide thermal comfort during the heating season as a primary concern. The final result of each parametric variation can be consulted in **Table 2**, a brief description of the studies is given here below:

A. Airtightness: Following pressurization tests by Figueroa et al. (2013) infiltration rates of 0.12 and 2.5 ach were further tested, corresponding to the minimum and maximums values of the sample. Results from the case study evidenced a great sensitivity to slight variations in air change rates, improving significantly performance from the highest to the lowest values tested, reaching up to 5K during occupancy hours, and nearly to 2.5K average across the whole period assessed. The airtightness standard of the building proved to be crucial to allow sensitivity to any other design parameter, thus further analysis was carried out under 0.12 ach, advocated as an acceptable limit for thermal efficiency.

B. Insulation of External Walls: As previously discussed in relation to the low exposure levels of the house, the addition of insulation on external opaque elements exhibited no significant influence. Different insulation thicknesses were added on exterior walls, including further testing of alternatives, at 75mm (U=0.5 W/m^{2}K), and 100 mm (U=0.4 W/m^{2}K). Results exhibited no meaningful differences in both seasonal periods, suggesting that even lower resistances can be specified.

C. Interior Shutters: Despite reduced windows areas, this parameter showed to be decisive for providing thermal comfort during winter evenings. This can be explained by the ratio of glazing surfaces when compared with all exposed elements, and by the low resistances allowed for windows in current regulations. Two different alternatives were tested, one by replacing single glazed windows with double glazing (U=2.9 W/m^{2}K), and other by the incorporation of interior night shutters (U=0.7 W/m^{2}K), operated between 8.00pm-8.00am. The use of the shutters exhibited great efficiency, increasing temperatures by nearly 2K during evening hours, while being considerably cheaper than the double glazing alternative.

D. Window Size: In order to assess passive solar heating potential, different window sizes were performed. The windows of the case study were decreased to meet the minimum allowable size set by social housing standards, a corresponding net glazing area of 1.0 m^2, and increased up to 2.0m^2. The results showed that by simply facing windows towards the equator, incoming solar radiation can provide sufficient amounts of heat to increase indoor temperatures above thermal comfort limits, although higher levels of thermal mass would be required to stabilize indoor temperature fluctuations.

E. Thermal Mass of External Walls: Thermal mass was examined through different brick masonry constructions used in social housing. The exterior walls, built on lightweight timber construction, were performed with two different brick constructions, a ceramic perforated brick, and a clay solid brick, using the same insulation thickness. Results evidenced that thermal mass had a great potential to reduce high daily temperature fluctuations, contributing to stabilizing indoor temperatures during both seasons. The solid brick solution proved to be remarkably cost efficient, since being more economic than its alternative, exhibited a more robust performance, reducing peak indoor temperatures by nearly 5K, and even further up, to 10K on some unfavourable winter days.

In order to conduct the cost benefit analysis, each design variant tested was compared against final construction costs. In order to reduce the data inputted in the analysis matrix, comfort indices were estimated only from bedroom performance results over a sample week selected in winter. **As shown in Table 2**, the matrix allowed a first improved house, based on the combination of best results obtained across the studies to be set. Since this did not necessarily represent optimum performance, either in terms of thermal comfort or costs, further tests were carried out to investigate the influence of each variant under the combined effect of the different design parameters. The results from the second improved house initially proved that thermal comfort can be achieved within reasonable costs. However a final simulation was required to test whether acceptable thermal conditions can be provided during critical occupancy hours.

IMPROVED THERMAL PERFORMANCE

Results from parametric studies were used to develop a final design proposal. A last simulation was performed to adjust the thermal environment of each room to the hours of occupancy when the main problems were identified to occur. As shown in **Figure 3a**, based on the optimized case study obtained from the matrix, resultant indoor temperatures were found to be above thermal comfort almost all day round, ensuring occupants had the minimum conditions required to perform their daily activities and safeguard the maintenance of health. Moreover, the sensitivity of the house in relation to solar radiation

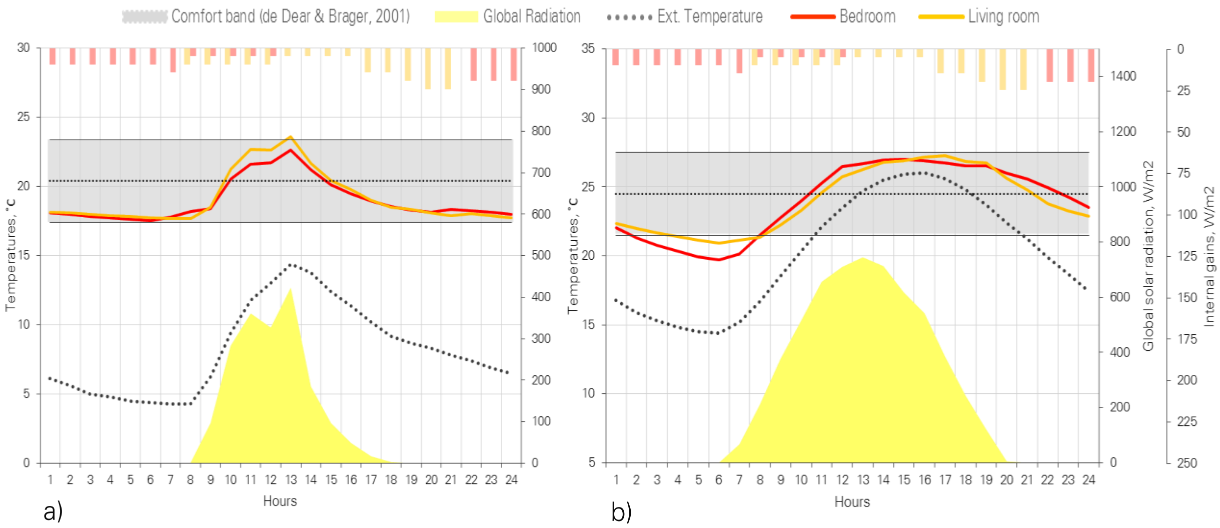

Figure 3 (a) Optimized building performance on a typical winter day and (b) on a typical summer day.

Table 3. Comfort Indices of the Improved House

		ΔTc (Degree- hours)	ΔTc (%)	To min (˚C)	To avg. (˚C)
Winter	Bedroom	205	8.1	14.8	21.0
	Living room	144	7.8	15.7	20.5
Summer	Bedroom	70	6.9	28.6	23.2
	Living room	64	5.2	28.7	22.3

offered the choice of achieving additional levels of warmth, providing appropriate thermal conditions to dispense with polluting space heaters.

Results from a typical day in summer proved that thermal comfort can be achieved through simple design techniques. The final building performed considered the addition of ventilation, either through windows opening or the operation of a fan, increasing air change rates by 12 ach and 15 ach during occupancy hours in the bedroom and living area, respectively. The use of exterior shutters was also considered, covering 25% of window areas. **As shown in Figure 3b**, the controls provided allowed indoor temperatures to achieve below thermal comfort limits for most part of the day, offering occupants the choice of adapting to changes in their thermal environment. Although in terms of fuel consumption this might not be relevant, overheating may lead to thermal stress and seriously affect the daily performance of different activities within the home.

Results from cost benefit analysis allowed to draw a final estimation of the construction costs required to meet the expected results. As can be observed on **Figure 4**, which comprised the replacement of standard aluminium windows with PVC; the incorporation of trickle vents; and the addition of 10mm of insulation on external walls (U=0.53 W/m^{2}K). As shown in **Table 3**, while resultant comfort indices where significantly reduced, the additional cost investment required was fully covered by the thermal conditioning subsidy reaching approximately 4,000 USD, the equivalent of 18% investment over the minimum construction costs allocated by the government.

CONCLUSIONS

The performance of the optimized house proved that adequate thermal comfort conditions can be provided in free-running buildings in the climate of Santiago. The findings from field studies were crucial to understand occupants' preferences and space heating consumption behaviours, which turned to be in some extent over estimated since both thermal expectations and consumption levels were remarkably low. The underlying problem was then, thermal comfort itself, followed by occupants' limited choice to afford clean and safe energy sources. Results from parametric simulations demonstrated that through simple passive heating and cooling design techniques thermal comfort could

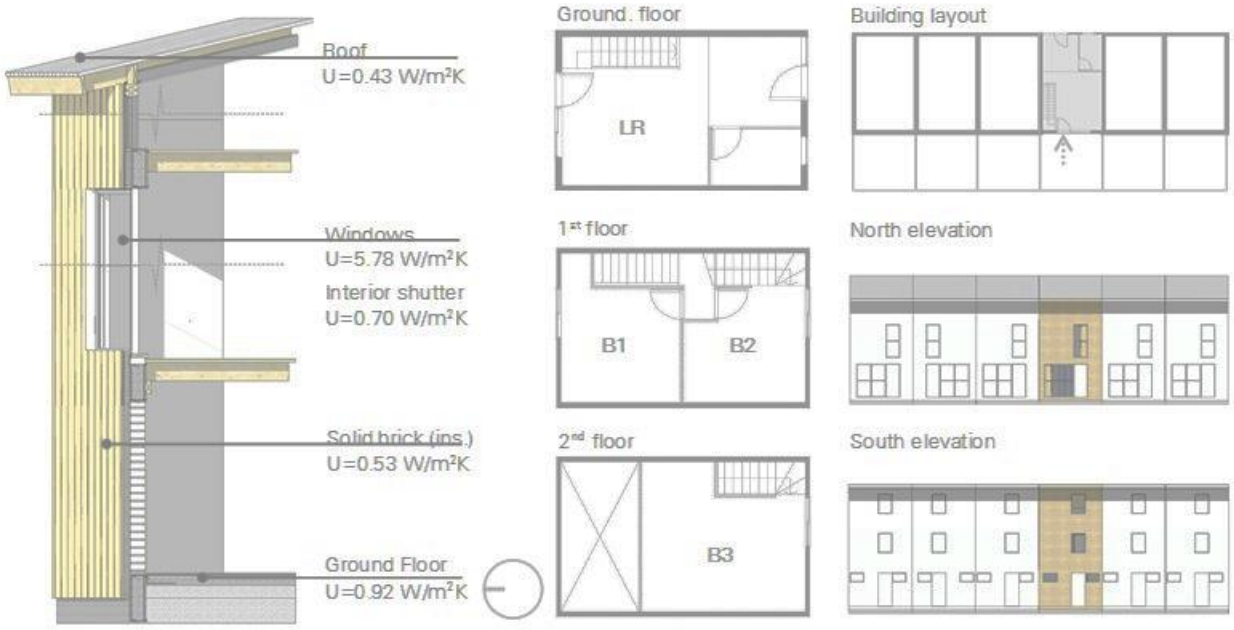

Figure 4. Optimized case study, plans and construction specifications.

be provided within minimum budget allocations, questioning the role of government authorities to ensure adequate housing conditions. The potential to reduce space heating down to nearly zero and provide thermal comfort all year-round could represent a significant contribution to improve indoor environmental performance and the quality of life of the urban poor, as well as open the debate towards energy autonomy by replacing combustion fuels with clean energy powered by solar energy technologies

ACKNOWLEDGMENTS

This study was carried out as part of a PhD thesis at the *Architectural Association School of Architecture* in London, UK. The author would like to thank to Prof. Simos Yannas and Prof. Paula Cadima for their supervision, support and fruitful advice. This research was supported by the National Commission for Scientific and Technological Research (CONICYT).

ABSTRACT

This paper aims to conduct an empirical test-bed research to improve design and construction process of the prefab multi-unit housing accommodating 50 college students, based on integrated co-works with different stake-holders (clients, architects, builders) and involving non-profit organization such as Habitat for Humanity Seoul. The purpose of the study is not only to develope optimal design technologies for the higher thermal efficiency but also to identify the ways in which the prefab houses could be supplied for low income groups.

INTRODUCTION

In Seoul, the capital of the Republic of Korea, the urban area developed to be quite overcrowded due to rapid economic growth and urbanization. After 2000, the population of Seoul had a steady while the number of households increased. This is because of the shift in the nuclear family composition, in which single or two-person households became more typical. With this, a housing shortage occurred in the urban area due to the increase in the number of households. The major concern in this housing shortage due to urbanization is the autonomy of the socially disadvantaged. As they are weak in terms of social standing, their residential environment is very poor. Therefore, in all levels of society the interest in the disadvantaged has increased, and diverse housing welfare projects for the socially disadvantaged as a low income group are actively being implemented. With this, the improvement of the residential environment is also becoming a critical issue.

In Korea, modular construction, which was presented for the first time in 2003, is proposed as one of the solutions to resolve this problem. The prefabricated house was presented as an alternative to resolve the problem of housing distribution for low income residents and socially disadvantaged persons in the urban area, and the current modular construction method that was introduced to Korea over 10 years ago is rapidly growing and is also recognized as a new construction system.[6]

Modular housing has become a very interesting issue, not only in Korea but also in other countries. In Korea, the modular construction system is generally applied for a range of purposes such as residences, commercial buildings, schools, hospitals, increasing during its short 10-year history, but there are still many problems to resolve.[7] This research focuses on potential applicability of the prefabricated house and the high-quality house distribution based on an empirical study on the modular house as a future method of residential construction with great potential.

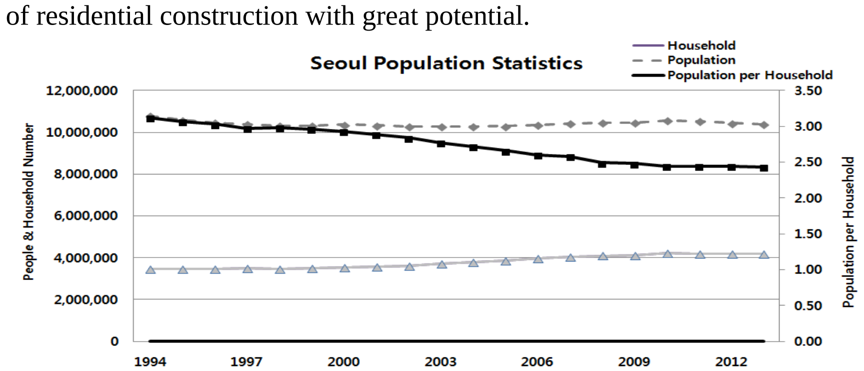

Figure 1. Seoul Population Statistics (National Statistical Office of Korea)

Background to Domestic Prefab System Housing

Most of the domestic modular houses from 2003 to 2008 were applied for education and military facilities, as the special characteristics of the modular construction were suitable to these applications. In modular construction the construction period is reduced, demolition and reuse after the life/duration of the building is easy and the application of new methods according to new policies is easier, as they are public facilities. In Korea since 2000, modular construction has been applied in different sectors such as for export, residence, the 2nd Antarctic Base, etc., and particularly in the residential sector, the Ministry of Land, Infrastructure and Transport revised the 'Industrialized Residence Acknowledgment Standard' for the first time in 2006 to enable the application of modular construction[7].

The residential sector in modular construction covers all areas, such as detached house, dormitory, small rental house, and mid-to-high-rise residences. This research will look at a 50-person capacity university dormitory, built recently with the modular construction method that has been gaining attention. Based on the above case, this research proposes the possibility of a model of house distribution for low-income groups through the cooperation of the government and private sector, by implementing an empirical study on a residence for students migrating from other provinces.

Characteristics and Need for A Prefab System Housing supply

The modular construction system is comprised of the factory manufacture/process of frameworks, electric works, construction equipment works and finishing and the assembly and installation of prefabricated parts on-site, the strongest point of which is the reduction of the construction period, procurement of equal/standardized construction quality, easy demolition process for aged buildings and the reusability of subsidiary materials. It can properly respond to working environment avoidance and to the demand for a reduced construction period. Also, through materials and specifications standardization in the factory the quality is uniform based on automated production technology.

The factory-manufactured prefabricated house is classified into different types according to the distribution and construction method, but the definition in this research is as follows:[8]

- Modular House : House composed of prefabricated parts that is constructed according to the local government or regulation of the construction site. House installed with module units transported from the factory to site.

When the material process and construction are fully performed on-site, problems can emerge such as deterioration of construction quality, increase in the construction price and extension of construction period, etc. In current domestic modular construction, the modules are generally manufactured for site construction, and therefore improvements in production efficiency are required.[2] Thus, even when the modules are assembled in the factory, the necessary materials must be detailed and standardized for every order/phase from the module manufacture and installation for an easier construction process. This will shorten the site construction period and improve the quality. The reduction of the construction period and improvement in quality results in a cost reduction, and this is the strongest point of the prefabricated house. Figure 3. shows a comparison of construction price composition between the British site construction method and the small and large modular method (OSM: Off-Site Manufacturing). The materials cost in the general modular method is larger than in the existing site construction method, in which the wall and floor of the modular house is basically formed by 2 floors.

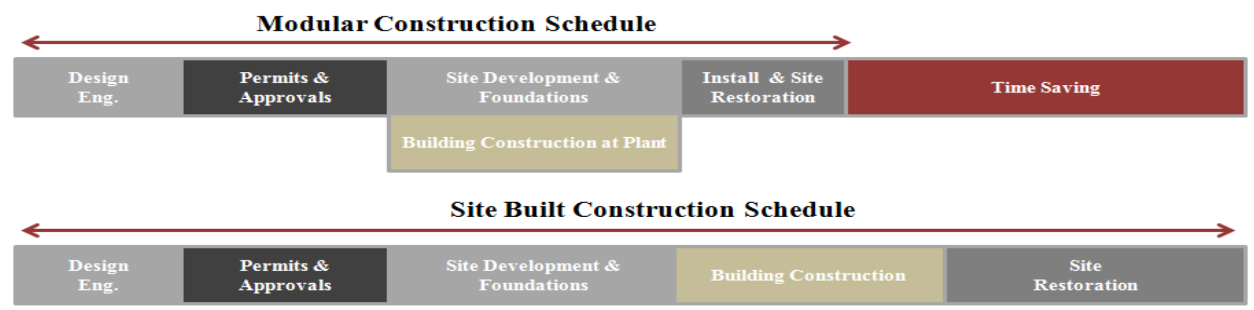

Figure 2. Advantages of a Modular Construction Schedule

Therefore, when the modular method is applied it must be considered that the material quantity is higher than in the existing site method. However, the reduction in unit price for quantity purchase, and reduction of loss on site can be considered as another strength of the modular method

Also, in the case of this factory-manufactured prefabricated houses, the building using of identical and standardized Materials simplifies the dismentlement at the end of the life, therefore the reuse value is also excellent due to the subordinate materials. This excellent reusability is a critical factor of the eco-construction method that may overcome the faults of waste production in the existing construction method.

In Korea the modular construction system includes reinforced concrete floor plate, and wet process as fire-proof paint in the ground plate phase considering the domestic residential environment. As shown in Figure 4, the modular construction system of this research requires production improvement and wet processes; sufficient design considerations, construction process and manufacturing planning to prevent cost increase for buildings over 5 floors, for which 2 or more hours of fire-proof treatment is required.[1]

CASE STUDY

"The Dreaming Attic for Student Residence CY"

As stated in Figure 5, Seoul is currently the city with the highest population density among all cities in OECD countries, at 16,700 person/㎢. This is 3 times denser than London. Many students come to the city to study in different universities but considering this high population density, it is actually difficult to satisfy the demand for student housing, placing a burden on the students. For this reason a project was implemented in which prefabricated houses were constructed on top of public parking lots managed by local governments to increase the added value of public spaces, and these were distributed to the socially disadvantaged in the form of rental houses. This became an object of empirical study as an alternative to using the ground space of the public parking lot, an indispensable facility in every urban area. Actually, the Dreaming Attic for Student Residence CY, which was completed in February 2014, is a representative case in which the NGO, Habitat for Humanity Seoul and Seodaemun district office cooperated to expand a building of 1F and 1 basement where there is a public parking lot for residents of the area into a 1 basement and 4-floor apartment building with housing units from the second floor to the fourth.

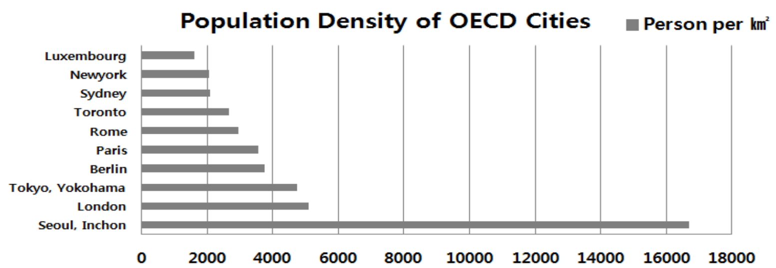

Figure 5. Population Density of OECD Cities (per/㎢)

Residents were strictly selected from nearby university students, and provided with a pleasant residential environment at a low cost. Figure 6 shows the assembly phase of the actual construction process. The project was implemented through cooperation between the NGO, the local government, the constructor and the module manufacturer to resolve the parking problem and to distribute low-cost, pleasant residences.

PERFORMANCE ANALYSIS & DEVELOPMENT

Environmental Performance of Prefab System Housing

Korea's Construction Act regulates the heat transmission coefficient in the basic insulation sector. Also, apartment buildings with 500 units or more are assessed in terms of preventing condensation to secure an adequate interior thermo-residential environment. In the anti-sweating performance assessment the value must be lower than the standard as the TDR (Temperature Difference Ratio) as stated in Equation 1. <Table 2> calculated the indoor minimum surface temperature of the wall using the computer simulation program PYSIBEL Trisco Ver.12 to interpret the electric heat of the wall. It was found that the weakest/poorest right angle TDR satisfied the domestic standard by scoring 0.233, showing performance equal to that of general apartment buildings built with reinforced concrete. The high-performance insulation effect of the prefabricated house secured a good indoor thermal environment, a reduced construction period and economic advantages. Given that the domestic climate has a clear difference in terms of the four seasons, a higher insulation performance is required when compared to prefabricated houses used in other countries. Table 3 shows the legal limits of the domestic apartment anti-sweating design standard. The target building of this research satisfies the existing apartment building standards and demonstrated an insulation performance similar to that of general residential buildings. While higher insulation performance can be secured, this will increase the basic unit price of the construction, and therefore we only showed the most optimal insulation performance.

A New Housing Supply Model for Low-income Groups

In existing construction projects there were economic problems and difficulties in site selection. These difficulties resulted in an increased construction price, and there was a perception that the prefabricated houses were expensive; therefore, it was necessary to change that perception. The new project model, "Dreaming Attic for Student Residence CY," is indispensable for presenting the necessity of prefabricated housing and guaranteeing the welfare cooperation for all of society. But it is a fact that the investment required of the government and enterprises is still a problem to resolve. In addition, the problem of management after construction is significant. It is important to provide more benefits to the socially disadvantaged, and to distribute these equally through transparent management and administration.

As we can see in Figure 7, through this project model the government, NGO, constructor, module manufacturer, the people and the disadvantaged will all gain great benefits. The government will have the benefit of a direct solution to a social problem, the enterprise will gain the advantage of experience through manufacturing and constructing prefabricated houses, changing perceptions of prefabricated houses and making a disadvantaged will all gain great benefits. The government will have the benefit of a direct solution to a social problem, the enterprise will gain the advantage of experience through manufacturing and constructing prefabricated houses, changing perceptions of prefabricated houses and making a social contribution. Above all, through the cooperation and social contribution of the government, NGO, constructor and manufacturer, more socially disadvantaged persons will receive more benefits, producing positive effects in general.

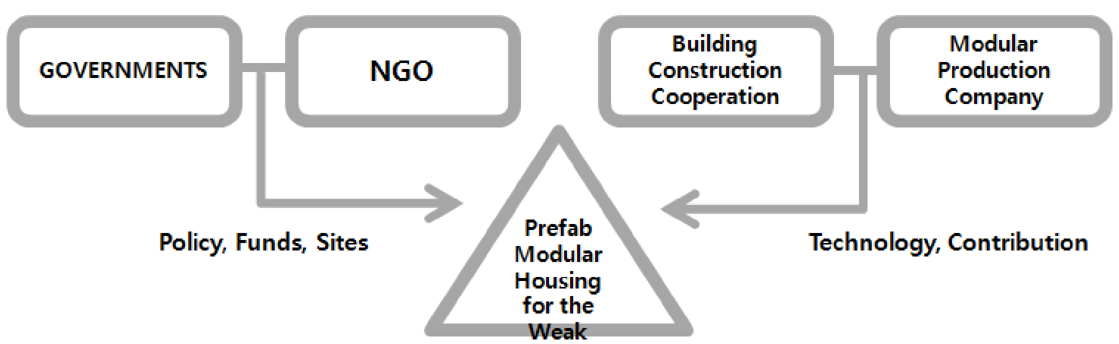

Figure 7. Concept of a Housing Supply Model

CONCLUSION

In this research we presented a project model based on the above-described empirical cases for a wider application and diffusion of prefabricated houses. The application of prefabricated system housing can be an excellent alternative that satisfies the demands resulting from high population density, the increase of single-person households, and the need for inexpensive small-unit housing and demands for better residential environment, etc. Nowadays, a better residential environment with uniform performance and quality can be provided through optimal performance evaluation within a scope where excessive design is avoided by reducing the construction period through the use of prefabricated houses.

In the prefabricated housing system, construction, equipment and electric works excluding civil and landscape works are performed in factory by the manufacturer, therefore the role allocation between the contractor and subcontractor is very different from that of existing site construction methods. Thus, with the development of the new module technology, the module manufacturer performs the new project model incorporated with the constructor and so the benefit is provided to everyone and is made available to society through its application in a housing welfare project. It will no longer be a simple economic activity, but an indispensable housing welfare project model for low income and disadvantaged persons and an excellent response to the government policies.

In addition to the public parking lot, it is necessary to expand the project by procuring diverse project sites to provide more benefits for the disadvantaged. This project model is applicable not only in Korea but in all other countries, and considering that it strengthens the benefits of prefabricated housing it will be an ideal alternative for us to open the future. The modular construction system which guarantees economic advantages based on a high technological level and experience offers a new paradigm in housing welfare projects through the improvement of the residential environment for low-income and disadvantaged persons living in inefficient residential spaces, through the cooperation and assistance of the government and diverse NGOs, and the probability of its application was clearly certified. More interest needs to be taken in housing provision methods for low-income and disadvanted persons.

Carbon dioxide emissions of green roofing – case study in southern Brazil

Giane de Campos Grigoletti, DrEng
[Universidade Federal de Santa Maria]
grigoletti@smail.ufsm.br

Marcos Fabrício Benedetti Pereira, MEng
[Universidade Luterana do Brasil]

ABSTRACT

Nowadays there are several efforts in define carbon dioxide emissions of buildings components and materials. This data shall be in accordance with local building technology or methods of construction. Therefore studies of local alternatives are important. This work presents results of carbon dioxide emissions for two solutions of usual green roofing in southern Brazil. The method considers production of main inputs, road transport from point of sale to the site of construction, workmanship transport. The two green roofs are compared with ceramic and asbestos-cement tiles solution. The data were obtained by surveys, interviews with owners and scientific literature. The building materials, distances of transport were quantified. The results demonstrate that the carbon dioxide emissions are larger than the emissions of the conventional roofing and the main contribution is due to the road transport of components and materials from the point of sale to the site of construction. However, we must consider that the green roofing has a high potential for the carbon sequestration, promotes thermal resistance, humidify and filter the air, reduce the urban surface temperatures.

INTRODUCTION

Civil construction is responsible for 40% of energy demand and 38% of air emissions that contribute for global warming. However there is 30% to 50% of potential for reduction of energy consumption and 35% for reduction of air emissions [1]. In Brazil the civil construction has substantial participation on greenhouse gases. Excluding the carbon dioxide (CO_2) emitted by burnoffs, the building construction represents a quarter of significant air emissions, either by chemical reactions of industrial processes of materials or by the energy sources involved in these industrial processes [2]. Further, the materials transportation, mainly by roads with fossil fuel, contributes significantly for CO_2 emissions [3]. Table 1 illustrates the CO_2 emissions coefficient (Kg CO_2 eq) for the mainly fuels used in Brazil [2].

Table 1. CO_2 emissions due to some fuel sources

fuel source	emissões de CO2 (kg CO_2/GJ)
diesel oil	79,8
natural gas	50,6
petroleum coke	72,6
other sources derived of petroleum	0,0
electrical energy	18,1
fuel wood	81,6

Table 2 ilustrates the embodied energy in some construction materials expressed in percentage according to [2]. The use of energy in industrial processes also significantly contributes for CO_2

Author A is a professor in the Department of Architecture and Urbanism, Santa Maria University, Santa Maria, Brazil. Author B is a professor in Brazilian Luterane University, Santa Maria, Brazil.

emissions; therefore the consideration of production emissions is important in the life cycle of construction materials.

Table 2. Percentage of embodied energy due to source for some materials construction

polymer	10	30		34	26	

The choice of the best environmentaly sound building technologies promotes the envinronmental impacts reduction, such as energy consumption and toxical gases emissions [4]. Technologies must be in accordance with local and regional traditional technology and disponibility of natural resources and industrialized local materials. Therefore the study of local solutions is important to achieve the building environmental performance.

In this study green roofs are understood as vegetal layer intentionally incorporate on top of buildings. They have been pointed as alternatives more sustainable if compared with conventional roofs, such as tile and asbestos-cement roofs. There are many vantages associated to green roofing, such as natural top ground, life cycle extended, better thermal performance and consequently building occupants comfort more acceptable, reduction of urban heat-island effect, carbon sequestration, among others [5]; [6].

A negative factor associated to green roofs regards to the water comsuption. This aspect is not studied in this research, but some authors pointed that there are benefits to manage stormwater in order to restore the capacity of water retation lost by excessive paving of soil in cities [7]. It is possible to reduce about 60% of runoff for rain water captation. Further, the use os plant species that require little irrigation can be reduce the water comsuption, one of negative factors associated to green roofing [7].

In Brazil some studies about green roofing has been already enhanced. Through computational simulation [8] and prototypes submitted to measurement [9] the potential of green roofs for water catchment and retention was verified. Also was verified the viability of green roofs for low-cost housing [10]. A research concerning to occupants' satisfaction indicated that the need for constant maintenance was one of the problems more mentioned [11]. However there are a few studies about the environmental impacts of green roofs mainly referring to CO_2 emissions.

This study aims to contribute to this issue through the quantification of carbon dioxide emissions of four roofs commonly built in Brazil, two green roofs built in two different regions, provincial medium town and industrial city, and two conventional ceramic and asbestos-cement roofing in order to compare their environmental performance due to carbon dioxide emissions. Additionaly the carbon sequestration potential was quantified in order to verify this important contribution of green roofs for sound environments.

METHOD

Selected green roofs

The green roofs are approximately 200km away each other (with different proximities of industries that produce the building materials involved), they are selected in accordance with the occupants permission to access the necessary data for the life cycle inventory, the construction system involves little labour and artisanal method. The ceramic tiles and asbestos-cement roof do not have the same thermal insulation, since the owners have chosen the green roofs for aesthetic and environmental sustainability, without refering their thermal performance. The Figure 1 ilustrates the green roofs studied.

Figure 1 (a) Layers of green roof located in a big city, (b) in a mendium town in country.

Inventory

The data for the inventory were obtained from interviews with the owners of analysed houses, invoices, private diaries and reports elaborated by owners, regular direct observations, *in situ* measurements during building production process. Layers constituting the roofs, quantitative of materials, products' points of sale, places of production of listed materials, distances of production, sale and jobsite area, materials modal transportation were collected. The demand of labour and the distances between jobsite, workers housing, means of transport also were measured from interviews and data registered by owners. The distances were obtained from virtual maps.

Quantification of carbon dioxide emissions

Contribution of different energy inputs was defined for constituting layers and materials. For each material, the total embodied energy CE was computed, the percentage of each significant source present in material production was also computed, obtained from [2], and is represented by P%. The individual contribution of each source was obtained by the product of total embodied energy and the individual carbon dioxide source contribution named $coef_{CO2source}$ obtained from [2]. The somatory of individual contributions is the total carbon dioxide emissions E_{CO2} represented by Equation 1.

$$E_{CO2} = \Sigma[CE\ (MJ) \times P_{\%}/100 \times coef_{CO2source}] \quad (1)$$

where

E_{CO2} is the carbon dioxide emission, kg CO_2;
CE is the contribution of different energy inputs, MJ;
$P_{\%}$ is the percentage of a kind energy in production process, %;
$coef_{CO2source}$ is an index representative of CO_2 emission of energy source, kg CO_2/MJ.

Since it was not possible to determine the characteristics of vehicle used as mean of transport and the kind of fuel, the indices established by [3], which studied carbon dioxide emissions for Brazilian road transport, were considered as reference. The mentioned author considers that it is possible to determine the CO_2 emissions with an admissible error considering the distances and a medium factor according to type of transport. The carbon dioxide emission index for transportation from place of production to place of sale, with heavy road transport, was considered equal to 0.895 kg CO_2 / km [3] since that is the conventional transport for construction materials in Brazil; for transportation from place of sale to jobplace (conventionaly transport of light load in Brazil) was considered equal to 0.106 kg CO_2 / km [3] by the same previus reason. The carbon dioxide emission related to mean transport for each material was calculated using the Equation 2.

$$\text{total emission material transport} = \text{emission}_{CO2/km} \text{ x } \text{distance}_{prod \rightarrow sale} + \text{emission}_{CO2/km} \text{ x } \text{distance}_{sale \rightarrow jobplace} \quad (2)$$

The Equation 3 was used for calculating the emissions due to transport of workers. The dioxide carbon emission index per day for mean transport was considered equal to 0.106 kg CO_2 / km.day, embodied energy was considered equal to 0.0015 MJ / kg and the weight for worker is equal to 70kg.

$$WT_{CO2} = EE \text{ x total weight x } distance_{home \rightarrow workjob} \text{ x worked days x } emission_{CO2/km}$$

where

WT_{CO2} is the total emission worker transport, kg CO_2;

EE is the embodied energy, MJ/kg;

$distance_{home \rightarrow workjob}$ is the distance between the home and the workplace, km;

total weight is the transported weight, kg;

$emission_{CO2/km}$ is the carbon dioxide emissions per kilometer due to worker transport, CO_2/km.

Carbon sequestration

Addionally the potential for carbon sequestration was calculated in order to verify one of main environmental contribution of green roofing. The larger carbon sequestration for grass with 20cm of substrate for plant growth is considered equal to 0.945 $kgCO_2$ / (m^2.year) [12]. The mentioned value was multiplied for the area of each green roof. Total calculated carbon dioxide emission for each green roof was divided for the index in order to obtain the number of years necessary to sequester.

RESULTS

Table 3 presents the carbon dioxide emissions due to materials production and Table 4 emissions due to transport for the green roof located at the big city (green roof 1) with 28,41m^2 of surface.

Table 3. Carbon dioxide emissions due to material production for green roof 1.

The major emissions are due to asphalt fabric that is the component with industrial process more complex among the green roof layers; involves large energy inputs; with centralized production. Therefore replacement of that layer is a possibility in reducing de CO_2 impact.

Table 5 presents the carbon dioxide emissions due to worker transport for the green roof 1.

Table 5. Carbon dioxide emissions due to workers transport for green roof 1.

	weight of transported workers (kg)	distance$_{home \rightarrow workjob}$ (km)	worked days	transport mode	embodied energy (MJ)	CO_2 emission (kg CO_2)

worker	140 Kg	15	1	car	10.815	1.59
total					10.815	1.59

For the ceramic tile roof built in the big city, the main contributions are due to production of ceramic tiles (481.17 $kgCO_2$) and due to transport of truss materials (peroba wood) (1,100.22 $kgCO_2$). In this case, the use of wood which production is strongly centralized (with environmental license) contributes significantly to carbon dioxide emissions.

For the asbestos-cement roof built in the same place, the main contributions are due to transport of truss materials (1,100,22 $kgCO_2$), since there are local industries that produce fibercement tiles.

Table 6 presents the carbon dioxide emissions due to materials production and Table 7 emissions due to transport for the green roof located at the medium town (green roof 2).

total per m^2							**42.66 kgCO_2/m^2**

Table 8 presents the carbon dioxide emissions due to worker transport for the green roof 2.

Table 8. Carbon dioxide emissions due to workers transport for green roof 2.

	weight of transported workers (kg)	distance$_{home \rightarrow workjob}$ (km)	worked days	transport mode	embodied energy (MJ)	CO_2 emission (kg CO_2)
owner	280 Kg	-	3	-	-	-
worker	280 Kg	11.4	1	car	8.2194	1.21
total					8.2194	1.21

In the same way of the precedent green roof 1, the major emissions are due to more industrialised component that is the waterproofing layers. The use of two waterproofing layers is critical for the poor performance of this roof.

For the ceramic tile roof built in the medium town, such as for the big city, the main contributions are due to production of ceramic tiles (958.12 kgCO_2) and due to transport of truss materials (peroba wood) (1,178.00 kgCO_2). In this case, the use of wood which production is strongly centralized (with environmental license) contributes significantly to carbon dioxide emissions.

For the asbestos-cement roof built in the medium town, the main contributions are due to transport of truss materials (1,178.00 kgCO_2). The incorporated cement in the asbestos tiles is responsible for 486.40 kgCO_2 emissions.

The Figure 3 illustrates the total emissions per square metres due to the six roofs, green, asbestos-cement, ceramic. In relation to transport materials both green roofs present lower performance than ceramic and cement-asbestos conventional roofs. This result is due to presence of layers based on fossil source (asphalt fabric and water proofing layer) with centralized production. In relation to carbon dioxide emissions produced from manufacturing the green roof 1 is more unsustainable due to asphalt fabric, presenting best performance only compared with the ceramic tile roof. Production of ceramic tiles envolves large energy for burning and transport due to their weight since this type of roofing has large embodied energy and carbon dioxide emissions. The cement-asbestos tile results in the best performance for the case study in the big town because there are local industries for this material. The three roofs type 2 located in the town far of production regions present the lower contribution in CO_2 emissions what is an unexpected result since is further away from production centers. This result demonstrates the importance of contextualized solutions. Green roof 2 is technically simpler; a despite of using a water proofing layer with large embodied energy and carbon dioxide emissions, it requires less amount of material to fullfil the same function comparatively with roof 1. The emissions associated to worker transport are insignificant compared to production and transport materials due to artisanal and auto-construction process, reforcing the use local workforce and techniques.

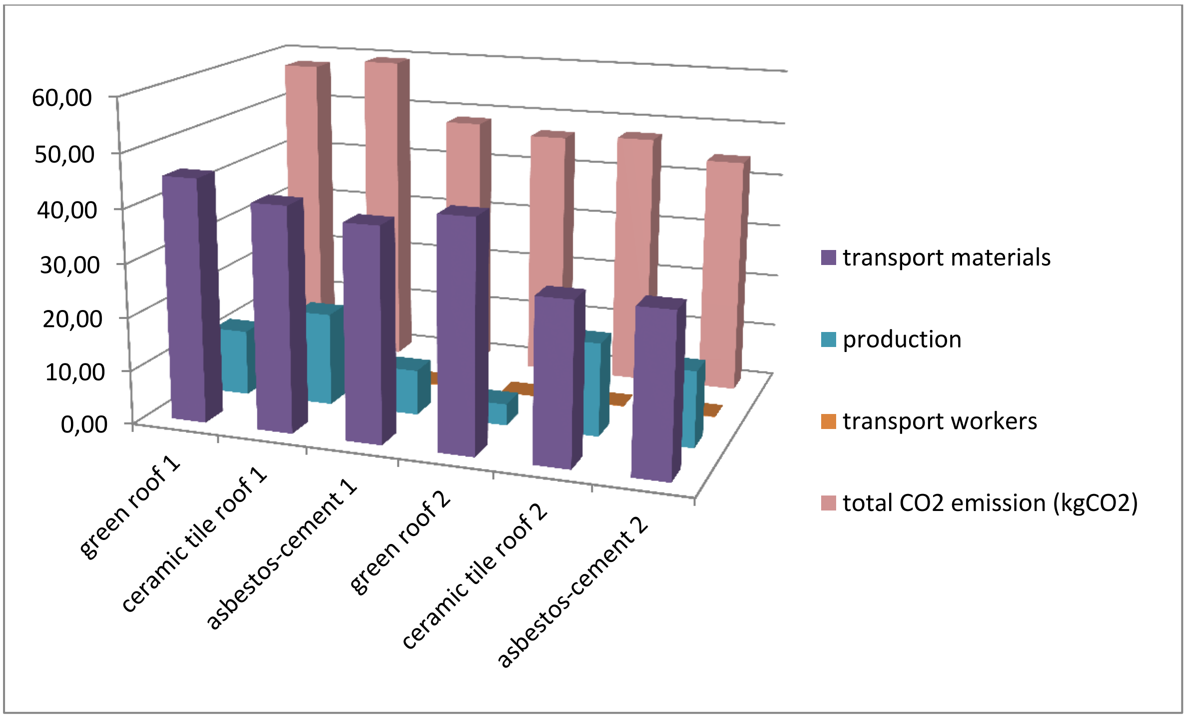

Figure 3 Partial and total CO_2 emissions due to different analised roofs per square metres.

Considering the three contributions analyzed, transport materials, production, and transport workers, there is little difference between the three roofing in the medium town, which is does not do in the case of roofing in the big city where the cement-asbestos is the best solution.

It takes the green roof 1 about 61 years for carbon sequestration due to production and transport of materials and workers. For the green roof 2, it takes about 50 years. These results demonstrate that the main benefit of green roof is obtained in very long time-lag, which counters to principal benefit associated to green roofs.

CONCLUSION

Through results the green roofs present large CO_2 emissions due to use of layers based on polymers or fossil source materials which production involves large embodied energy and several emissions that contributes for greenhouse. It pointed to need to replace the waterproofing layer based on fossil source for another one more environmentally sound. For the case studies illustred material transport is responsible for the largest emissions for six simulated roofing. Results reinforce the importance of choosing local and regional technologies, materials, and workforce. The cement-asbestos roof has the best performance relative to carbon dioxide emissions; it flies in the face of common sense in considering the green roof necessarily an environmently good solution. Furthermore, one of benefits associated to green roofs, the carbon sequestration, is reached in a long time opposing to general idea of sustainability.

Green roofing has been considered as a building system with low environmental impacts. The analyses of carbon dioxide emissions demonstrated that it has lower performance than the conventional solutions even if were regarded the potential for carbon sequestration. However the easiest solution adopted for the conventional roofing, without a thermal insulation, collaborate for the results achieved.

Design and Testing out of an Insulating Floor Element, Composed of Recycled Rubber and Inert Demolition Waste

Vincent Buhagiar, PhD
University of Malta
vincent.buhagiar@um.edu.mt

Simon P. Borg, PhD
University of Malta

ABSTRACT

Even if initially dominated by cost concerns, energy-awareness is today maturing towards a vision aimed at curtailing energy consumption and reducing carbon emissions.

In consideration of today's large amount of tyres being used and disposed of, the purpose of this research was to investigate options for utilising recycled rubber as a building material (in combination with inert demolition waste), namely as insulation in flooring elements such as tiles, such a mix could replace new underlay insulating materials typically having a higher embodied energy content. This paper evaluates the potential of recycling used tyres in specially fabricated floor tiles for different design mixes and evaluates the success/failure of such a building element as a floor finish.

The study also looks into the best combination of materials to form a durable, non-abrasive robust tile, yet also acting as a thermal and moisture barrier. An added value of the proposed tile is its acoustic property, where the shredded rubber makes it also resilient to impact and airborne noise. Its light colour also proves ideal for solar-exposed flat roofs, where, it is also aesthetically pleasing for the outdoor evening lifestyle in a Mediterranean climate.

INTRODUCTION

Since prehistoric times human beings have always searched for ways to protect themselves against the elements, first through the use of naturally formed shelters such as caves and then evolving into proper building-shaped constructed dwellings made using either naturally occurring materials extracted from the earth or man-made artificial materials. Through time, with the introduction of energy-intensive heating and cooling systems, energy consumption in buildings has however increased. This is requiring that new methods for making a building more energy efficient be researched and studied.

In this context, particular attention is being given by researchers not only to provide building elements with good thermal properties, *e.g.* low thermal transmittance which prevents high rates of heat transfer, but also to the fact that these building elements are made from materials, possibly recycled ones, having a low embodied energy. One such material is recycled rubber from end-of-life automotive tyres. Due to the heavy metals they contain, rubber tyres are a very problematic waste source. If disposed incorrectly, the chemicals they contain can contaminate ground water sources. Also, other problems arise from their size which makes it very hard and expensive to dispose of. To minimise volume burning them is an option, however today this is practically forbidden due to the toxic gases discharged into the atmosphere (typically carbon monoxide and sulphuric acid). This problem is aggravated by the fact that each year millions of tyres are consumed to meet vehicle road standards. If properly recycled, this rubber however, can be made

Vincent Buhagiar and **Simon P. Borg** are respectively Professor and Lecturer in the Department of Environmental Design at the University of Malta, Malta. **James Bonnici** is a practicing architect and civil engineer.

to good use given its inherent thermal properties, which give it a low thermal conductivity value, ideal for use in building components.

Recycled Rubber Embodied energy

Material selection and technologies used in building construction should aim to achieve the building occupants expected performance as well as aiming to minimise the environmental impact as much as possible, not only in the context of reducing energy consumption during its lifetime, but throughout its lifecycle, starting off from its production to the time when it is disposed off. In this context, Table 1 shows the specific total embodied energy per kilogram of tyre material produced. The rubber used for the production of tyres has a very high embodied energy and therefore finding alternative uses, especially at the end of lifecycle, can be beneficial to the environment.

Table 1. Embodied energy and greenhouse emissions of manufactured rubber tyre

Material	Energy (MJ/kg)	Greenhouse ($kgCO_2/kg$)
Natural Rubber	8	0.4

Recycled Rubber as a Building Material

The use of recycled rubber as a building material is not something completely new and various attempts have been made to make use of this resource to improve the properties of a building element.

Recycled Rubber as Asphalt A study made by the University of Toronto (Way *et al.*, 2011) was carried out to investigate the use of recycled shredded rubber in normal road asphalt. Metro Toronto Roads and Traffic Department resurfaced five main roads using this new mix and no serious difficulties were encountered. In actual fact it was noticed that the new roads offered a greater durability with a lower requirement for maintenance and a subsequent higher expected lifetime, and a better overall performance with respect to road safety due to a higher frictional response (Piggott and Woodhams, 1979).

Recycled Rubber Floorings Rubber floorings is another use for recycled tyre rubber. Floor tiles made using recycled rubber are relatively soft, despite them being used for commercial grade durability standards. Such properties in fact render these floor tiles a particular viable option for flooring systems in retail outlets were people walk for long periods of time and in playrooms and public spaces where the impact absorption properties of such floor tiles, adds an element of safety for children playing in these spaces. Gyms also often use this product as it absorbs sound made from falling weights and the continuous uses of cardio machines. Finally, rubber floorings can also be used in bedrooms and other living spaces as an alternative to fitted carpets (Ecosurface, 2014).

THE NEW BUILDING ELEMENT PROPOSED

The aim of this research was to create a new type of roof tile using recycled material generated from vehicle worn out tyres and inert demolition waste, originally both intended to be disposed of, and both requiring large volumes at waste disposal facilities. In warm climates where flat roofs are the norm, solar ingress through the roof is a main source for heat gains inside buildings, since these receive the beating of a persistent scorching sun in summer, unlike walls that could be typically shaded. Therefore the provision of thermally isolating materials as part of roofing elements is of primary importance for reducing such solar gains. This is particularly important in a hot Mediterranean Island such as Malta.

Element Composition

Aerated concrete was used as the base material with shredded rubber from recycled tyres added in varying percentages, namely 20%, 30% and 60% to constitute different tile mixes. Aerated concrete, classified as a lightweight concrete, is made up by mixing concrete with an aerating agent which causes the creation of a number of air voids inside the mix. The main advantage of this type of concrete is its lightweight composition and the high degree of thermal resistance which reduces the need of adding extra insulation to improve the thermal performance of a building element. The tile, having dimensions of 300mm by 300mm, was finished with a thin layer of a glass fibre coating. Polyester resin fibreglass is an impermeable material, thus adding this element would benefit the tile from making it water proof. Another added benefit of the fibreglass finish is in terms of its strength. Since the fiberglass contains and supports the aerated concrete which is considered to be weak, due to the presence of a large amount of air cavities, the tile performs better with regards to flexural strength, as the fibreglass encloses the tile creating a more compact system of materials.

SPECIMEN BUILDING AND TESTING

This section focuses on the procedure adopted in building and testing the proposed tile using a parametric methodology, whereby a number of design mixes were produced to analyse the effect of a selection of parameters on the thermal performance of the tile.

Test Specimen Preparation and Construction

Preparing the specimen involved using a mixture of recycled rubber granules, sand, cement and water to create the base constituents for the recycled rubber-infused aerated concrete mix. For the aeration process aluminium powder and sodium hydroxide were then added. In order to allow enough time for the aeration process a popular retarder was added to the mixture, to slow down the cement hardening reaction process. Once the mixture was prepared and the aeration process started, the tiles were left for two days to set within a specially designed mould. Once ready the moulds were dismantled revealing the tile. A fibreglass coating of around 4mm thickness was applied at the end of the process to give the tile a smooth clean dust-free, cream-white finish. Figure 1 shows a schematic of the different layers of the tile (inverted).

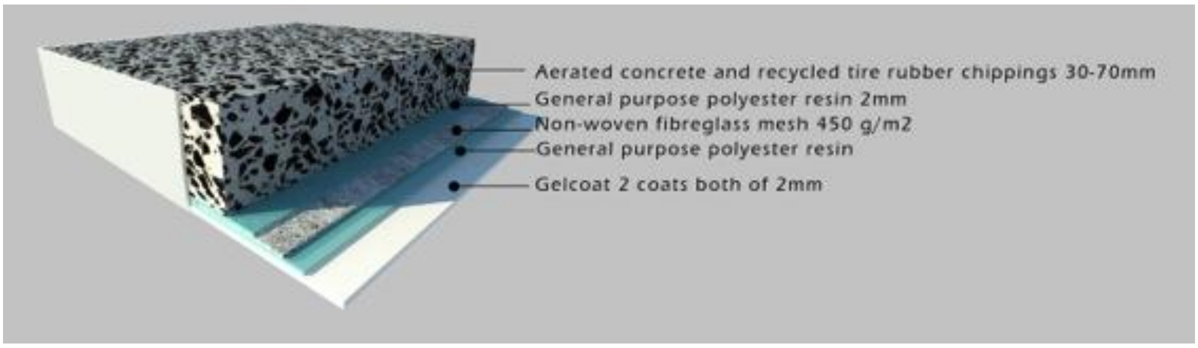

Figure 1 Schematic of propsed tile (inverted as cast)

Testing the different design variables

As part of the testing procedure various design mixes were produced with the intent of testing the variability in thermal performance of the different proposed design variables. The main variable parameters tested were the rubber percentage and the tile thickness, with each variable being tested for three possible permutations for a total of nine combinations. The rubber percentage was varied between 20%, 30% and 60% of the design mix. For each rubber percentage three tile thicknesses were moulded, namely 45mm, 70mm and 90mm thickness. Table 2 summaries the different combinations created.

Table 2. Tile Mix Material Values

Rubber Percentage (%)	*Thickness (mm)*	*Sand (g)*	*Cement (g)*	*Water (g)*	*Rubber (g)*	*Aluminium (g)*	*Sodium Hydroxide (g)*	*Retarder (g)*
20	**45**	2	900	54	460	22	22	15

60	**90**	3	1300	78	2016	34	25	18

Testing inside the Hot Box

The testing of the tiles was carried out using an established insulated Hot Box previously used and tested in the Environmental Lab. This was originally built according to BS EN 8990:1996 (BSI, 1996). The Hot Box was constructed using concrete block work, filled with C30 concrete with all joints sealed to reduce any heat losses. In order to measure the overall heat transmittance (U-Value) of horizontal building elements the Hot Box is divided into two chambers, a controlled artificially heated '*hot*' chamber and an underlying '*cold*' chamber, separated by a typical Maltese roof construction, as shown in Figure 2.

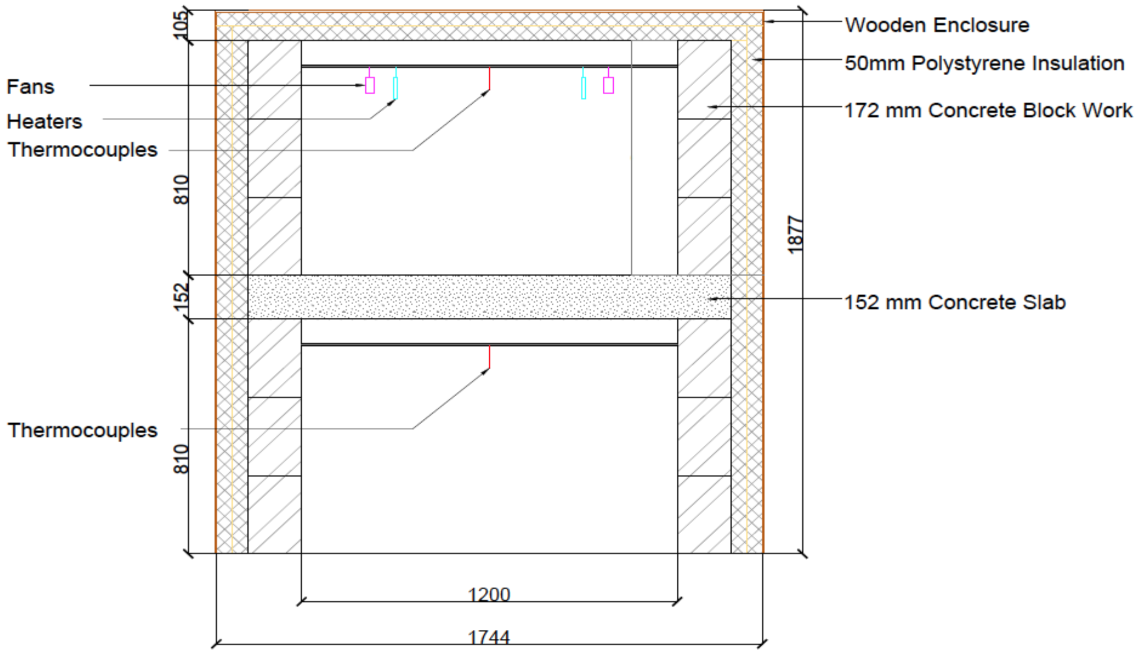

Figure 2 Sectional Elevation of the Hot Box

The top-most warm side of the Hot Box was set up with four heaters, grid-lined, each having a power of 700 Watts suspended from a steel square mesh connected to the top part of the Hot Box, as the grid-matrix. Four fans were also connected to the mesh to create a continuous air flow thus creating an evenly distributed temperature profile throughout the interior warm side of the Hot Box.

Each combination of designed tile mix was tested inside the Hot Box, by laying the tiles on top of the '*hot*' chamber floor, as shown in Figure 3, and measuring the temperature difference between the two chambers once steady-state is obtained.

Figure 3 Hot Box set-up comprising the composite tile, 50mm globigerina sand, damproof membrane

In order to measure the temperature difference across the two chambers a total of 18 thermocouples were used. In the top '*hot*' chamber, eight thermocouples were fixed on top of the tile surface while a ninth thermocouple was suspended in mid-air to measure the air temperature inside the chamber. The setup was mirrored in the '*cold*' chamber. Each thermocouple was connected to a central data logger which recorded the readings from each individual thermocouple. The ambient room temperature was also monitored.

Surface temperature readings were recorded at 15-minute intervals until a until the hot box reached steady state i.e. the temperature gradient between both chambers remains at a constant rate. Once the hot box reached this thermal status, the steady state the temperature difference was calculated.

The composite tiles laid and tested into nine different categories. Each category had sixteen similar tiles, (4x4no.x 300mm each tile), fitted in the calibrated hot box. Each category has a variation in either thickness or rubber content as indicated in subsequent output results, Figure 4.

RESULTS

Figure 4 shows how the overall heat transmittance, the building's element U-value, as it varies with respect to changes in the recycled rubber content and the tile thickness. It can be observed that the major governing factor in decreasing the U-value of the proposed tile is by varying the thickness. As the thickness increases the lower is the U-value obtained. Increasing the rubber content also decreased the U-value but to a lower extent.

The main advantage of this design mix is that the rubber can be used to increase the volume of the tile, replacing quarried limestone sand, thus saving embodied energy, with the added benefit of making the tile more thermally resistive. With an increase in rubber content from 20% to 30%, the U-value dropped by -0.05, -0.06 and -0.13W/m^{2}K for the 45, 70, 90mm tiles respectively. With an increase from 30% to 60% further drops of -0.07, -0.02 and -0.03 W/m^{2}K were noted for the 45, 70, 90mm tiles respectively, as can be seen in the summarised values in Table 3.

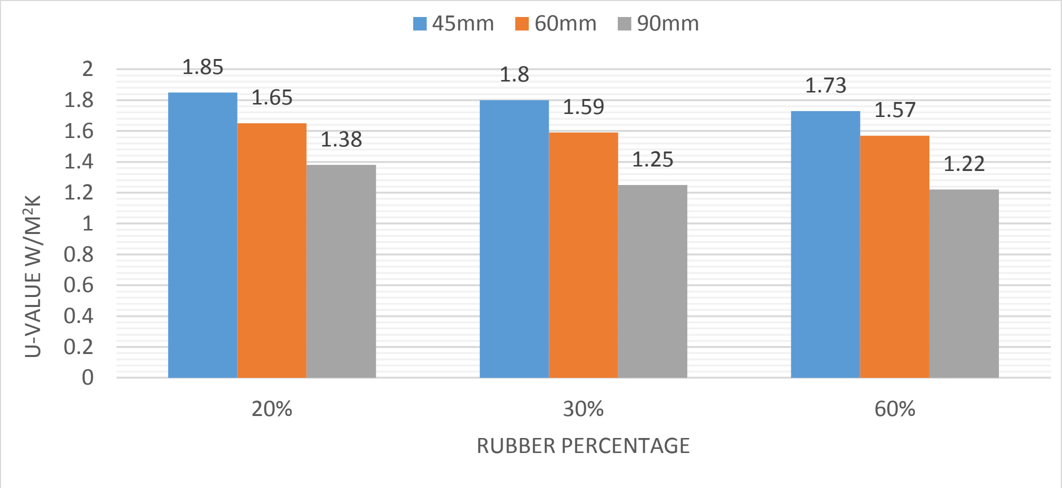

Figure 4 U-value vs. Percentage rubber content for the 45mm, 60mm, and 90mm thick tiles

Table 3. Percentage Rubber content *vs.* Tile Thickness & respective U-values

Rubber Ratio	**20%**	**30%**	**60%**
45mm tile	1.85 W/m^2K	1.80 W/m^2K	1.73 W/m^2K
Change in U-value		-0.05	-0.07
70mm tile	1.65	1.59	1.57
Change in U-value		-0.06	-0.03
90mm tile	1.38	1.25	1.22
Change in U-value		-0.13	-0.03

This further indicates that with a change of mass the drop in U-value is more pronounced than with the increase in rubber percentage. Moreover, an increae in rubber content with an increase in thickness sees het U-value drop by -0.13 W/m^2K. Although no further increases in %rubber or thickness was made, by extrapolation results indicate that the U-value would decrease further. An increase in mass would evidently increase its embodied energy and its cost given the greater mass per unit volume ratio. Such results can only be obtained through further studies or prediction modelling.

CONCLUSION

Currently Maltese building construction norms are slow to adhere to building regulations, technical guidance document part F, even though it has become national law. Most of the traditional Maltese roof constructions never had insulation since their thermal mass, composed of composite limestone strata in different forms, did the job reasonably well. Admittedly comfort standards were also less sttingent than today, with older folk and farmers leading an outdoor life more than ever.

In warm climates where solar gains through flat roofs is a predominant heat source, roof insulation is a necessary requirement to reduce heat absorption into the building. This should reduce cooling loads particularly given the increase use of fossil-energy based HVAC systems. Based on this premise the use of the novel recycled rubber tiles reduces the overall U-value of the roofing element. Moreover, the benefit of using a material such as recycled rubber and inert waste, both with a high embodied energy content, means that there is also a lower demand for quarried limestone sand as a raw land-based resource. This is certainly one added value of using such tiles as insulation or as a complement to it to say the least. Waste rubber tyres are also shredded for re-use rather than dumped, taking precious voluminous space. So this is already a win-win scenario from a waste management perspective.

The objective of this paper was to create a new, thermally insulating roof tile made from recycled rubber as a replacement or complement to any insulating material. It can be laid on roofs and open terraces over habitable spaces, thus increasing the energy performance rating of buildings, particularly dwellings.

SCOPE FOR FURTHER RESEARCH

Parametric tests were performed to test the best percentage ratios in the mix design composition of the tile. From results obtained the newly designed tiles generally increase the thermal efficiency of the building. By increasing the thickness and also the rubber content of the tiles, the average range of U-values obtained scaled from 1.85 to 1.22 W/m^2K. This is still higher then the minimum requirement for thermal transmittance allowed ofr roof structures in Malta, that is, 0.59 W/m^2K (Technical Guidance Document, Part F, of the Building Regulations of Malta).

Although results are already promising, unless a very thick tile is used one would not achieve sufficient reductions in thermal transmittance therefore testing the tile further is recommended with the addition of complementary insulation. More work also needs to be done on varying the basic parameters, namely the design mix of rubber to sand ratio, beyond 60%, as well as the thickness of a tile over 90mm. Another area to be delved into is the aerated concrete itself, where a greaeter porosity brings with it a greater insulating property; hence modifications to the design mix can be tested. Different types of rubber as well as its granulated size (larger granules to pulverised) is also worth investigating. Moreover, the tile's abrasive resistance, inherent durability, and its resistance to moisture are among a few other areas within the scope for further research.

Design Interventions to Encourage Pro-Environmental Behavior:

An Action Research Study on Waste Diversion in a University Residence Hall

Jessica Moreland,
The Ohio State University
Moreland.56@osu.edu

Susan Melsop
The Ohio State University

ABSTRACT

This action research study examined the effectiveness of four design interventions, which aimed to encourage students to recycle and compost in a university residence hall. The study took place at a major university in the United States, where recent efforts have been made toward a "zero waste campus". Zero waste is defined as diverting more than 90% of waste from landfill. In 2011, The Ohio State University successfully implemented a zero waste program in their football stadium and now plans to convert the entire campus to zero waste by 2030. Implementing zero waste across campus, however, proves challenging—especially in residence halls as they require a more complex logistical infrastructure and rely heavily on students' knowledge, attitudes, and practices. Using approaches from social practice design and anthropology, this study examined practical and scalable interventions with the ultimate goal of assisting in the future transition to zero waste. On a larger scale, these results may provide new knowledge in comprehensive waste management and methods of social practice design that encourage pro-environmental behavior change.

INTRODUCTION

Comprehensive solid waste management is a major challenge to sustainability. The practice of recycling diverts materials from landfill, reduces pollution, saves raw materials and conserves energy. Still, inconveniences of recycling and engrained social practices lead to minimal participation in recycling and composting programs—only 34 percent of America's waste was recovered in 2012 [1]. Academic institutions have begun to realize their environmental obligations to promote sustainable behavior among students, faculty, and staff [2, 3]. Zero waste is an emerging goal of sustainable materials management, where 90% or more of solid waste is diverted from landfills. To assist in recent efforts towards a "zero waste campus," this action research study explored the decision-making process associated with recycling on campus and examined the effectiveness of four design interventions encouraging students to recycle and compost in a university residence hall.

CONTEXT

The study took place at a major university in the United States, where recent efforts have been made toward a "zero waste campus". Achieving zero waste requires a shift from a *waste* management mindset to a *resource* management mindset where technical and biological nutrients are treated separately and have productive destinations [4, 5]. Zero waste plans are comprehensive and require diversion and aversion efforts including: material capturing, waste stream modification, and waste

Jessica Moreland is a graduate student in the Department of Design, The Ohio State University, Columbus, Ohio. Susan Melsop is a professor in the Department of Design, The Ohio State University, Columbus, Ohio.

prevention. While waste stream modification and waste prevention are ongoing, material capturing can be improved through proper sorting practices.

In recent years, The Ohio State University (Ohio State) has made great strides in zero waste. In 2011, the Office of Sustainability started a zero waste program in their football stadium—one of the largest in the country. The stadium frequently holds over 105,000 fans and on average accumulates 8-10 tons of waste per game [6]. By 2013, the program was successful in diverting over 98% of waste—an average of 8 tons per game! Control over the material stream, cooperation from fans, and the ability to sort on the back end were critical components to the project's success [7].

After achieving zero waste in the football stadium, Ohio State set an ambitious goal to transition their entire campus to zero waste by 2030. This goal was articulated in 2008, and in 2013—five years later—the campus was still only capturing 31% of their waste (Fig.1)[8]. To determine how much of their waste had the potential to be captured, Ohio State completed a comprehensive waste audit in 2013. The audit found that 89.1% had the potential of being recycled or composted (Fig. 1). In other words, Ohio State has the ability to increase their current diversion rate of 31% to their potential diversion rate of 89% by improving sorting practices. This shift to zero waste not only involves structural changes in how waste is collected and processed, but also behavioral changes for members of the institution [9].

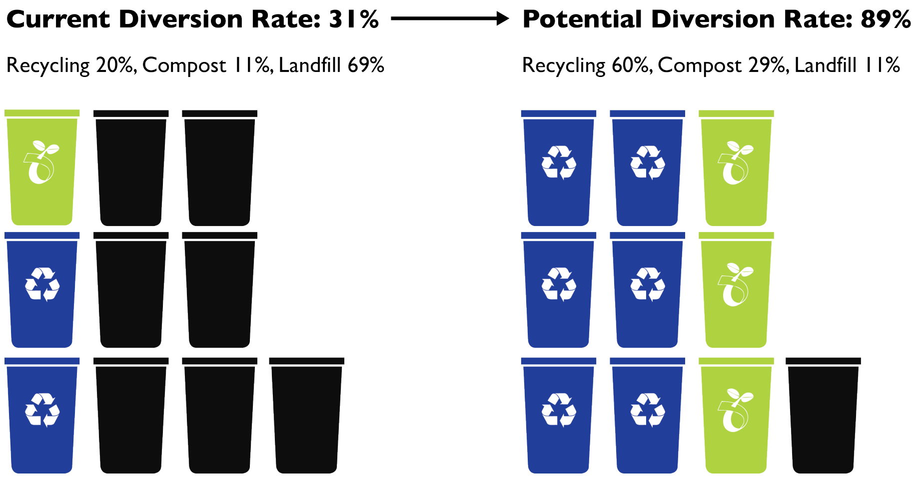

Figure 1: Current Diversion Rate (31%) compared to Potential Diversion Rate (89%), 2013

APPROACH

Interventions that promote recycling are not new, but these strategies typically address recycling as planned behavior that is guided by a rational decision-making process. Many decisions made throughout the day, however, are not rational. In terms of decision-making, people are governed by two systems of thinking: the automatic system guided by intuition, and the reflective system controlled by rational thought [10]. With a limited capacity for rational thought, many decisions turn to the automatic system where the least amount of *thinking* occurs. Months of observations across campus suggest that recycling is often one of these automatic decisions. As a result, the way recycling choices are presented can greatly influence the choice that is made [10]. On campus, throwing waste in the trash currently requires the least amount of thinking, in other words *trash is automatic* and as a result *many people do not recycle*. The intervention strategies in this study targetted the automatic system and the reflective system to determine what factors most influenced students' recycling practices. All interventions targetted the automatic system by sharing a new infrastructure where *recycling and compost became automatic*. Incrementally higher-level interventions targetted the reflective system by introducing education, eco-feedback, and social influence. This study used approaches from social practice design and anthropology and was completed in four iterative phases: ethnography, intervention design, intervention experiment, and analysis.

Ethnography

The research team used a grounded theory approach to observe recycling behavior and ask students why they recycle or not. The goal was to identify students' knowledge, attitudes, and practices in regards to recycling in order to develop a theory of student decision-making. Observations and interviews took place in the participating residence hall and the main dining facility.

Students admit that they typically choose the easiest way to dispose of their waste. Many students even throw things "away" subconsciously. They often choose the nearest bin out of convenience and rarely go out of their way to recycle. Some students will recycle more obvious items such as bottles and cans, but many students throw everything in the trash because they do not have to think about *what can be* recycled. Some students fail to recycle because they feel their individual behavior does not make a significant environmental impact. And while there is some social pressure to keep an environment clean by not littering, students feel little social pressure to recycle. These findings became the theoretical framework that guided the strategy and development of the design interventions.

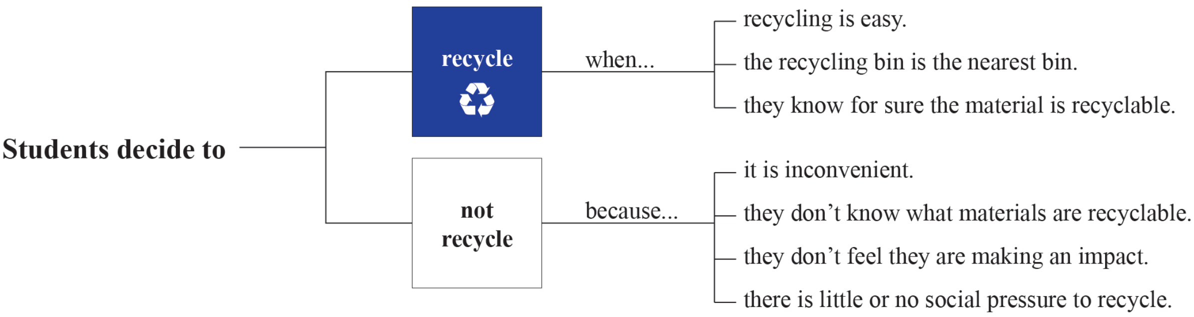

Figure 2: Emerging theory of students' decision-making process in regards to recycling

Intervention Design

Prior to the intervention experiment, the participating residence hall provided students with 2 large trash bins that were picked up by housekeeping daily (one in the bathroom and one in the common living room). If students wanted to recycle, they were given a small recycle bin and it became the students' responsibility to collect recycling and empty the bin. Students had to find a location for their bin, decipher what could be recycled, collect recycling, and empty on a regular basis—a much more laborious activity (mentally and physically) than throwing waste in the trash.

The emerging theory of decision-making suggested that students will recycle if it is easy, accessible, and they know what is recyclable—in other words they will recycle if it *becomes automatic*. On the other hand, students may not recycle if they have a limited understanding of their environmental impact, or a lack of social pressure. So, are clear instructions and an easy/accessible system enough to achieve zero waste in residence halls? Or do education and/or social pressure lead to higher diversion rates? The four interventions were designed to answer these questions. Interventions were incremental. That is, each intervention had increased involvement with students and thus, built in complexity. Design interventions 1–4 had the same baseline zero waste infrastructure and instructional signage. While, interventions 2, 3, and 4 built in complexity with increasing levels of environmental messaging and social pressure. The hypothesis was that higher-level interventions would have more influence on students' compliance with the zero waste program.

The interventions were implemented as follows:

Intervention 1: New Waste Collection Infrastructure. The previous system made trash disposal very easy and recycling more difficult. In this new system (Fig. 3), the trash bin in the common room was converted to *recycling* and the trash bin in the bathroom was converted to *compost*. A small *landfill* bin was added to the bathroom for personal hygiene waste. The housekeeping staff emptied all three bins daily. Both the compost and recycle bins were accompanied by a simple instructional poster.

Figure 3: Recycling, compost, and landfill bins with instructional signage

Intervention 2: Education. To further eliminate confusion about recycling and composting, intervention 2 utilized educational posters to provide general information about questionable materials (Fig. 4). These posters showed the environmental impact of recyclable and compostable materials and encouraged students to reuse and reduce. Posters were placed on the bathroom stall doors.

Figure 4: Informational posters

Intervention 3: Eco-feedback. To help students reflect on the impact their everyday practices had on their community and the environment, intervention 3 utilized social media to educate students on their behavioral impact, and suggest ways to make an even greater impact. Digital white boards were also placed beside the resident advisor's (RA) room to allow students to ask questions and offer feedback. This gave students an opportunity to get involved in the conversation.

Intervention 4: Social Influence. To create a sense of peer-pressure, students volunteered to be *Zero Waste Agents* who made sure their suitemates complied with the new zero waste system. Casually but consistently the behavior and attitude of the Zero Waste Agents set examples for pro-environmental behavior.

Intervention Experiment

The participating residence hall consisted of eight floors and approximately 400 students. There were two floors and approximately 100 students per intervention. During the 30-day intervention experiment, a new logistical infrastructure was implemented (Fig. 5) where the housekeeping staff collected one large recycle bin, one large compost bin, and a small landfill bin daily. In addition to the new infrastructure (easy access and clear instructions), three higher-level design interventions were evaluated.

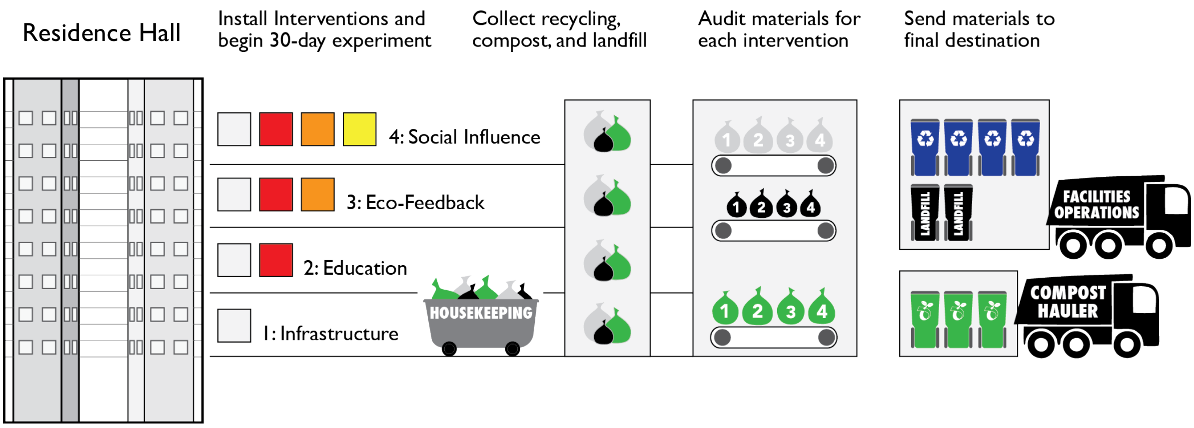

Figure 5: Logistics of waste collection during the 30-day intervention experiment

Analysis

The intervention effectiveness was measured and analyzed in two ways: (1) changes in practices—measured by overall waste diversion and accuracy of sorting, and (2) changes in perceptions—measured by reported knowledge, attitudes, and practices. Professional waste audits and weekly visual assessments were recorded to determine diversion rates and sorting accuracy. Questionnaires were administered before and after the interventions to assess changes in perceptions. 101 students (43 women and 59 men) responded to the pre-experiment survey and 26 students (16 women and 10 men) responded to the post-experiment survey. Data was analyzed for each individual intervention and all interventions as a whole.

FINDINGS

Changes in Practices

During the program, students sent an average of 71% of their waste to be recycled and composted, a significant increase compared to the 31% campus average in 2013. Figure 6 shows the waste distribution before the experiment (campus average), during the experiment (in a single residence hall), and the goal to achieve zero waste in 2030. The results show a significant step towards zero waste residence halls in a very short period of time.

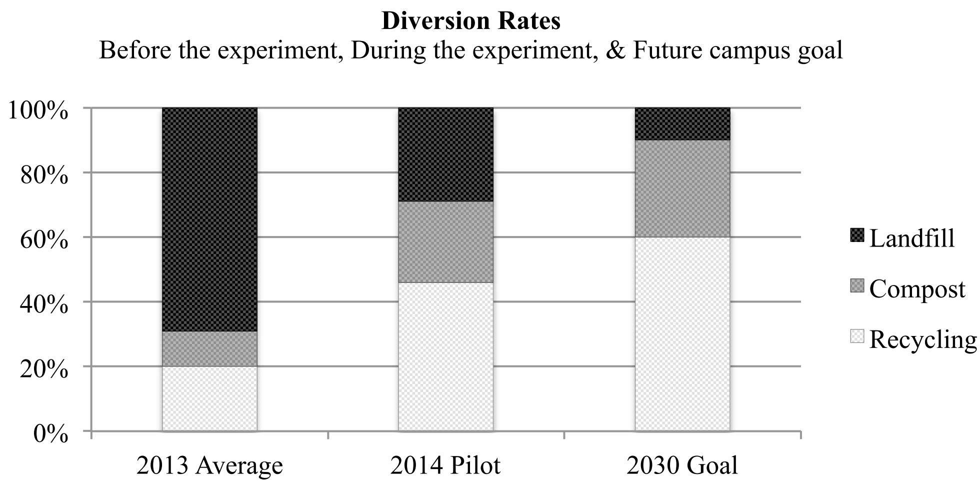

Figure 6: Results of experiment in comparison with campus average and campus goal

Comparatively, the four interventions showed no significant difference in the amount of waste diverted, however, there was a significant difference in the accuracy of sorting (Fig. 7). The baseline intervention achieved 82% overall sorting accuracy. The highest-level intervention—using *Social Influence*—achieved 85% sorting accuracy, but showed no statistical difference from the baseline intervention. The second and third level interventions, however, both achieved 76% sorting accuracy and showed a statistically significant (and surprising) decrease of 6% from the baseline intervention. In addition to differences between interventions, across the board, sorting accuracy of recycling (62% average) was significantly lower than sorting accuracy of compost (92% average).

	1	2	3	4
Recycling	72%	63%	63%	73%
Compost	92%	90%	90%	97%

Figure 7: Results of sorting accuracy for each intervention

Changes in Perceptions

As a whole, students' perceptions about recycling and composting changed significantly after experiencing the design interventions (Fig. 8). In general, students reportedly had a better understanding of how to recycle properly and tried harder to comply. After the experiment, they found recycling more rewarding and felt more strongly that it could positively impact their community and the environment. Students also felt more optimistic that by recycling they could motivate others to recycle. Comparing pre and post surveys, students in intervention groups 1&4 reportedly tried harder during the experiment, while students in intervention groups 2&3 showed no significant change in their effort.

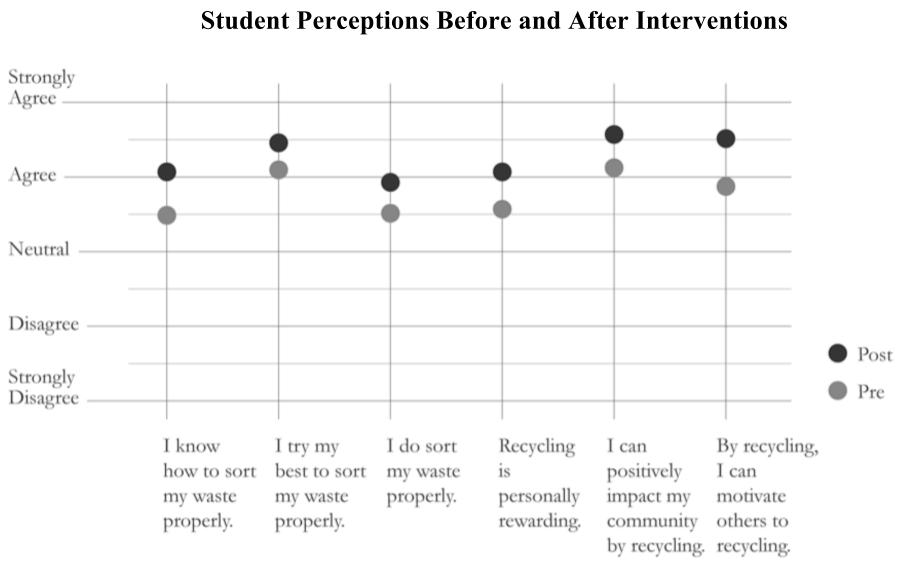

Figure 8: Changes in students' perception before and after the intervention experiment

DISCUSSION

Overall, having large, accessible recycle bins that were picked up daily by housekeeping drastically increased (more than doubled) the amount of recyclables collected—although sorting accuracy could be improved. To increase sorting accuracy, the authors believe it would be beneficial to have the compost bin directly next to the recycle bin in the common room. Students typically ate in the common room, and the main recycling contaminant was food waste. In order to dispose of food waste properly, students had to walk to the compost bin in the bathroom. The primary reason for having compost in the bathroom was to easily dispose of paper towels. However, if paper towels could be eliminated or minimized, the compost bin could be next to the recycle bin, making it easier for students to dispose of their food waste.

When comparing intervention effectiveness, student participation did not increase with each level as hypothesized. However, students in intervention groups 1 and 4 reportedly tried harder and achieved greater success during the experiment. Why is this? What did intervention group 1 and 4 have in common? To find out, we interviewed students at the end of the study and asked why the baseline intervention might have done as well as the highest-level intervention. One of the *Zero Waste Agents* mentioned that the RAs on the floors assigned to intervention group 1 and 4 were highly involved with their residents. Although the RA involvement was not a controlled variable, it was certainly an unavoidable influence that could vary widely from floor to floor. It seems that peer influence was present on all floors (not just intervention 4) in the presence of an RA, and that some RAs are better than others at getting their students to participate in activities; in this case, the zero waste pilot program.

It is important to note the limitations of the study. First, the intervention experiment was implemented in the middle of the school year. Students were accustomed to the existing waste system, and compared to starting a system at the beginning of the year, they could have been more resistant to change. Second, the study did not include a waste audit of the participating residence hall prior to the intervention experiment. Therefore, an assumption was made that the material stream and recycling rates in the residence hall did not widely vary from the campus-wide stream. Observations made prior to the intervention experiments confirmed that students were recycling 25-30% of their waste, however these limited data points could not be used for statistical analysis.

CONCLUSIONS

How close to zero waste can we get with a simple and efficient infrastructure? Is education as important as we think when it comes to encouraging recycling behavior? What kind of influence does social influence have on student's recycling behavior? This study suggests that when people are faced with a choice, a large number will accept the default, the option that requires the user to do nothing [10]. A simple and efficient infrastructure can be a great start to achieving zero waste. And suprisingly, education may not be as important as we think, but social pressure can significantly influence students to recycle and compost.

In this study, a simple and efficient infrastructure was the foundation for a successful zero waste program. Many residence halls offered frequent pick-up of large trash (landfill) bins, but students took out recycling in small crates. Offering recycling and compost pickup made the recycling process easier and more accessible to students. In addition, appropriate bin size and bin placement were essential to the success of a zero waste program. In general, bin sizes should more accurately reflect a university's material stream (which Ohio State determined to be 60% recycling, 30% compost, and 10% landfill waste) and bins should be placed in the room where the majority of that material stream is accumulated. Students also need clear and simple instructions.

Beyond instructions, additional education about recycling, composting, and environmental impact had little impact on the greater success of this zero waste program. Students did, however, show an interest in having access to additional information online. Perhaps additional information could be shared through currently used social media channels (e.g. links to zero waste information on an existing residence hall homepage) accessible to those students with a desire to know more. Additional information that is available, but not invasive, may be the motivation some students need to become advocates for change.

Finally, social influences played a very influential part of students' daily recycling practices. This study addressed peer-to-peer relationships and authority figures as influencers of student perceptions and behavior. A peer influence, especially from a mentor who is relatable and respected, can significantly motivate students to participate in pro-environment behaviors such as recycling. While changing the default from trash to recycling through a simple zero waste infrastructure was the first step towards increasing diversion rates, behavioral reinforcement from recycling advocates, especially resident advisors, significantly increased compliance.

This study specifically targeted the residential population at a large university in the United States, however findings from the study revealed significant considerations for comprehensive waste management as well as design intervention strategies that encourage pro-environmental behavior. This study focused on waste management, but the findings can be applied to many institutional behavior change endeavors.

ACKNOWLEDGMENTS

This action research project would not have been possible without the support and funding from Student Life and the Coca-Cola Sustainability Grant. The authors would like to personally thank Carlos Lugo, Thyrone Henderson and Tom Reeves for providing managerial guidance and support. The authors would also like to thank Corey Hawkey for providing the foundation for the zero waste residence hall project, Dr. Mark Moritz for his guidance and expertise in ethnographic methods and research design, Mallory Ray and Devin Griglik for their assistance with data collection and analysis, Graham Oberly for his assistance with waste audits, and the Behavioral Decision Making Initiative for funding the ethnographic research phase. The authors also gratefully acknowledge Facilities Operations and Development, Eartha Limited, Housekeeping management and staff, and all the student participants for their co-operation and support of the project. Thank you.

ABSTRACT

Thermal comfort in outdoor settings is a topic that, until recently, has received little research attention. Previous studies have shown that thermal comfort is the main component of comfortability in an urban open space. A stretch of major road surrounded by mixed development in Dhaka city was selected as the study area. The goal of this research was evaluation of effect of urban canyon on surrounding microclimate. Data from ENVI-met simulation were compared to field survey data to understand the dynamics of mean temperature (MT), mean radiant temperature (MRT), relative humidity (RH) and wind speed from 9am to 7pm in the selected urban canyon. The result of this research shows canyon microclimate penetrated 75 to 100 meters deep into the branch roads. The effect of penetration increased with increasing width of the canyon. Green and open spaces around the canyon had impact on reducing temperature as well as penetration. Wind speed and relative humidity depends on road pattern, orientation and build environment characteristics of surrounding urban area. The results of this study can be helpful in defining architectural guidelines for typical urban canyon surrounded by mixed development in densely populated cities similar to Dhaka.

INTRODUCTION

Many cities in South Asia are currently undergoing rapid urbanization. This is causing changes in land use, urban form, and ground cover. However, the planning and design issues related to climate are not properly considered. Size of the city, orientation and width of streets, density of the built-up area, height of the buildings, and the presence of green areas and open spaces are important elements that affect the urban microclimate. Only In the last 20 years the transfer of knowledge from climatologic and biometeorologic studies to urban & architectural design tools has begun to take place [(i)].Dhaka is a densely built tropical city with unplanned road network. Improper ratios of primary and secondary road create a unique urban canyon scenario which also characterized by highly dense built area and less open spaces. This canyon or adjacent branch roads can be converted to urban outdoor activity spaces if thermal comfort is ensured. Air temperature mean radiant temperature, relative humidity and wind speed are the environmental parameters that primarily affect thermal comfort of a human being. In urban areas, the great variety of different surfaces and sheltering obstacles produces a pattern of distinct microclimate. To simulate these local effects, micro scale surface– plant–air interaction schemes with a special extension to typical artificial urban boundaries are required.

OBJECTIVES OF THIS STUDY

- To explore the nature of major urban canyon and its effect on urban micro climate.
- To identify the intensity of urban canyon effects penetrated in surrounding build area.
- To prepare a basis for further study to investigate the consequences of urban canyon effects.

AREA OF STUDY

Dhaka city is located at 23.24°N, 90.23°E, and 8.8 m above sea level. A stretch of 25m wide road of Begum Rokeya Avenue, Dhaka was chosen for this study. For survey, an area of 500m X 230m was taken along the road which is 14^0 inclined with North-South axis. Neighborhood buildings are one to nine stories high. Secondary road width varies from 3m to 7.5m. North-East part of the study area is highly dense with buildings, mostly 6 to 9 stories. South-East part has low rise buildings, mostly one to two stories. South-West part consist of many open and green spaces and low rise buildings. An indoor stadium is situated at North-West side which stands on a large landscape. Footpath and road of West side has lots of trees whereas, the East side is faced with buildings. Island of this road has 2m high plants. Data has been taken at different selected points of the footpath, road and island as field measurements and simulation was studied at road level to understand and compare micro climatic situation at different time of the day.

Figure 1 *Areal view of study area (1) west & east side footpath of main canyon (2&3) branch road (4)*

METHODOLOGY

A field measurement of mean Temperature (T), relative humidity (RH) and mean radiant temperature (MRT) was conducted with humidity/temperature meter (LUTRON HT-306) in study area at 3:00pm. All measurements were taken at 1.8m height to observe human comfort in urban canyon. Data readings were taken at footpath, road and island at both East side and West side of the canyon. The survey output was then plotted and analyzed. A computer simulation was carried out in ENVI-met by using weather data of Dhaka city on that particularly day. Simulation of the parameters was done for 9:00am, 11:00am, 1:00pm, 3:00pm, and 5:00: pm and 7:00pm at the height of 1.8m to understand the micro climate at different times of the day.

Simulation with ENVI-met V3.0

ENVI-met is three dimensional microclimate modeling software for simulating the surface, plant, air interactions in urban environment with a typical resolution of 0.5 to 54 m in space and 10 sec in time. ENVI-met uses a prognostic model based on the fundamental laws of fluid dynamics and thermodynamics (ii). ENVI-met outputs binary files which have to be imported into the visualization program LEONARDO, a graphical interface for displaying and analyzing numerical data. The output file displays the data with color coding.

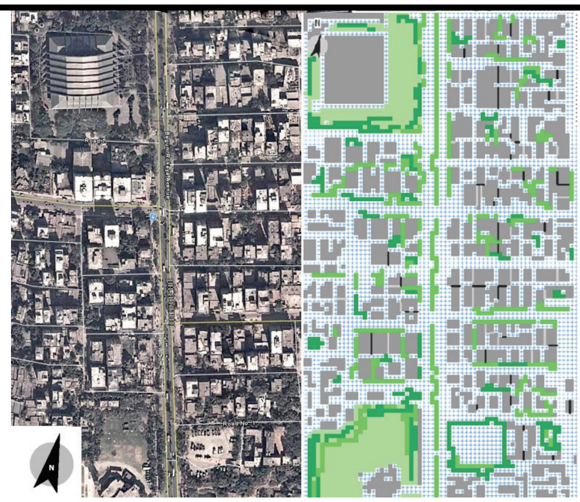
Simulation period was from 9:00am to 7:00pm of September 4, 2013. Study area of around 230m×500m×54m was transformed in the ENVI-met model grid with the dimension 57.4 µm, 125 µm and 18 µm respectively. This resulted in 34 grids with a resolution of 4µm×4µm×3µm for the study area.

ENVI-MET CONFIGURATION

The ENVI-met configuration file (.cf) was created using the environmental readings listed in Table 1.

Table 1: ENVI-met Configuration information for simulation and the model file

Sl	Simulation parameters	Values
1	Start Simulation at Time (HH:MM:SS)	09:00
2	Total Simulation Time in Hours	10:00
3	Save Model State each	120
4	Wind Speed in 10 m ab. Ground [m/s]	3
5	Wind Direction (0:N.90:E.180:S.270:W..)	180
6	Roughness Length z0 at Reference Point	0.1
7	Initial Temperature Atmosphere [K]	293
8	Specific Humidity in 2500 m [g Water/kg air]	7
9	Relative Humidity in 2m [%]	72



RESULTS AND ANALYSIS

The field survey readings from the study area are tabulated in Table 2. The potential reading for climate components of the same study area done at the same time points of the same day were deducted from simulation through ENVI-met. The simulation readings are tabulated in Table 3. Figures 2 to 5 show the simulation results.

At 9:00 am, Canyon is moderate cool with medium humidity and high wind speed. East side of the canyon is warmer than west side. Canyon beside green space is cooler than building sides. Urban open space, green area and low rise low density built area have more humidity and lower MRT than canyon. Tunnel effect created around branch road connecting points.

From 11:00 am to 3:00pm, Canyon is heated up and humidity level decreased along with wind speed. Branch roads on east west direction are cooler where secondary roads parallel to main canyon at N-S direction is warming up.

From both simulation study and field study, it was found that around 1:00 pm heat of the canyon is partially (35m to 76m) permeate to the branch roads on east direction. Secondary roads parallel to the main canyon also heated like this and have some similar heat permeation. Overall MRT increased and humidity decreased specially in secondary branch roads. Presence of tree cause noticeable lower MRT in some part of road's island and footpath. Trapped heat of urban canyon permeated to surrounding build area through branch roads. Trees and Green areas decreased this permeation rate. At 3:00 pm, west side branch roads began to affect by canyon heat permeation because of direct solar radiation. All spaces have high MRT. Wind shadow created at East - West oriented branch roads.

After 5:00 pm, canyon and surrounding area start losing temperature and gaining humidity. Green areas lose temperature at higher rate .Wider part of the canyon affects more. It is found that green areas cool down more quickly rather than build area.

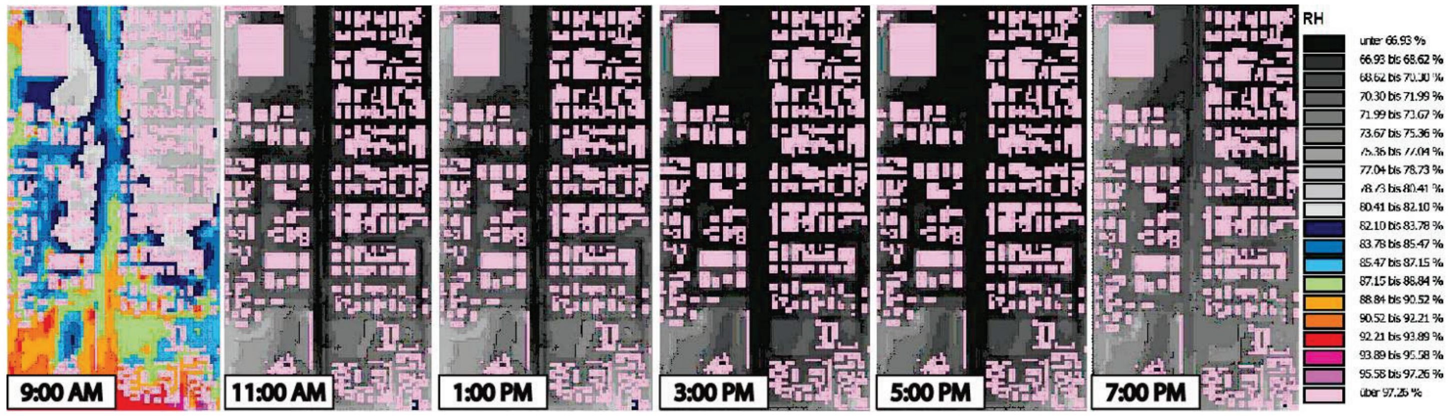

Figure 4 *Potential Relative Humidity Simulation Result from 9:00 AM to 7:00 pm*

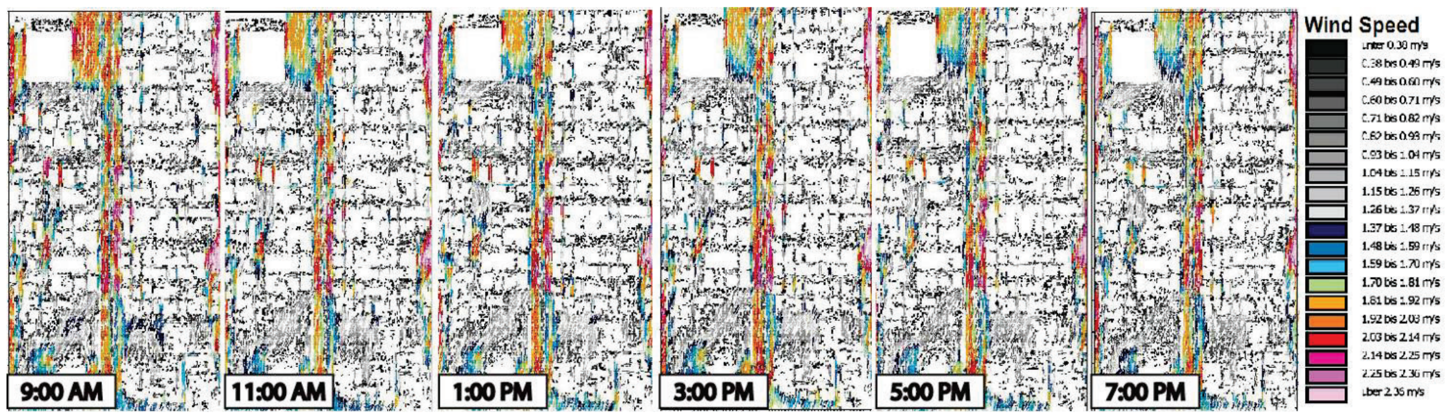

Figure 5 *Potential Wind Speed Simulation Result from 9:00 AM to 7:00 Pm*

At 7:00 pm, Build area trapped more heat rather than major urban canyon. Overall RH increased maintaining same ratio. MRT at secondary roads are higher than main canyon. MRT at urban open space, green area and low rise low density, high density built area is lower than canyon. It is found that heat trapped down inside build area. RH improves with decrease of temperature. Branch road and canyon contain some MRT for long time.

Table 3. ENVI-met simulation result of canyon at study area

Time	Pot. Temperature(ºK)	Relative Humidity (%)	Mean Radiant Temp (ºK)	Wind Speed (m/s)
9:00 am	297.00 to 297.70	84.85 to 91.17	332.31 to 337.11	1.31 to 2.35
11:00 am	302.63 to 303.67	65.73 to 73.05	337.11 and above	0.78 to 2.25
1:00 pm	303.88 to 305.12	61.67 to 65.45	339.51 and above	1.15 to 2.35
3:00 pm	303.84 to 304.5	62.87 to 66.50	338.13 and above	1.04 to 2.25
5:00 pm	301.54 to 301.88	67.06 to 73.60	303.56 to 322.73	0.93 to 2.25
7:00 pm	299.02 to 300.00	70.17 to 73.46	292.61 to 293.13k	0.78 to 2.14

FINDINGS AND DISCUSSION

(1) It was observed that environmental effects of canyon microclimate permeate to surrounding built-up area depending on characteristics of built environment and road pattern. This can be increased by additional solar penetration and width of branch roads. Row of trees at footpath reduced the effect of heat permeation from urban canyon.

To reduce permeation of canyon's thermal effect, connected branch roads should not align with solar direction. North – south aligned branch roads may contain less MRT, more shadow and RH to ensure better thermal comfort. Proper landscaping can improve thermal comfort of canyon as well as reduce permeation to surrounding built-up area. Medium high trees which provide better shadow at footpath should place along with junction of footpath and road. Large trees which act as better barrier against permeation should place at other side of footpath. Shrubs and low high plantation have less impact on overall canyon microclimate.

(2) Heat permeation increase with branch roads width.

Narrow branch roads may restrict traffic, but has better thermal comfort. Designers may consider separate traffic system to convert narrow branch roads into live and comfortable urban interaction spaces for pedestrians.

(3) Adjacent Open and green area had comparatively low temperature (2-3K) and wind velocity with higher RH than the canyon.

Idea of connect green open space to the canyon can be an effective way to control canyon's microclimate. It significantly reduces heat built-up at canyon as well as provides refreshment to the pedestrians.

(4) Urban canyons heated up and cooled down more quickly than the surroundings. The impact of MRT lasted for a while in canyon but comparatively longer in narrow branch roads. Plantation at road dividers effectively reduced MRT.

Trapped thermal condition of narrow branch roads can be considered at designing urban outdoor spaces. Branch road's orientation, placement and character should design with consideration of solar position in different seasons to provide comfortable outdoor spaces throughout the year. Selection of trees at road dividers can play a vital role to shape up canyon's microclimate in different seasons.

(5) Wind velocity was higher where urban canyon and branch roads were oriented with gradient wind flow. Road junctions often created tunnel effect where dense built-up areas remained in wind shadow.

Intelligent placement of small pocket spaces in dense built-up area considering tunnel effect and wind direction can be interesting. Before design build area, designer should have consideration of gradient windflaw pattern of the particular area as well as future prediction of wind map to reduce wind shadow zone.

SCOPE AND LIMITATIONS

This analysis specially focused on the impact of urban canyon on the micro-climate of the surrounding area on an urban canyon. Similar study can be done on other types of urban canyon in term of orientation, size and build area pattern.

In this research, field data varies from simulation result 5 to10%. The tools to create the urban environment in ENVI-met are limited to buildings, soils/pavement materials and trees/vegetation. It was not possible to add the thermal heat capacity of the building materials; but only a single constant indoor temperature.

ACKNOWLEDGMENTS

We are grateful to Dr. Khandaker Shabbir Ahmed in Department of Architecture, Bangladesh University of Engineering & Technology (BUET) for directly supporting and supervising this study. We also acknowledge the assistance of Mr. Irfan Ahmed Khan in preparing this paper.

Study on the Sustainable Renewal of Poor Rural Communities of Southwest China

Xinan Chi, MArch
[The Chinese University of Hong Kong]

Edward Ng, PhD
[The Chinese University of Hong Kong]

ABSTRACT

Cities and counties in China experience unbalanced development as well as vulnerable economies and environments despite the rapid country-level progress. These poor villages thus face the enormous challenge of sustainable development. The government's attempt of improving the situation through its "urban–rural integration" policy to promote the development of rural areas has helped achieve short-term objectives in building construction and some other aspects. However, this policy is a disaster for long-term development in rural areas. Specifically, only 5% of the rural areas in Southwest China, especially those located near cities, are suitable to the government's policy; the remaining 95% of villages, especially those in remote areas, need to find their own ways to realize sustainable development.

This study combines the theories of sustainable development in China and other countries and proposes the use of the "endogenous development" concept to meet the development needs of poor rural areas. Under this model, the villagers can use the modified "traditional ways" to improve their housing conditions (i.e., space, materials, daylighting, and ventilation), public health circumstances, and financial and cultural situations. This study tests the theory using two case studies of the Yangliu and Ma'anqiao reconstruction projects and provides strategies for the sustainable renewal of poor rural areas of Southwest China.

Keywords: *sustainable renewal, Endogenous development, poor rural communities, Southwest China*

1. INTRODUCTION

The Chinese government invests in and provides preferential policies for rural areas. However, several of these policies are unsuitable for Southwest China, a multi-ethnic area with a considerably diverse and complex natural environment, which remains undeveloped despite the country's rapid development. This study combines the sustainable development theories in China and other countries to introduce the concept of "endogenous development" that could solve the problem. The study likewise establishes a sustainable development framework for poor rural areas in Southwest China.

2. BACKGROUND AND PROBLEMS

The scope of the study includes Sichuan, Yunnan, Guizhou, and Chongqing in Southwest China (Figure 1). These four provinces have a total land area of 1,134,400 square kilometers (Wan, 2013). Southwest China is home to ethnic groups and minority nationalities, many of whom have a low educational level. This mountainous area with complex topography and bad transportation is frequented by natural disasters; such characteristics seriously impede the development of both its society and its economy.

2.1 Poverty Problems

The mountainous Southwest China has inconvenient transportation and low land-use efficiency. Its productivity level is relatively backward, and its agricultural structure is unbalanced. The villagers lack the ability to abandon the traditional agricultural model. Therefore, an increasing number of villagers go to large cities to seek jobs to feed their families; this phenomenon has caused villages to become empty and lifeless. The per capita net income of rural households of Southwest China is less than the average level of China (Figure 2).

Figure 1: the scope of Southwest China

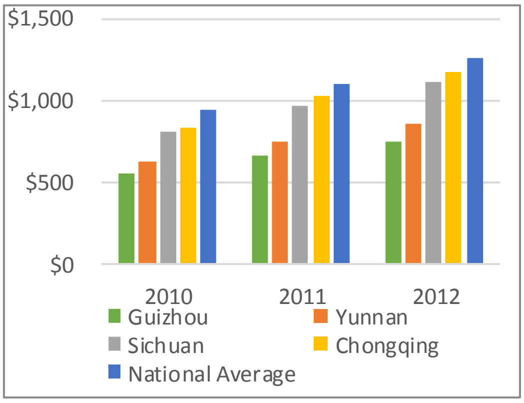

Figure 2: Per capita net income of rural households by region in China

2.2 Environmental Problems

Villagers cannot determine an appropriate method for waste management in poor rural areas because of deficient knowledge on public health. As a result, solid and liquid wastes pollute land and water resources. The so-called solid white waste pollutes both soil and water. Non-treated waste can produce toxic substances that attend to the top of the food chain. This environmental problem seriously damages the liver and the nervous system of humans (Zhang & Yu, 2007).

2.3 Public Health Problems

Lack of consideration for health issues is a common problem across the poor rural areas in Southwest China. Villagers do not fully understand the importance of health, and this situation adversely affects people's health and lives. For instance, burning firewood is the principal source of indoor air pollution; high indoor levels of PM10 in rural areas lead to several diseases, such as upper respiratory tract infection and asthma (Guo, 2005). Moreover, dry latrines that are extensively used in poor rural areas typically cause infectious diseases and zoonoses (Hu, 2009).

2.4 Building Renewal Problems

Various architectural forms follow unique regional conditions, such as those in the rural areas of Southwest China. However, traditional architecture lacks systematic ecological strategies and has technical problems with regard to anti-seismic design. At present, rural communities lack proper infrastructure and public service facilities; therefore, a suitable strategy for building renewal must be developed by comprehensively considering community planning and building design.

2.5 Government Policy Problems

Several important policies for rural development have been implemented in China, such as the 11th Five-Year Plan, which puts forward new countryside construction in 2005, and the Third Plenary Session of the 18th Central Committee, which emphasizes urban–rural integration as the fundamental solution to rural issues in China. However, these policies insufficiently focus on poor rural areas with complex topography and deficient transportation and have thus failed to produce the desired effects.

3. A SUITABLE MODEL FOR RURAL DEVELOPMENT

Cities and counties of Southwest China have unbalanced development and extremely sensitive economic, environmental, and public health situations. Therefore, these areas face an enormous challenge in terms of sustainable development. The government has implemented the urban–rural policy to promote the development of rural areas and thus improve their situation. This policy is a means for officers to achieve the short-term objective in building construction and other aspects. However, this policy is a disaster for long-term development of rural areas because only 5% of villages, especially those counties near cities, are suitable for urban–rural integration; the remaining 95% of villages, especially those in remote areas, should determine their own means of realizing sustainable development (Qiu, 2007). Thus, endogenous development may be the appropriate model for poor rural areas in Southwest China.

Endogenous development entails "respect for the cultural identity, [wherein] people have the right to own their culture. . . . Humans are the power [and] also the purpose of development. In form, development should be generated internally; in purpose, development should serve the people" (Huang, 1988). Compared with the old rural development model, the theory of endogenous development is defined by three key points (Table 1): first, the shift in emphasis from inward investment to endogenous development, which promotes the development of resources found within the region instead of attracting investment from external sources; second, the shift in delivery mode for rural development from a top–down to a bottom–up approach; and third, the shift in the structure of rural development policy from sectoral modernization to a territory-based integrated rural development (Michael, 2011).

Table 1. Features of the modernization paradigm and the new rural development paradigm

Modernization	New rural development paradigm
Inward investment	Endogenous development
Top-down planning	Bottom-up innovation
Sectoral modernization	Territorially based integrated development
Financial capital	Social capital
Exploitation and control of nature	Sustainable development
Transport infrastructure	Information infrastructure
Production	Consumption
Industrialization	Small-scale niche industries

4. STRATEGIES FOR RENEWING POOR RURAL COMMUNITIES

Sustainability comprises three dimensions, namely, environment, economic, and social dimensions. Social sustainable development covers several issues, such as peace, security, social justice, and human settlement. A sustainable social environment focuses on health and education, and sustainable societies provide high levels of health and wellbeing to their members (Jeremy, 2003). The strategies for renewing poor rural communities are expounded in this paper from the social, environmental, and economic aspects according to the practical application.

4.1 Fully Respect the Autonomy of Villagers

In 2005, the Central Committee of the Communist Party officially launched the "construction of a new socialist countryside" policy as "a major historic task [that] relates to the Chinese modernization process in the future" (Xinhua News Agency, 2005). The local government has used unified management, as well as unified planning and designs, to merge smaller villages or to move them to another site. A "rural house standard atlas" was used for reference in building apartments, which were not easily changed according to the opinions and the difficult-to-meet needs of villagers. However, the endogenous development model suggests that designers actively listen to the villagers' viewpoint and follow their actual needs. Furthermore, in this model, the completed construction is evaluated through value orientation of villager groups. This approach provides an effective way to enhance public participation in architectural design and to improve the design quality of new residential communities.

4.2 Provide More Public Space

In the traditional development model, the local government prefers to support the construction of infrastructure, such as roads and bridges, and a “village center” serves as a venue for village leaders to hold their meetings. In endogenous development, more attention is paid to communication infrastructure than physical infrastructure. However, very few public spaces in most rural communities of Southwest China are available for interflow or for educating villagers of all ages.

4.3 Make Use of Local Material and Resource

In the pursuit of rapid economic development, the traditional development model often overlooks the effect of development on the environment. By contrast, endogenous development finds ways to increase the value of natural resources in rural areas through prescriptions. For instance, a regional climate analysis is conducted prior to the architectural design to find the most suitable passive design to minimize energy consumption of buildings. Local natural materials should be used during construction. Furthermore, construction wastes generated during the project should be recycled. Natural energy sources, such as solar energy and wind energy, are good alternatives to non-renewable energy sources. Architectural strategies that follow local conditions can reduce the negative effect of construction and development on the environment.

4.4 Develop Traditional Construction Techniques

Large-scale intensive house construction is difficult in poor rural areas with a complicated mountainous terrain. This terrain results in traffic inconvenience, which means that the transportation cost of industrial construction materials will be high. Meanwhile, low education level villagers are not easy to accept the specialized construction techniques. Traditional construction techniques have an irreplaceable regional advantage in rural areas. Thus, architects should investigate local traditional techniques and combine them with modern technology by using the “high science and low technology” concept for innovation and improvement, while preserving the technical mastery of the farmers.

4.5 Villagers Participation and Cooperative Construction

Local villagers are the main targets and movers of efforts toward the renewal of rural communities. During the period of house construction, villagers help each other by way of “labor exchange” and exert effort to build their own homes. Participation and cooperation enhance the cohesion of villagers; such relationship can be used as motivation for people to remain on their own lands and not fall for labor migration. On that basis, the semi-self-construction system and regional cooperatives were also established.

4.6 Proper Economic Strategies

The use of indigenous technology and local materials greatly reduces the purchasing and transportation costs in projects for the renewal of rural communities. The participation of the local workforce not only improves labor skills but also maximizes the value of labor because it encourages “labor exchange” and “volunteer work.” Therefore, local resources are effectively utilized by the most appropriate configuration in this region.

4.7 Environment-Friendly Strategies

The effect of the rural community development process on the environment should be reduced. Household wastes and those generated from production should be properly classified, and small-scale landfills should be available for the disposal of such garbage. Sewage needs treatment before being discharged to rivers so that the water could be fit for everyday household use after sedimentation and purification processes. These strategies will help improve the ecological carrying capacity of the environment.

4.8 Public Health Strategies

Implementing ecological toilets and separating livestock are important aspects of public health strategies. In Southwest China, animals and humans share very limited land, especially in residential areas, because of economic and land conditions. By optimizing the residential design, rational space can be designed to separate animals from humans in rural communities. In addition, the establishment of eco-toilets will eliminate the "dirty and messy" status of traditional toilets and will significantly improve public health. People's awareness of public health could also be enhanced by the promotion and popularization of related knowledge.

Generally speaking, the sustainable renewal of poor rural communities of Southwest China could follow the below steps:

1. Before the start of the design process, local climate, culture, and traditional techniques should be analyzed systematically.

2. During the design period, the practical needs of the villagers should be considered. Local materials and resource should be used, and traditional techniques should be improved by the "high science and low technology" concept.

3. During the construction period, villagers should participate and learn the modified techniques, which will be the ways to make their living.

4. After the construction period, the modified techniques and the renewal model should be publicized and promoted to improve the endogenous development of these areas.

5. CASE STUDY

5.1 RECONSTRUCTION OF YANGLIU VILLAGE

Yangliu Village has suffered a major geological damage in the 5/12 Wenchuan earthquake in 2008 when more than 85% of the rural houses were damaged. To avoid further geological damage, the village government decided to relocate the entire village to an open area near the Minjiang River. Architect Hsieh Ying-chun and his team carried out the overall planning and architectural design for the new site based on traditional customs and lifestyle. The construction work was successfully completed with good use of "collaborative construction" (Figure 3) and sustainable ecological strategies. The cost of per square meter is less than brick-concrete building in the same region (Figure 4).

Figure 3: collaborative construction

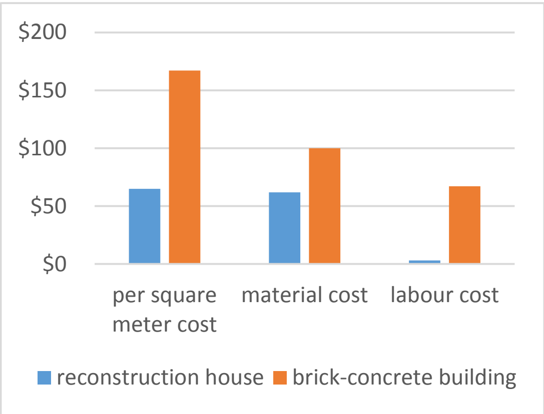

Figure 4: cost comparison of reconstruction house and brick-concrete building

The framework in the reconstruction of houses mainly used cold-formed steel, which has good seismic performance. The entire framework was connected by bolts, and the villagers were able to build it themselves after a one-time demonstration. The walls were filled according to traditional ways by using local materials. The houses looked identical because of the recycled old materials (Figure 5).

The framework has these other features:

1. Large-scale standardized production. The period of construction was short, which was very suitable for reconstruction;

2. Direct molding of the framework depending on the level of construction skills. This feature was suitable for villagers who built houses by themselves.

3. The openness of the structure. Villagers could easily add a room to the original building because of structural flexibility.

4. Similarity of this architectural framework to the traditional "through type timber frame." Such similarity helped steer the reconstruction of houses toward having the same spatial form as that of traditional houses.

Figure 5: framework of reconstruction house *Figure 6: a double-sided hot-dip galvanized network*

Architect Hsieh Ying-chun was also concerned about a building's energy efficiency and sustainable development. Given that Maoxian is in the hot-summer-and-cold-winter area, the thermal performance of a building during winter should be considered. The main envelope of a house is composed of three layers of exterior walls: the first layer is made of local stone, which has strong local characteristics; the second layer is a double-sided hot-dip galvanized network with concrete-filled gap to effectively reduce the weight of the wall and to increase the strength of the structure to resist horizontal forces (Figure 6); and the third layer mainly uses insulating form board with grass soil, which is likewise used in the main structure of the roof. In this way, the house has good thermal performance. Compared with traditional houses, the roof and three layers of exterior walls can save 45.61% and 39.45% of construction energy consumption, respectively (Du, 2010).

Furthermore, the lesser energy consumption of cold-formed steel compared with clay bricks and the local availability of stones lead to effective control of CO_2 emissions.

5.2 Ma'anqiao Reconstruction Project

Ma'anqiao is a small and poor village located in the impoverished mountainous area of Southwest China, in the southernmost side of Sichuan Province near the Jinsha River and close to Yunnan Province. An earthquake in August 2008 severely damaged most of the village houses. Rebuilding materials (e.g., bricks) are too expensive for the villagers and are also difficult to be transported across the river. The remote location, poor accessibility, and resource limitations hampered the rebuilding efforts of the villagers. Considering that many other remote villages in Southwest China are similarly situated as Ma'anqiao, the challenge for development workers and rebuilders was "how to make use of local materials to create an anti-seismic, comfortable, and cheap [but sustainable] house." The post-earthquake village reconstruction project in Ma'anqiao Village is the first comprehensive village demonstration project in the poor rural areas of Southwest China after the 2008 Wenchuan earthquake. Professor Edward Ng of the Chinese University of Hong Kong and his team from the Wuzhiqiao Foundation worked on the project for three years.

Before the initiation of the design work, the team conducted a series of survey and investigation in the village, communicated with the villagers to define the key problems, and conducted research to find an appropriate solution (Figure 7). This project provided several designs suitable to the needs of different family sizes. Villagers could choose the appropriate design according to their own needs.

The old rammed earth building has poor seismic performance because the building's foundation is not solid enough, and the tensile strength of mud wall is insufficient. After a series of investigations, the team invented and proposed a series of anti-seismic designs and strategies. Timber frame inside the mud wall became an important part of an effective anti-seismic design, and a building's foundation with appropriate size and correct cement mortar enhanced the integrity of houses. Bamboo strips, which are embedded into the mud wall, can bond the frame with the walls; some concrete belts were added into the wall to improve structural integrity and to avoid vertical cracking. Light lime and cement were added into the mud to strengthen the wall. Ramming tools were improved to pound the mud better by fitting them with iron heads (Wan, 2013). The resulting anti-seismic rammed earth building could satisfy the demand of seismic fortification in the area (Figure 8). The cost of per square meter is $32 which is only 20% of brick-concrete building in nearby village.

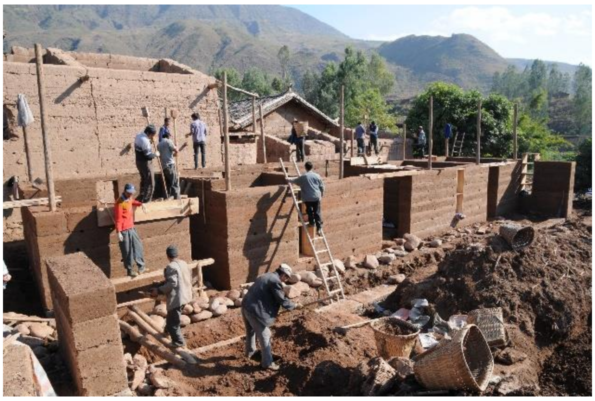

Figure 7: communicate with villagers *Figure 8: build a demostration rammed earth house*

The traditional rammed earth houses in this village were ill ventilated and dark. Therefore, windows of proper sizes and cross ventilation were provided to improve daylight and natural ventilation (Figure 9). Biogas has since then been used to turn waste into fuel for lighting and cooking. Water cellars were built to supply clean water from the nearby spring instead of people directly collecting "dirty" water from the river. In addition, storm water was naturally channeled to the land.

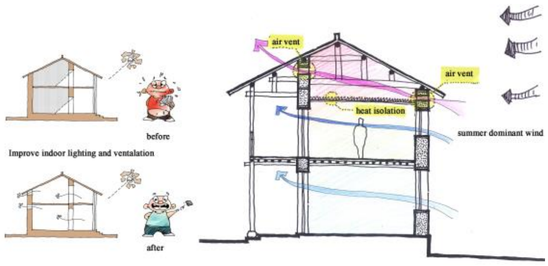

Figure 9: improve indoor lighting and ventilation *Figure 10: the round yard of village center*

After the rural houses have been reconstructed for basic living needs, a village center with a clinic, reading room, kindergarten school, shops, and other facilities was built to provide public space and to make its facilities available to the villagers. The village center could also function as an ethnic cultural exhibition center and was built in a round yard because Dai and Yi people prefer dancing together in a circle to celebrate festivals or for entertainment (Figure 10). This yard has become a public communication space and could maintain the minority culture of the village.

As in the Yangliu Village, the villagers of Ma'anqiao were employed in the reconstruction process. Given the effective, economical, and easy-to-learn anti-seismic strategies, the villagers were able to build their homes by themselves without hiring a contractor and without using complex technology. The occupied houses were also inexpensive and easy to build and repair. In this way, the villagers built anti-seismic rammed earth houses and learned an economical way to make their living. The idea of the project was to transfer knowledge and skills during the construction process rather than merely teaching the villagers using drawings.

5.3 Discussion

The case studies show that both of reconstruction projects fully respected the traditional cultures and the autonomy of villagers and also made rational use of local materials and local technology to rebuild the rural communities. The concept "collaborative construction" not only provided an opportunity for the local labor force to learn new skills but also reduced the economic pressure on house construction. The two cases also considered the reduction of environmental and ecological damage in the entire process. Case 2, in particular, was an overall reconstruction project of a community, and its supporting facilities (i.e., construction of village center, setting up ecological toilets, and promoting public health awareness) have good social effects. The sustainable practices of Village level (ie. the orientation of houses should respect to climate, rain water harvesting system and water supply etc) and settlement level are also important aspects for this study. Due to the space constraints, the related strategies will be discussed in the further study.

6. CONCLUSION

Endogenous development emphasizes the concept of sustainability and focuses on the importance of humans living in rural areas. Endogenous development suggests a self-sufficient, regional characteristics-based model that is suitable to the situation of poor rural communities in Southwest China, which have poor transportation and backward economy. This model can also reduce the communities' dependence on inward investment by emphasizing the use of local resource and traditional core values. The discussed strategies could provide a systemic way to further study sustainable renewal in the poor rural communities of Southwest China.

Asaad Almssad, Ph.D

[Karlstad University]

ABSTR ACT

Basrah is the most beautiful part of Iraq. In terms of size, it is the second largest city after Baghdad. For more than 25 years, Basrah has almost constantly been at war or been in an Aggressive situation. Three major conflicts have dominated, from 1980 to 2003. The wars have brought great suffering to the Basrah population and city. The bombing caused great material damage. Today with reconstruction process the city require to take a stabile process of reconstruction by using environmental cods in urban planning and design which offer an exciting opportunity to achieve environmental, social and economic benefits. The concept of biophilia deserves a deeper explanation. The hypothesis is that this affiliation leads to positive responses in terms of human performance and health even emotional states. The new movement aims to create environmentally friendly, energy-efficient buildings and developments by effectively managing natural resources. This path will discover a far deeper integration of nature with the built environment and the potential synergies in exchanging energy and nutrients across the human-nature interface. The research will take in reading different experiences from 1980 until now, in which we will try to put all practical consideration necessary to be able to select competent urban and architectural elements adequate to Basrah condition.

INTRODUCTION

An urban settlement, town or city, is one of the primordial and predominant expressions of human sociability on a territorial basis. The outward, visually perceptible manifestation of the complex, multiform social structure that constitutes a town is the three-dimensional plastic townscape [Acta Tongressus madviciani 1958]. A sustainable city is organized so as to enable all its citizens to meet their own needs and to enhance their well-being without damaging the natural world or endangering the living conditions of other people, now or in the future [Herbert Girardet 1999]. Arid zones are characterized by various conditions that can be affected by different combinations of physical determinants. Planners must decide which conditions are desirable and adopt criteria designed to maximize them in selecting the best site for a new settlement [Gideon Golany 1977]. The region of Basrah, the city of Sinbad, is, some would say, the most beautiful part of Iraq. It is Iraq's second largest city and principal port. Its commercially advantageous location, localize near oil field. In 1948 many oil refineries have been built in the city. It is an area of countless birds and a variety of animals, full of trees and gardens and canoes

Author A is a Associate Profesor at the University of Basrah , Basrah, Iraq. Author B is a Associate Profesor at Karlstad University, Karlstad, Sweden

gliding on the mirror-surfaces of calm lagoons [Amjad Almusaed 2004:14]. The human being entered the third millennium without the hope of achieving permanent peace on our beautiful earth, sustainable development and equality for all. We must seek what we have in common, namely, codes of understanding [Amjad Almusaed 2004:11]. A biophilic city is a healthy city, a city with abundant nature and natural systems that are visible and accessible to urbanities. It is certainly about the physical conditions and urban design parks, green features, urban wildlife, walkable environments, but it is also about the spirit of a place, its emotional commitment and concern about nature and other forms of life, its interest in and curiosity about nature, which can be expressed in the budget priorities of a local government as well as in the lifestyles and life patterns of its citizens. [Timothy Beatley 2011:13]. Natural and biophilic elements require being significant in everything and anything we design and build, from habitations, schools and hospitals to neighborhoods and urban configuration, to street and road structures and larger urban- and regional-scale design and planning. One of the classics of town and country planning is a garden city movement which it founded and inspired, has had a profound influence on town planning throughout the world, though its essential proposals are only now beginning to be properly understood and applied. Garden City history is that it carried further than Letchworth the technique of civic design and architectural harmony, and in the organization of its shopping center and factory area, it conducted interesting experiments which merit careful study by all who are concerned with the economics of large-scale development [Ebenzer Howard 1918:2]. Garden City is a Town designed for healthy living and industry; of a size that makes possible a full measure of social life, but not larger; surrounded by a rural belt; the whole of the land being in public ownership or held in trust for the community [Ebenzer Howard 1918:5].

There are several obstacles prevent us to achieve a biophilic city and/or neighborhood, and many interruptions in contemporary life navigate as far afield from nature. Such technological interruptions as digital communications devices are often seen as substantial permanent factors in our rising interruption with the natural ecosphere. Biophilic cities reflect a humility that understands the wisdom of nature and natural systems and the need to learn from them and model design and planning after them. McDonough is famous for imploring us to design “buildings like trees, cities like forests.” A city the functions like a tree is a model for our time, as we imagine cities that are carbon neutral and energy-balanced (that produce as much power as they need and live within the limits of current solar income), that are zero-waste, and that integrate and celebrate diversity (from which cities will become more resilient in the face of climate change and a highly dynamic world) [Timothy Beatley 2011:49].

CLIMTE CONDITIONS IN ACTING THEATER

The average temperatures in Basrah range from higher than 48 degree ºC in July and August to below freezing in January [Gideon Golany 1977:6]. The summer months are marked by two kinds of wind phenomena: the south and southeast, a dry, dusty wind with occasional gusts to eighty kilometers an hour, occurs from April to early June and again from late September through November. Basra climate is hot, dry summer, cold winter, and a pleasant spring and fall [Daniel E. Williams 2007:32]. Roughly 90% of the annual rainfall occur between November and April, most of it in the winter months from December through March [Amjad Almusaed 2004:12]. The remaining six months, particularly the hottest ones of June, July, and August, at approximately 32 ºC, air dry. The influence of the Arabic Gulf on the climate of Basrah is limited. But near the gulf the relative humidity is higher than in other parts of the country. Most nights are clear in the summer, and about one third of the nights are cloudy in the winter [Amjad Almusaed 2004:13].

PROBLEM PROPOSED

There were two major catastrophic actions caused a great environmental catastrophe over Basrah city from 1980 until now. The first starts after the terrible consequence of the Iraq –Iran war and recently USA attack over Iraq the urban green covering disappeared from large areas of the city, beside the extension of the city development axes over the green areas. The negative effect of the heat island phenomenon over the city area, consequently the human's thermal comfort becomes more perceptive [Amjad Almusaed 2004:176]. Other action was after the decision of the Iraqi regime over the south Iraqi marshes, which is located in the north part of Basrah city. The Mesopotamian Marshlands, nearly destroyed in the 1990s, have been partially restored but remain at risk. The Mesopotamian Marshlands are the largest wetland ecosystem in the Middle East [William J. Mitsch et al 2010]. Construction of numerous dams, water diversions and hydropower facilities on the Tigris and Euphrates Rivers over the past century and the deliberate draining of the marshes by the Iraqi regime in the early 1990s had almost destroyed the wetlands by 2000 [Aoki, C. and Kugaprasatham, S. (2009)]. Iraq's southern marshes were a historic area, which had been a traditional hideaway for rebels. They were the largest wetlands in the Middle East, and some believed they were where the first human civilization began.

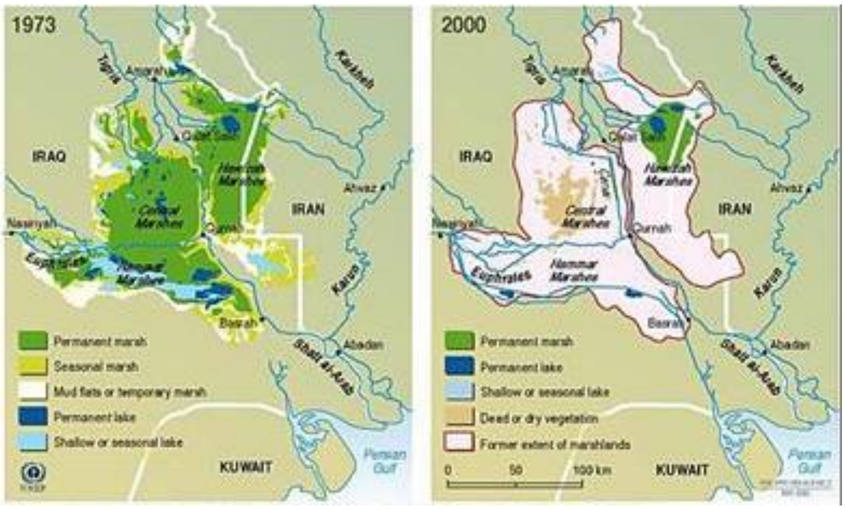

Figure 1 The southern marshes before and after Saddam's campaign of destruction[Herbert Girardet 1999]

Ecosystem recovery, however, has been seriously undermined by a severe drought (2008-2010) and uncoordinated water-related developments in the Tigris-Euphrates basin [Garsteck and Amr 2011]. The lack of a water sharing agreement between riparian countries and potential declines in Euphrates flows are a major threat to the wetlands' survival [Herbert Girardet 1999]. Today we can observe clearly the negative effect of urban heat island in the center of Basrah city, precisely in physical frameworks of the city, where we can detect a typical phenomenon with a large negative effect for the period of summer heating that is a natural thermodynamic phenomenon. International sanctions are supposed Iraq in 1990 prevented the development process of the civil city requirements. Therefore the city requires many civil elements. The major negative acting is:

- Basrah is a rich petroleum city; therefore city development axes are under governor petroleum minister control.
- A bad city zoning after 1989's reforming

The city today is in a bad condition, where the main urgent requirements are:

- A huge requirement for residential units for more than 1.5 million inhabitants
- Efficient social and cultural zones
- Additional open green areas

- Efficient management of vernacular buildings existent
- Competent and suitable civic centers and arteries

Sustainable cities are created by people who are knowledgeable about sustainable solutions. Decisions about sustainable development made by people whose have knowledge of the opportunities and implications inherent in sustainable choices. Decision makers can only choose sustainable solutions if they know they exist. Arid settlement and development in virgin areas require, as we noted, vision and pioneering spirit or ideological motives in the young, dynamic settlers for quite a long time after its initiation [Golany, Gideon S. 1995:4].

DISCUSSIONS AND RECOMMENDATIONS

Good stories and narratives are crucial to change in the future. Key questions are therefore:

- How town's functions do is that we make a difference in the city?
- What visions they have for how they can and will contribute to the city in the future?

We are looking to condense and in outline form / imagery to translate into a strategy proposal [UNITED NATIONS CONFERENCE ON HUMAN SETTLEMENTS (HABITAT II)]. Understanding the natural history of a city helps us to see cities as ever-changing, ever-evolving palettes of life [Timothy Beatley 2011:14]. The study aims to achieve an overall development strategy with the following strategies:

Activation of vernacular concepts of urban texture structure

Where vernacular habitat units are compact with interior courtyard; the streets are sinuous and pass through houses volumes. The shady interior courtyard has the effect that the rooms do not communicate directly with the overheated air outside, but through intermediate buffer spaces. Windows are often protected from the appalling [Amjad Almusaed 2004:23].

Moving towards a compact urban city

A compact form can reduce the length of utility networks, the maintenance they require, and the expenditures of energy and thereby prove economical. However, such a form mandates special designs that may increase construction cost [Golany, Gideon S. 1995:16]. It is necessary to create a more judicious urban microclimate than that dominant in the neighborhoods. They have to reflect the requirement for verticality (as opposed to horizontally) in the conceptual process of urban structures; this could involve some subterranean construction.

Implementation of a Linear City model

In old regions of the city we can implicitly, the concept of the linear city to rebuild and recover the deteriorate regions of the city, in a new ecological one that can go beyond the laws and restrictions of Iraqi petroleum ministers, where the main feature of the linear urban form is its ability to deal with the rapid and efficient mass movement of people and goods within and between cities. A further quality of the linear structure is its ability to deal, in theory, with infinite growth. Fig. 2 shows the possible extension in linear of the city by axes and the positioning of civic centers.

Figure 2   the possibility of linear city extensions by axes and civic centers

In this context, it be required to respect the following parametric factors:

- Divide Basrah in a great main center includes all private and public buildings, and many other small centers. The centers can be connected through a large classified transport network.
- A better organization of the Basrah has to divided city in many different levels
- The city has to be built by determining an urban point called 0 zone. Development process and city orientation start on this form.
- The city's borders have to be Determined through roads and streets.
- City district and development process can be arises by redefinition of the streets and buildings with sustainable vision
- Divide the city in many environmental zones can help in improving the macro- climate
- The city has to give city coherence through a clear road and transport networks.
- Conversion of Basrah marsh has to be built in an optimal way.

Application of bioclimatic architecture policy

The building design likewise should be governed by the climatic realities. The architecture itself is important, as are the shading devices, the landscaping, the shielding that a designer provides against adverse conditions, and the ventilation. The heating and air-conditioning plants of a structure must be designed with the climate in mind. Another very important element in arid-zone building design is insulation, because it is the one thing that tempers extreme outside variations in climatic factors. The easiest way to reduce the variations between daytime and nighttime temperatures is to put something between the inside and outside worlds: insulation does just this [Golany, Gideon S. 1995:32].

Initiated the concept of biophilic city and healthy environmental concept

The biophilic structure of the earth is a valued and appreciated part of life, where areas and human carrier green is not only an excellent synthesis of both qualitative and quantitative research that documents the bond between people and plants, it is a synthesis of the life's work and thinking of one of the most important figures in people-plant relationships. A biophilic community is a place where residents can easily get outside, where walking, strolling, and meandering is permissible, indeed encouraged, and evidence suggests that these qualities now carry an economic premium [Timothy Beatley 2011:3]. A green building uses considerably less energy and water than a conventional building, has fewer site impacts and generally higher levels of indoor air quality [New York City Department of Parks and Recreation]. It also accounts for some measure of the life-cycle impact of building materials, furniture and furnishings. These benefits result from better site development practices; design and construction choices; and the cumulative effects of operation, maintenance, removal, and possible reuse of building materials and systems [Jerry Yudelson, 2006:19]. A biophilic city is one that is full of varied sights, sounds, smells, and textures, many, but not all of which are natural [Brian Burton 2009].

First of all, an urban area invariably absorbs more heat from the sun than does an undeveloped one because the building materials usually have an albedo lower than that of most natural land environment. Thus, they necessarily absorb more energy [Ken Yeang, 2006:294]. Second, an urban area rejects man-made heat because machinery, combustion processes, and a man in a city are heat rejecting [Gideon Golany 1977:33]. The urban heat island mitigation strategies, can support to diminish direct energy utilize in buildings, and if applied in a community-wide basis, can decrease generally ambient air temperature in a specified region [Gallo, K.P.; Tarpley, J.D (1996)]. There are many assumptions, average leaf, and average plant. Hospitals and health facilities utilize the therapeutic benefits of green areas [Wolf K. L. 2007]. . These facilities sometimes use gardening as a tool to enhance the healing process for patients. In addition, the person can enjoy the comfort, fresh air, and landscape while restoring their health [Ismail Said (Jun 2003)].

Reducing of CO2 emissions and increasing energy saving and efficiency concept

We require to control the traffic-systems reduction, distraction and rerouting to reduce the production of air and noise pollution, and heat discharges. For parking the optimal solution is in building vehicular parking spaces underground or as covered structured parking. Use an open-grid pavement system (with impervious surfacing such as porous concrete) for the parking-lot areas [Ken Yeang, 2006:318]. Reducing carbon dioxide emissions from the building sector is critical to our ability to combat global warming. Green buildings are an important component in the effort to bring carbon dioxide emissions back to 1990 levels, as required by the Kyoto Protocol, so that we can begin to stabilize carbon dioxide concentrations in the atmosphere at levels no more than 20 percent above todays [Jerry Yudelson, 2006:41]. Topography by vertical variations in the landscape is helpful in creating potential energy saving idea. Gravity is one of the most significant sustainable forces. It can distribute water for free, and even stratification of microclimatic air temperature is related to its presence.

Increasing of environmental, human thermal comfort

Communities can take as many steps to lower the temperature of the environment. These temperature reduction strategies include: By means of the greater concept of biophilic city, vegetated green roofs, living green walls and planting trees and vegetation employ the evapotranspiration and evaporative-cooling procedures of vegetation on construction surfaces and integrate open green spaces. In addition, trees, shrubs, and other plants help reduce ambient air temperatures during a process known as "evapotranspiration." This happens when water absorbed by vegetation evaporates off of the leaves and surrounding soil to naturally cool the surrounding air. Trees also insert oxygen to the atmosphere, break down a quantity of pollutants and diminish dust [Amjad Almusaed 2004:231].

Decreasing the level of heat-absorbing surfaces

Adjust current and new urban city block layouts and configurations with explain patterns, materials and surfaces that absorb a small amount of solar energy [Berdahl, P. Bretz, S., 1997:25, 149-158]. Building materials and finishes appropriate to the impacts from the climate and the weather. Earth building can achieve great heights of structural and aesthetic achievement [J.C. Moughtin 1985:21]. Earth can be used in a variety of ways which encompasses a wide range of architectural styles and aesthetic appeal [Peter Shirley, J. C. Moughtin 2006: 30].

Facade cladding systems is a most popular building material uses for façade in Basrah today. It's made of different materials such as steel, aluminum, Cor-Ten and glass. The material absorbs a huge amount of heat in the day at summer period and its release it at night. It works such as thermal mass. The montage of this material in Basra is without thermal insulation. This contributes in amelioration of the heat island phenomenon. Application of other environmental material is essential today. [Myer, W. B (1991)]. The current surfaces (roofs, infrastructure, pavements, etc.) with vegetated surfaces such as green roofs or green gardens and open - network road surface or specify cool materials to decrease the heat absorption. In other hand, we need to employ the well reflective and high emissivity building surfaces, materials upon walls and roofs, or by installing of a green roof or walls. Therefore, we have to increase the reflectivity of building surfaces such as rooftops and using frequently of light colors to create a highly reflective building climatic surface to keep buildings cooler in summer season to reduce energy consumption

CONCLUSION

Planning and architecture must work together to be sustainable. To design sustainable is to integrate the design into the ecology of the place the flows of materials and energy residing in the community [William D. Solecki, et al,2005]. One of the major problems facing us is how to establish and maintain environments that support human health and at the same time are ecologically sustainable. Green areas seem too important to people. Most people today believe that the green world is beautiful. Biophilic habitats are still often seen as an unadulterated esthetical element in architecture, as a spleen of some “Greenies”. In fact, green areas by now contribute, some extent, to a better microclimate through evaporation, filtering of dust from the air and reduce inside temperatures at the building's surface. Besides improving the microclimate and the indoor climate, the retention of rainwater is another important advantage. The aesthetic form requires, escalating the value of the possessions and the marketability of the building as a complete, mainly for accessible green areas. Urban and regional planners should view the world's arid zones as potential locations for future urban expansion and for food production, and as energy resources. No matter what function these areas serve, the construction of settlements of different forms and functions which respond to the unique nature of a desert climate will be needed. Generating more biophilic cities will also necessitate political governance, of course, and there are currently strong suggestions that politicians are capable to gain political benefits from sustenance for green developments. The green areas can take a differ places in relation to the non-greenly areas where the green area appearance aim to be synchronized by means of another area in concordance with architectural perception upon biophilic habitat.

ABSTRACT

In high-density mega cities, air pollution has a higher impact on public health than cities of lower population density. Apart from higher pollution emissions due to human actives in densely populated street canyons, stagnated airflow due to closely packed tall buildings means lower dispersion potential. The coupled result leads to frequent reports of high air pollution indexes at street-side stations in Hong Kong. Therefore, high-density urban morphology design science is needed to lessen the ill effects of high density urban living. This study addresses the knowledge-gap between planning and design principles and air pollution dispersion potential in high density cities. The air ventilation assessment for projects in high-density Hong Kong is advanced to include air pollutant dispersion issues. The methods in this study are CFD simulation and parametric study. The SST κ- ω turbulence model is adopted after balancing the accuracy and computational cost in the validation study. Urban-scale parametric studies are conducted to clarify the effects of urban permeability and building geometries on air pollution dispersion. Given the finite land resources in high-density cities and the numerous planning and design restrictions for development projects, the effectiveness of mitigation strategies is evaluated to optimize the benefits. A real urban case study is finally conducted to demonstrate that the suggested design principles from the parametric study are feasible in the practical design of high-density urban areas.

INTRODUCTION

Emissions from motor vehicles contribute to air pollution in urban areas, particularly at street canyon level. The European Environment Agency (EEA) (2012) has reported seven types of pollutants that urban dwellers are exposed to. All of these pollutants are primarily or secondarily related to road traffic emission (fossil fuel combustion). The World Health Organization (WHO) (2008) has therefore explicitly recommended the concentration limits for various air pollutants such as O_3 and NO_2. The risks associated with exposure to air pollution are relatively low for individuals but are a significant public health concern (Kunzli et al., 2000). Understanding the problem in densely populated urban areas from the urban and city scales is therefore paramount.

To decrease traffic pollution, an improved vehicle emission control program has been implemented in Hong Kong by the Hong Kong SAR Government. Nonetheless, the roadside concentration of NO_2 continues to increase (Environmental Protection Department, 2011). Similar findings are also being reported in Europe by EEA (European Environment Agency, 2012). High hourly, daily, and annual average concentrations of NO_2 have been recorded at the road-side stations in the Central, Causeway Bay, and Mong Kok in Hong Kong. Air pollution far exceeds the limits recommended by the WHO (Environmental Protection Department, 2011). These three areas are high-density metropolitan areas and traffic hotspots. As shown in Figure 1, vehicles crowd the streets of these high-density urban areas. The reported higher concentration of NO_2 is the result of the larger NO_2 percentage in total traffic emissions (European Environment Agency, 2012; Grice et al., 2009) and of poorer urban air ventilation in high-density urban areas (Ng et al., 2011). The bulky building blocks, compacted urban volumes and very limited open spaces seriously block the pollutant dispersion in these deep street canyons (Tominaga & Stathopoulos, 2012). Therefore, apart from having control measures to decrease vehicle emissions, understanding pollutant dispersion as related to the urban planning and design mechanism is necessary in order to guide policymakers, planners, and architects in making better evidence-based decisions.

Figure 1 Vehicle fleets in the deep street canyons of Mong Kok and Wan Chai in Hong Kong; high concentration of NO_2 is frequently measured at the roadside stations in the areas.

The Severe Acute Respiratory Syndrome (SARS) episode in 2003 triggered the Air Ventilation Assessment (AVA) study in Hong Kong. Since 2006, AVA has been implemented as a prerequisite for urban development and old-district redevelopment (Ng, 2009). The 'Sustainable Building Design (SBD) Guidelines (APP-152)' have also been drawn up by the Hong Kong Government. These guidelines allow architects to evaluate the effects of their proposed building designs on the surrounding wind environments, and then to enhance urban environmental design (Hong Kong Building Department, 2006). This study builds on the previous work (Yuan & Ng, 2012) by conducting parametric studies to statistically evaluate and further develop the efficacy of the AVA TC-1/06 guidelines and the SBD's APP-152 guidelines with regard to air pollutant dispersion. This study aims to provide significant and sufficiently accurate insights on the air pollutant issue at the beginning stage of the design practice. These insights are helpful to avoid the mistakes that cannot be easily corrected at the late stages of the design process. The result of this study, as a piece of design science, is intended to facilitate a paradigm shift from the typical experience-based ways of designing and planning to a more scientific, evidence-based process of decision making.

METHOD AND VALIDATION

This study used the Eulerian method to model the air pollutant dispersion. Compared with the Lagrangian method, which considers the species as a discrete phase, the Eulerian method considers phases as continuum and is solved based on a control volume, which is similar in form to that for the fluid phase (Wang, Lin, & Chen, 2012; Zhang & Chen 2006). Wang, Lin and Chen (2012) compared the performance of Reynolds-averaged Navier-Stokes (RANS) model with Eulerian method and Large Eddy Simulation (LES) model with Lagrangian methods. The later one is more accurate but also with higher computational cost. Zhang and Chen (2006) used a user-defined founction in Fluent to calculate the pollutant concentration, because the lagrangian method does not direclty output the concentration value. Therefore, the Eulerian method is more convenient for calculating the air pollutant concentration, which was the index that this study used to evaluate air pollutant dispersion.

In this study, the wind tunnel data provided by Niigata Institute of Technology (Tominaga & Stathopoulos, 2011) was used to validate the Eulerian method. The effects of the different turbulence models on air pollutant dispersion simulation were also investigated in this validation study. RANS and

LES models were included in the validation study. In RANS models, the standard and realizable κ-ε model, Reynolds stress model (RSM), shear-stress transport (SST) κ- ω model were used, in which approaches of dealing with Reynolds stresses are different (Murakami 2006).

Ethylene (C_4H_4) was used as tracer gas, and the tracer concentration was set at 1000 ppm, duplicating the setting in the wind tunnel experiment (Tominaga & Stathopoulos, 2011). The tracer gas was released from the point source in the model with a wind velocity W_s ($W_s/U_b = 0.12$, U_b is the input wind velocity at the building height, 3.8 m/s).

The model configurations were set to match those in the wind tunnel experiment too (Tominaga & Stathopoulos, 2011). The H/W and H/L aspect ratios were set to 1.0 and 0.5, respectively, where H is the building height, W is the width of the street, and L is the length of the canopy. All modeling settings followed the Architectural Institute of Japan (AIJ) guidelines. The input wind direction was perpendicular to the street canyon. Input wind velocity (U_x) and turbulence kinetic energy (TKE) profiles were set by a user-defined function.

The simulation results of the different turbulence models were collected at two test lines and cross-compared in Figure 2. The simulation results were closer to the experiment data particularly near ground (X/H=0.1, X is the height of the test line). However, comapred with LES model with best accuracy, all RANS models overestimated the concentrations at upper lines (X/H=0.5, for example), particularly at the windward side of the street canyon. Among the RANS models, the SST κ- ω model best performed in terms of air pollutant modeling at the windward side. The special near-wall region (the shear layer) treatment by the standard κ- ω model (Menter, Kuntz, & Langtry, 2003) was considered helpful for estimating the air pollutant concentration near surface regions. Balancing the computational cost and accuracy, for this study, the SST κ- ω model was selected as the preferred turbulence model to simulate the air pollutant dispersion in the parametric study.

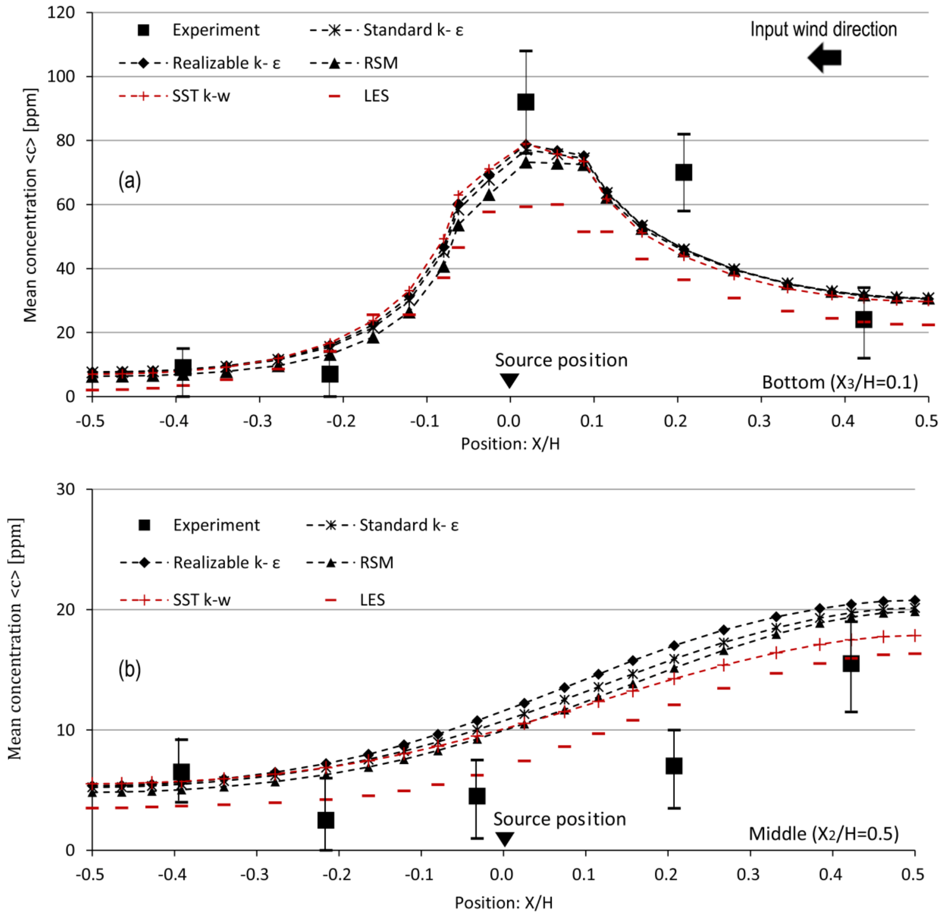

Figure 2 Cross-comparisons of time-averaged concentrations <c> at the street canyon between the wind tunnel experiment and different turbulent models: a) <c> at the bottom line; b) <c> at the middle line. Error bars: standard deviations of the measurements in the wind tunnel experiments.

PARAMETRIC STUDY

The parametric model was at the urban scale and established from urban conditions in Mong Kok (Figure 3), a high-density downtown area in Hong Kong, using a regular street grid. As shown in Figure 3, eight strategy cases were designed to create their corresponding parametric models, establishing a total of eight simulation scenarios with different building geometries and urban permeabilities. Their details were tabulated in Table 1. Plot ratios of Case 3 to 8 were set to be same to that of Case 2.

Given the different building geometries, the corresponding urban permeability of the eight cases were different, as shown in Table 1. The permeability of buildings (P) (Hong Kong Building Department, 2006) and site area ratio (λ_p), which respectively represent the vertical and horizontal permeability, were calculated. High values of P and λ_p indicate low permeability.

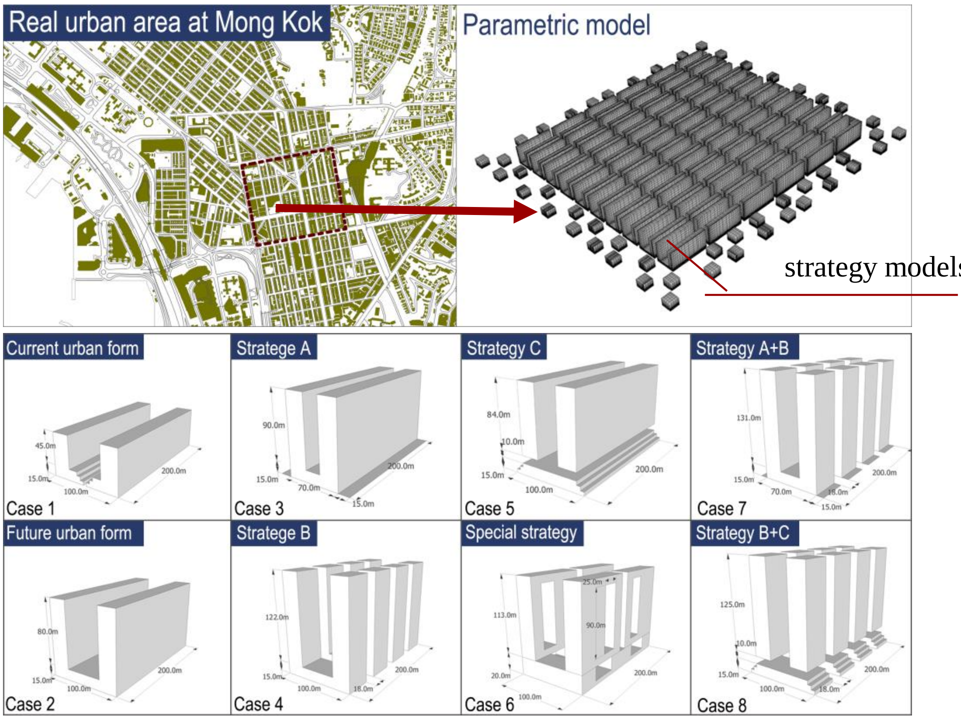

Figure 3 Actual urban area located at Mong Kok, the corresponding parametric model and eight strategy cases.

Table 1 Eight simulation scenarios with different building geometries and permeabilities.

Cases	Building geometry		Land use	Urban permeability			Performance
	Parameters	H (m)	Plot ratio	P	λ_p	λ_i	Percentage of 'pollutant concentration ratio >1'
1	Current urban form	60	8.9	0.9	0.7	0.9	100%
2	Future urban form	95	14	0.9	0.8	0.9	75%
3	Building setback	105	14	0.9	0.5	0.7	70% (Unsuitable)
4	Building separation	137	14	0.7	0.6	0.5	29% (Good)
5	Stepped podium void	109	14	0.8	0.6	0.7	75% (Unsuitable)
6	Building porosity	133	14	0.7	0.8	0.7	33% (Good)
7	Building separation & Build setback	146	14	0.7	0.4	0.3	0% (Excellent)
8	Building separation & Stepped building void	150	14	0.6	0.4	0.4	0% (Excellent)

Note: H: building height; P: permeability of buildings (P = sum of projected building areas/Area of the assessment zone); λ_p: site coverage ratio; λ_i: integrated permeability

RESULT ANALYSIS AND DISCUSSION

This study used the normalized concentration ($\overline{c}$) as the index to analyze the effects of different urban permeability and building geometries on air pollutant dispersion in the street canyon. This was given by:

$$\bar{c} = < c > / < c_0 > \qquad (1)$$

Where $<c>$ is the modeling result of the time-averaged concentration of NO_2 and $<c_0>$ is the reference emission concentration, the norm of $<c>$. Given the definition of $\bar{c}$, the threshold value of $\bar{c}$ was set to 1.0. When the value of $\bar{c}$ is less than 1.0, air pollutants disperse away and do not concentrate in the street canyon.

Building scale analysis

The simulation results, contours of $\bar{c}$ at the vertical sections (Figure 4), firstly indicated that mitigation strategies for the air pollutant dispersion are necessary in the high-density urban planning and design. In current urban conditions (Case 1), air pollutants are seriously concentrated in the deep street canyon. Most values of pedestrian-level normalized concentration ($\bar{c}$) in the street with emission sources were larger than 1.0, indicating that air pollutant does not disperse but concentrate in the street canyon. If current planning and design activities do not change, the air quality will worsen with future urban development (Case 2). Given the negative effects of air pollution on public health and that of the high population density in Hong Kong, mitigation strategies are necessary to alleviate this negative impact.

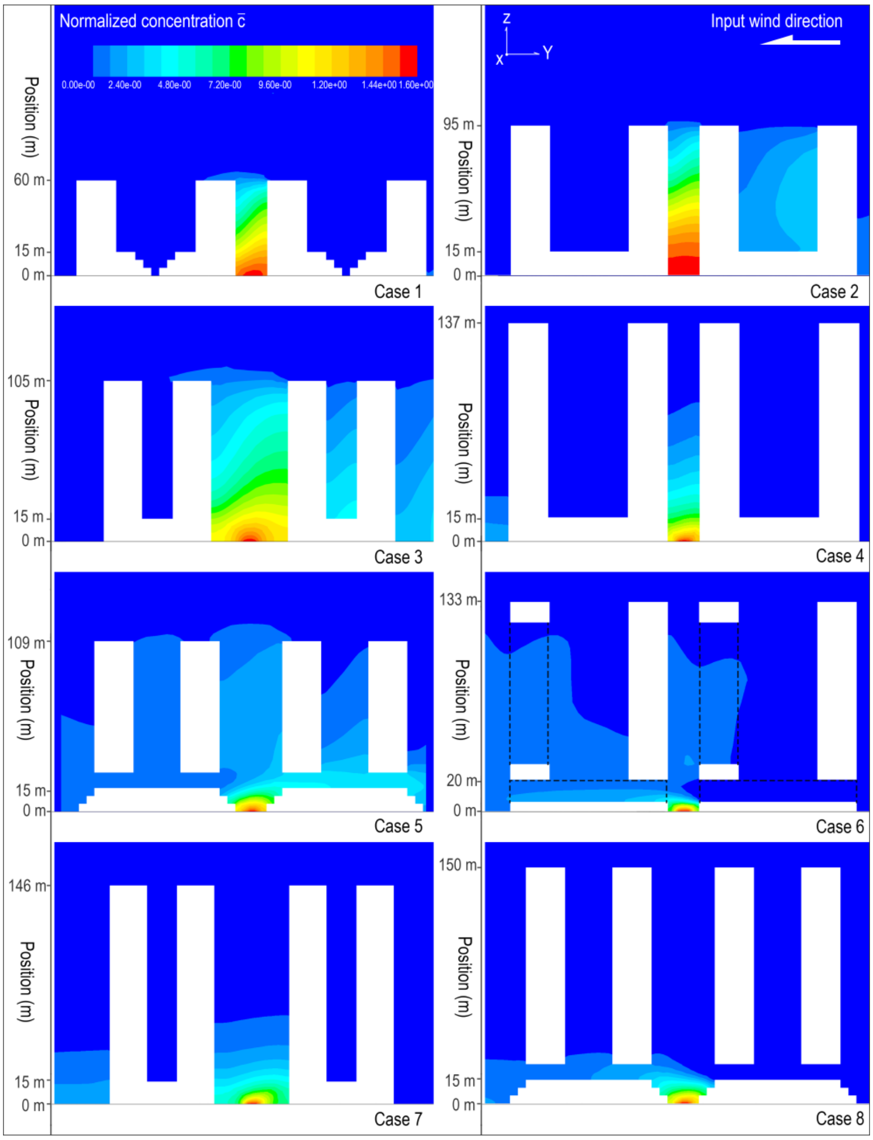

Figure 4 Contour of $\bar{c}$ at the vertical sections in Cases 1-8.

Secondly, the modeling results indicated that the air pollutant dispersion in high-density cities can occur if strategies which promote convection effects, such as building separation (Case 4), stepped podium void (Case 5), and porosity (Case 6), are implemented and could be more efficient than strategies for larger turbulence diffusion, such as building setback (Case 3). Unlike what the AVA knowledge indicates, pedestrian-level pollutant concentration depends on the permeability of the entire street canyon. Although a high building porosity off ground level cannot increase the wind speed at pedestrian level, it can decrease pedestrian-level air pollutant concentrations as Case 6 did in the parametric study. In the design and planning process, appropriate strategies need to be chosen based on the particular concerns in different projects. The performances of various mitigation strategies were quantitatively investigated and tabulated in Table 1, as the practical design reference. Consequently policy maker can determine what and how much needs to be modified in the practical design. Strategies recommended in this study can be applied into both the new project design and the urban redevelopment.

Urban scale analysis

Furthermore, this study conducted a linear regression analysis to statistically weight the effect of permeability of buildings (P) and λ_p (Table 1) on the spatially averaged pollutant concentration at the street with emission. Based on the results plotted in Figure 5, it is clear that the spatially-averaged normalized concentration depends on the permeability of buildings (P) more than on the site coverage ratio (λ_p), as the R^2 for P, 0.78, is larger than the R^2 for λ_p, 0.47.

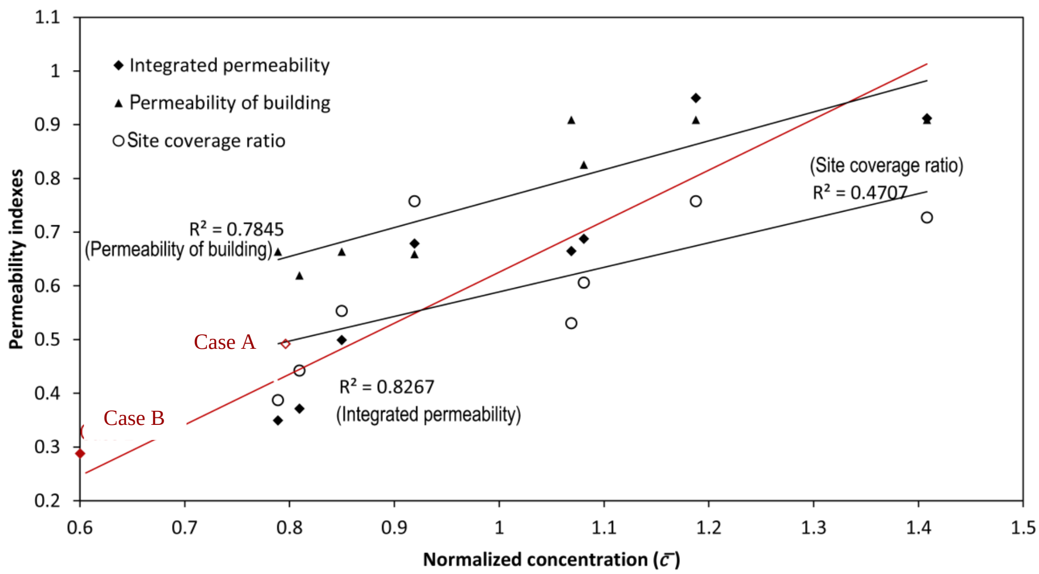

Figure 5 Linear relationships between pedestrian level air pollutant concentration and permeability indexes, P, λ_p, λ_i (Table 1). The values of two real urban Cases, Case A and B, were also plotted. (significant level: 95%)

To better predict spatially-averaged $\bar{c}$ in high-density urban areas, the integrated permeability (λ_i) was calculated based on Counihan's roughness model (Grimmond & Oke, 1999) for estimating urban permeability as following:

$$\lambda_i = (C_1 \cdot \lambda_P - C_2) \cdot P \quad (2)$$

The coefficients C_1 (1.4352) and C_2 (0.0463) were for the contribution of λ_P, considering that λ_P, as the horizontal permeability, is less important than P, as the vertical permeability. The values of λ_i in all eight cases were given in Table 1. As shown in Figure 5, a strong relationship between λ_i and spatially-averaged $\bar{c}$ (R^2=0.83) indicated that λ_i is a better urban permeability index than P and λ_p to estimate traffic air pollutant dispersion. This analysis result makes possible to map traffic air pollutant concentrations in urban areas by using urban morphological indexes in GIS.

URBAN IMPLEMENTATION BASED ON THE REAL CASE STUDY

A real case study at Mong Kok was conducted to demonstrate that suggested design principles and knowledge are feasible in real urban design practice. As shown in Figure 6, based on the current urban morphology (Case A), an urban design was produced (Case B) to improve the local air quality. Based on the characteristic of existing buildings, different mitigation design strategies in Table 1 were employed in street blocks. To avoid reducing the land use efficiency, the plot ratio in these two cases were same, 8.3. The site coverage ratio in Case A and B were 0.51 and 0.42, respectively. The averaged building permeability (P) of the total area was estimated at 0-60m above the ground and was 0.7 in Case A and 0.5 in Case B, as shown in Figure 6.

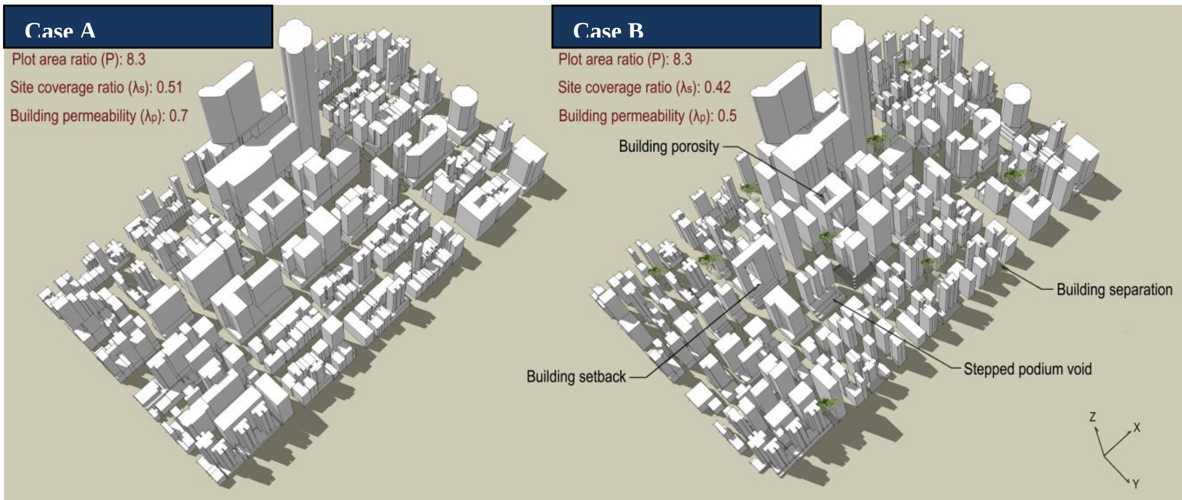

Figure 6 Case study of urban redevelopment at Mong Kok. Case A: the current urban area of Mong Kok; Case B: the urban morphology of Mong Kok with mitigation strategies.

For comparison purpose, a CFD simulation study was conducted to model air flows and traffic air pollutant dispersion in the above two cases. The simulations were constructed in accordance with the methodology in the parametric study. The comparing results in Figure 7 demonstrated that the wind permeability in the entire area significantly increased in Case B. Therefore, Case B significantly increased the local dispersion. The normalized concentration data was collected at the street with emission and cross-compared in Figure 8. It is clear that the probability of high concentration ($\overline{c}$ >1.0) in Case B was far less than the one in Case A. This result validated the suggested mitigation measures suggested by this study.

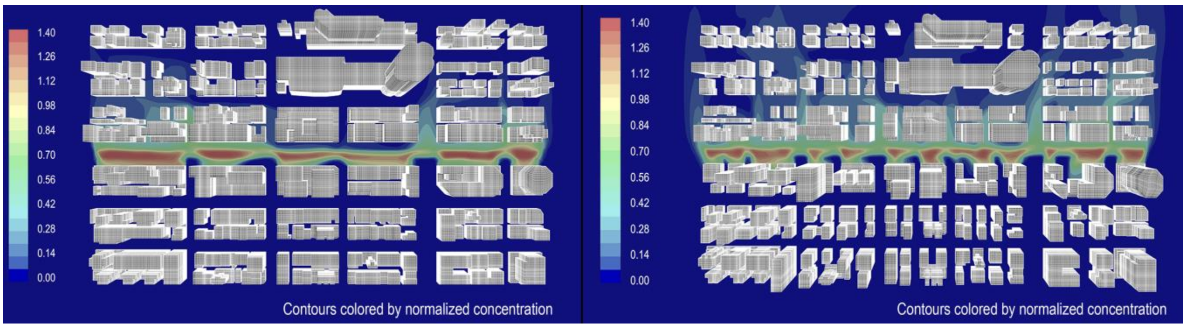

Figure 7 Simulation results. The mitigation strategies in Case B can significantly increase the wind permeability and decrease the traffic air pollutant concentration.

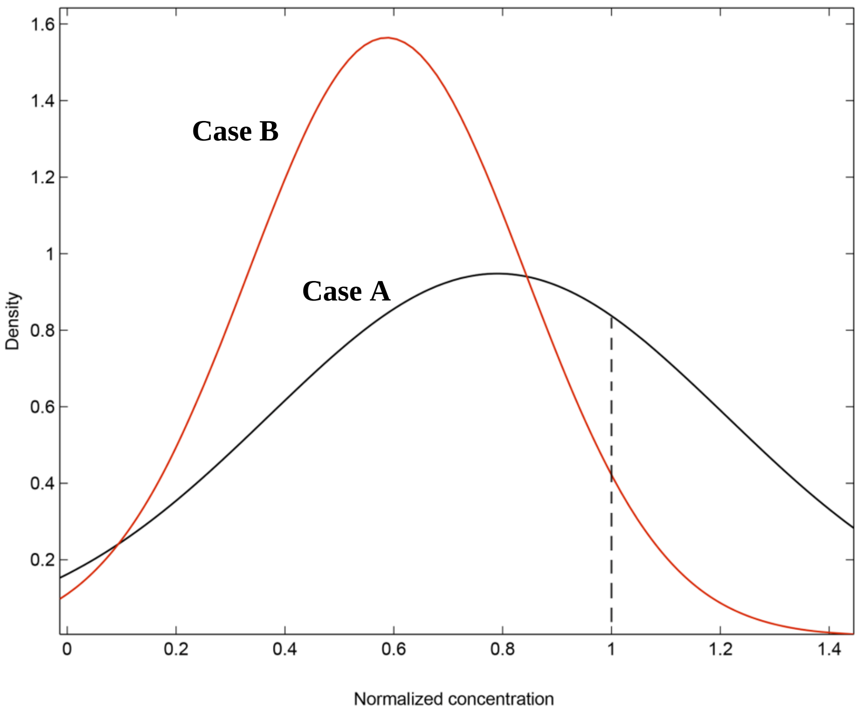

Figure 8 Normal distribution fit of the normalized concentrations in Cases A and B. The probability of high concentration ($\bar{c}$ >1.0) in Case B is far less than the one in Case A.

Based on the Equation 2, the urban permeability λ_i at two real cases was also calculated, which was 0.48 in Case A and 0.27 in Case B. Correspondingly, the spatially averaged normalized concentration ($\bar{c}$) at the street with the emission source decreased from 0.79 in Case A to 0.59 in Case B. These results were plotted in Figure 5. It is clear that these results coincided well with the linear relationship and validated that the supposed knowledge of urban permeability for air pollutant dispersion is feasible in the practical urban design.

CONCLUSION AND THE WAY FORWARD

The planning guidelines for air quality in Hong Kong Planning Standards and Guidelines (HKPSG) point out that '*In the preparation of land use plans, due consideration should be given to the location of major polluting uses with a view to improving the regional air quality.'* and *'Concentrations of NO_2 and particulates are high, particularly at the older urban areas where motor vehicle usage is intense and vehicle exhausts are trapped between narrow roads and tall buildings*' (Chapter 9, Hong Kong Planning Department, 2011). It is clear that the 'due consideration' is needed especially at the existing urban areas. But, meanwhile, the major factors in these guidelines are too rough to make 'due consideration', using only the topography factor. No urban development factors are included. This study clarified the effect of urban development factors on outdoor air quality and provides the practical design knowledge. The architect can choose the corresponding design strategy based on the particular design concerns. The outcomes mainly focused on the building design strategies but urban scale analysis was also included, so that the research has the great potential to be extended for the urban planning implementation.

ABSTRACT

Cities and rural environments differ substantially in their land surface temperature, which leads to urban heat island effect (UHI). Cities have a dynamic relationship with the microclimate. Landscaping is one of the most effective passive design strategy compared to other passive design strategies in mitigating the UHI effect. The degree of 'greenery' or 'greenness' (Green space factor) is usually defined and measured as the percentage of total urban area that is devoted to open green spaces. The higher the percentage of green cover, the greener that particular city becomes. National forest policy, India states that a 20% to 33% of green cover is considered to be fairly good. The green spaces help to alter the temperature, reduce the urban heat island effect and improve the air quality. In most cities, concentrated vegetation is seen only in parks or recreational spaces. This lowers temperatures on the microclimate of the park but does not have any effect on the microclimate of the neighbouring built environments. By placing vegetation within the built space of the urban fabric, the effect of UHI effect can be reduced where people live, work and spend most of their lives. Such approaches have been investigated in the fields of planning, urban design, landscape architecture, environmental engineering. Selection of right plant in the right place can be based on many aspects such as its thermal performance. It further depends on various plant typologies and their characteristics which will have significant role in urban heat balances by reducing the land surface temperature and reduce energy consumptions in the dense built up areas. It also helps to improve the microclimate performance in the built environment and also create a visually appealing environment compared to other passive techniques. This paper describes the importance of relationship between green space factor and microclimate and implementation of these guidelines in a neighbourhood with various case examples from research papers, literature and theories. The study has been carried out with on site observation and Envimet simulation methods.

1. INTRODUCTION

Climate, buildings, and green spaces have been explored worldwide by many researchers due to their interesting interrelationships and significant impacts to the environment. In recent years, urban heat island effects(UHI), induced by urban form, anthropogenic heat from buildings and Air conditioning systems have been studied extensively in cities around the world (1). Since the mid twentieth century, the global surface temperature has increased by 0.7±0.18°C during the 100 years ended in 2005. Thus the increased temperature is connected with increase in UHI through expansion of built up areas and populated area. The heat island during daytime increases rapidly and takes 3-5 hours to reach the maximum after sunset. These increased temperatures have implications on electricity, energy consumption and use of resources which inturn affect the environment. The most sustainable solution to these energy and environment problems is following more natural passive cooling techniques. Urban green spaces can directly or indirectly affect local and regional air quality by modifying the urban climates. Many studies have highlighted how landscape in urban design and planning can improve microclimate and thermal comfort (2). Plant processes such as photosynthesis, Evapotranspiration helps to reduce the Mean radiant temperature and anthropogenic heat generated from the buildings which leads to urban heat island effect. This in turn reduces the cooling load of the buildings. The environmental conditions of urban green space have significant impact on the comfort conditions experienced inside them especially in seasons of stressful climate and the development of sustainability in cities(6). Many researchers agreed that plants have an effect on the urban temperature and the cooling loads of building (6, 8). For instance the air temperature distribution was closely related to the distribution of greenery in the urban areas where for some large urban park, the ambient temperature was 2-3°C lower than surrounding built-up areas and it shapes a pleasant urban environment (14). Furthermore, the effects of plants density, plants species, plants distribution and large space of greenery give a large impact, where greenery reduce the surface temperature and urban heat effect (11). Green interventions in terms of trees, shrubs, ground covers, green roofs, bioswales or rain gardens, green walls, permeable pavement may be adopted to achieve comfort and reduce UHI in urban areas. These green interventions are to be quantified to achieve the specific green space factors. The main objective of this study is to find the effect of the green space factors in modifying the microclimate.

2. GREEN SPACE FACTOR CONCEPT

In the literature reviewed, the primary metric used to mesure the percentage of green spaces under the land cover based on the plant types such as lawns, turfs, shrubs and trees are their biological parameters such as LAI – Leaf area intensity, LAD – Leaf area density. There are several benefits associated by incorporating plants in the neighbourhood. There are remarkable efforts being made at different scales for the different types of green space factors which are developed across the world. Table 1 shows the examples of such initiatives across the world; California's attempt to reduce C02 emissions by 25% by 2020 (5); Vancouver's Eco- Density initiative (7); Portland's effort to reduce stormwater runoff (1); from an urban landscaping viewpoint, Biotope Area Factor (3), Seattle's Green Factor (10) Green Plot Ratio (15), and Malmo Green Space Factor (9), which discusses the usefulness of various Green Factor. These green rating systems are designed to examine the relationship between the Green factors or the landscape elements and their performance in the built environment. The green factor systems are designed to increase the quantity and quality of planted areas while allowing the flexibility for developers and designers to meet development standards. These studies deal the metric of green spaces at the scales from one dimension to three dimensions but there is no evidence whether these metrics are climatically sound. This study analyses the performance of these green space factors.

3 METHODOLOGY

Methods to study the green space factor in modifying the microclimate include both numerical modeling and empirical analysis, such as using on site measurements using instruments and weather data obtained from nearest weather stations. With empirical data, the study can be more specific, but have limitations on time and space. Thus, to have a theoretical understanding of performance of different vegetation scenarios and their effects on the microclimate, numerical modeling with on site observations is required. The simulation has been carried out with the help of Envi-met models and simulated alongwith initial onsite observation which was conducted on 20.03.2014 for the climate monitoring and the plant distribution was accounted. In this paper, different scenario such as (i) with existing base case, (ii) nil vegetation, (iii) with turfs and (iv) with trees was selected to assess the air temperature. For the selected sites, the green plot ratio (15) has been applied and evaluated for its performance on the microclimate.

Table 1. Green metrics and policies used around the world(15)

Category of metric	Place	Green metric	Goals	Description and characteristics	Year
One dimensional		Inventory of plants	To increase the number of plants	The number of plants being managed in an area. Simple to use for homogenous or hetrogenous plant populations. Does not provide information on plant species	
Two dimensional	Berlin	Biotope Area factor	Retain high densities of development, whilst also developing the city's green infrastructure	Attempts to account for various types of ecologically effective or environmentally friendly green systems	1994
	Malmo	Greenspace Factor	Increase of green space per inhabitant from $33m^2$ to $48m^2$ in the urban area and increase the area of accessible green space in the countryside from 2% to 33%	Quantifies the planting area. Does not account for vertical stacking.	2001
	Portland	Portland's Green Building Policy	All new City-owned facilities to include an eco-roof systems	Advancement in green roofs design to include an eco-roof with at least 70% coverage	2005
	Vancouver	Eco-Density	Building green liveable and affordable Communities	Cities' densification systems	2006
	California	California Global Warming Solutions Act of 2006(5)	Reduce GHG emissions in the state to1990 levels (25%) by 2020, and 80% below 1990 levels by 2050		2007
	Seattle	Green Factor	New developments in commercially zoned areas must commit 30% of the parcel area to urban landscaping	Attempts to account for various types of ecologically effective or environmentally friendly green systems	2007
Three dimensional	Singapore	Green Plot Ratio	Greening the buildings in cities	Sum of total leaf area developed in the site divided by the site area. Better correlation with the environmental performance of greenery	2003

3.1 AREA OF STUDY

Madurai is the oldest inhabited city in the Indian peninsula and is referred as Kadambavanam (forest filled with kadamba trees) at the banks of river vaigai. Madurai city has an area of 52 km², within an urban area now extending over as much as130 km², and it is located from 9°56′N to 9.93°N Latitude and from 78°07′E to 78.12°E Longitude. It has an average elevation of 101 meters above mean sea level. The climate is hot and humid, with rains during October to December. Summer temperatures range between 40 and 26.3 degrees Celsius. Winter temperatures range between 29.6 and 18 degrees Celsius. The average rainfall is about 85 cm and the average humidity is 65%.

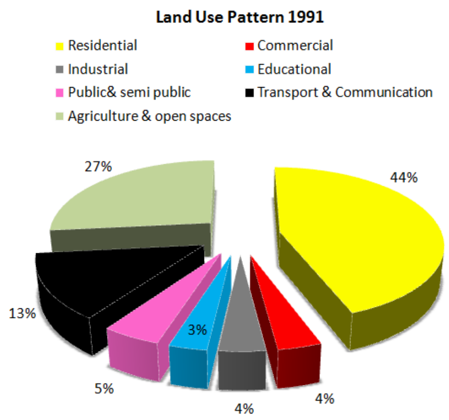

Figure 1 Land use pattern

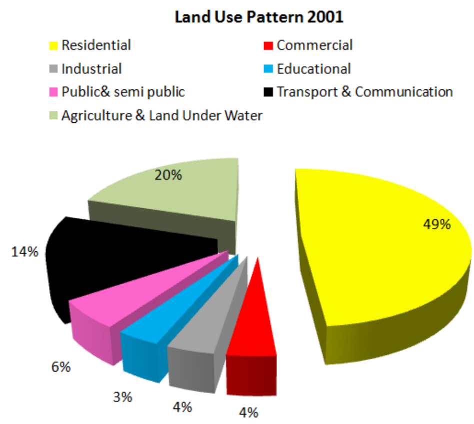

Figure 2 Land use pattern

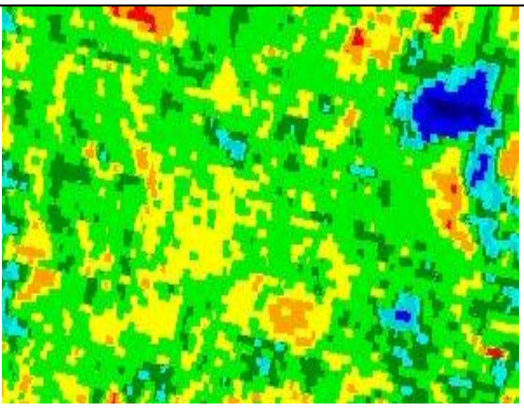

Figure 3 LST in 1991TM image. Source - Author

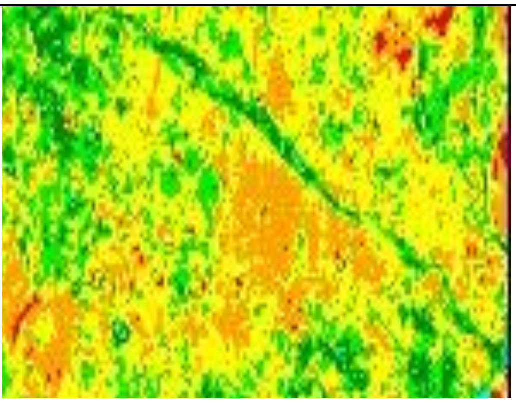

Figure 4 LST in 2001 ETM+ image. Source - Author

The impact of green spaces on the urban heat isalnd is more comprehensive if supported by the appropriate green space factors. The urbanization in Madurai has rapidly increased and has also increased land surface temperature of Madurai since 1990 to 2001. To substantiate this, study has been done with Land use patterns for 1991 and 2001 (Figure 1&2) and land surface temperature maps (Figure3&4) were prepared by using 1990 TM image and 2001 ETM+ image. Land surface temperature type indicates; "red and orange" with average temperature of 43.9°C and 41.9°C respectively for urbanized area a with a greater density of buildings and paved surfaces that absorb and retain heat from the sun, "yellow" with average temperature of 38.9°C for urbanized area a with a medium density of buildings and paved surfaces that absorb and retain heat from the sun, "green" with average temperature of 36.9°C for urban green areas, and "blue" with average temperature of 30.9°C for water bodies. This map shows that urbanization has spread rapidly from year 2001 especially in the central business district of Madurai. This rapid urbanization has contributed to the increase of urban temperature in Madurai. This map also shows how extremely green spaces are replaced by the grey spaces without considering the impact of huge loss of green space to the urban environment. Therefore, this study has examined the potential of green space factor in modifying the microclimate. Urban neighbourhoods was selected with dense (Study area 1 – Railway colony) and sparse vegetation (Study area 2 - Periyar) as shown in Figure 5 and compared with hypothetical conditions with mentioned scenarios and has been studied for their microclimatic performance is studied using micro scale model ENVIMET (4) due to its advanced approach on plant atmosphere interactions in cities. The numerical model simulates the complex urban structures with resolution between 0.5m and 10m according to the position of sun, urban geometry, vegetation, and soil by solving thermodynamic and plant physiological equations

3.2 Model and its validation

Envi-met Version 3.1 (Bruse 2013) has been employed to simulate the potential impact of urban form and vegetation on the urban microclimate for March 20, 2014, during mid summer day when peak temperature is experienced. Envi-met is a three dimensional computational fluid dynamics and energy balance model that simulates plant air interactions in urban environments with a typical horizontal resolution of 0.5m to 10m in space and 10 seconds in time for built environment from microclimate scale to local climate scale at any location. Although Envi-met mainly uses a 3D prognostic model, it also uses 1D models to transfer all data input for wind speed, wind direction, air temperature, relative humidity, specific humidity and turbulence quantities (Bruse 2004). In order to conduct the simulation, basic data about the location, cloud cover conditions, initial temperature, wind speed at 10m above ground level, specific humidity at 2500m and relative humidity at 2m are required. In addition, the initial temperature, soil temperature (at 0m-0.2m, 0.2m-0.5m, 0.5m-2m), heat transmission in walls and roofs of buildings can also be defined in the mentioned model. The model gives a large number of output data that include air temperature, surface temperature, wall temperature, long wave radiation, shortwave radiation, latent and sensible heat fluxes, PMV, PPD, and MRT as the indicators of outdoor thermal comfort. In order to achieve realistic results, a simulation of an existing urban area in Madurai was carried out and the results were compared with on-site measurement temperature (1300LST on 20th March 2014) as shown in Figure 6. Envi-met was carried out for a 24 hour period starting at 0600LST with model output for every 60 minutes, using the configuration parameters. The relationship of both results was found to be correlated with an R-squared value equal to 0.876 (Figure 6). The verification process further rationalizes the use of ENVI-met to study the microclimatic issues in Madurai with hot and humid climatic conditions.

4 RESULTS AND DISCUSSIONS

Envi-met simulation was conducted for both the selected areas and the results reveal that the green spaces play a major role in modifying the microclimate.

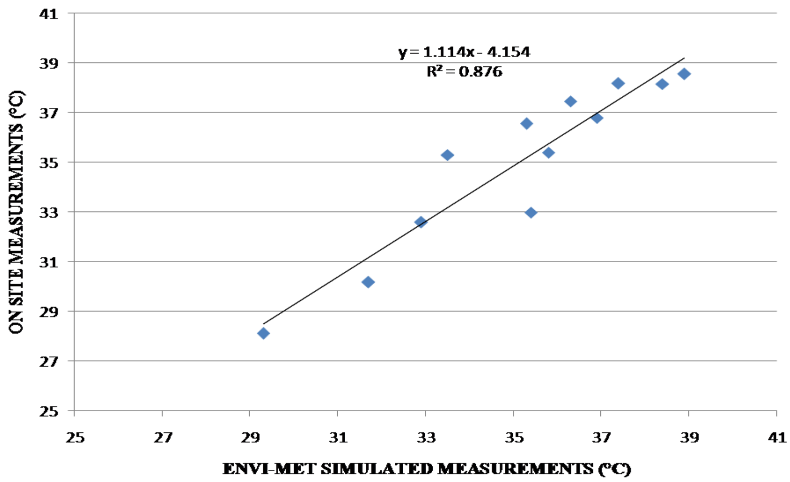

Figure 6. The relationship between ENVI-met simulation temperature and onsite measurement temperature (1 pm on 20th March 2014).

4.1 AVERAGE AIR TEMPERATURE

Figure 7 shows the average air temperature for different scenarios such as (i) with existing base case, (ii) nil vegetation, (iii) with turfs and (iv) with trees. Figure 8 shows the average air temperature for different scenarios such as (i) with existing base case, (ii) nil vegetation, (iii) with less number of trees and (iv) with increased number of trees since providing turf or lawns is not possible in this case as it has dense urban pattern with wall to wall construction.

4.2 APPLICATION OF GREEN SPACE FACTORS

Green plot ratio (GnPR) by Ong (2003) was known as an effective green assessment method to determine the ratio of green space distribution. According to Ong (2003), the GnPR has been defined as the average leaf area index (LAI) of the greenery on the site and also can be equivalently defined as the ratio of the total single-side leaf area of the planted landscape to the plot or site area. GnPR can be define as the area-weighted average LAI of a site, which account for unequal amount of area occupied by different plants in a landscape. Leaf area index can be defined as one-sided area of leaf tissue per unit ground surface area where the green plot ratio is the only green assessment method that relies on LAI.

For the selected sites, the green plot ratio (15) has been applied and simulated alongwith initial onsite observation which was conducted on 20.03.2014 for the climate monitoring and the plant distribution was accounted. This on site observation was only focused on the study areas, Madurai and during the observation the temperature found to be 31°C with clear sky conditions.

In this study the green plot ratio have been considered for all the scenarios as shown in equation 1. The green plot ratio have been carried out as following; existing base case, scenario (i) with no vegetation of 0 green area factor, scenario (ii) with lawn of green factor 0.304 and scenario (iii) only trees of green area factor 0.304 had impact on the reduction of temperatures. The calculations, assumptions, and results were given in Table 2 and 3.

Based on the understanding of the parametric study and Green space factor, the following key observations were found as given in Figure 7 and 8 which can be useful for urban planners.

First, greening is beneficial in cooling the urban environment and creating better urban microclimatic conditions for human activities at the ground level.

Second, tree planting is more beneficial than turfs or lawns (where trees provide shade for the lawns, to other vegetations and buildings) as evident from the study.

It also suggests that the green factor of above 0.45 is essential to reduce a maximum of 2°C in the built environment. Whereas in the study area 2 the temperature is reduced a maximum of only 1°C.

This also shows that the green factor of maximum 0.34 is not sufficient as it reduces about only 1°C and green factor of above 0.45 is as essential as to reduce a maximum of 2°C in the built environment.

Table 2.Green plot ratio conditions and ENVImet parametric results for study area 1

	Existing Base Case Recorded with outdoor weather monitoring station.	Existing Base Case Simulated with Envimet	Scenario 1	Scenario 2	Scenario 3
Total site area	12800	12800	12800	12800	12800

Average Temperature found byENVImet	37.8°C	37.98°C	38.1°C	37.54°C	37.24°C

5 CONCLUSION

Design strategies for open spaces and landscape in a site development not only require to accommodate their density in the site development standards, but also it plays an important role in modifying the microclimate and create thermal comfort since it controls the access of sun, light and wind. The microclimatic effect of the Green area factors were done with Envimet Numerical model. This has been done considering only the lawns and the trees. The results shows that trees perform better then the turfs or lawns. This lead to further investigate and develop green space factors for the thermal comfort conditions outdoors, based on the empirical data and numerical modeling. This Green space factor when included and applied in Madurai will help the Urban Designers, Planners and Landscape architects to decide on the percentage of green space to be included in the city which can create comfortable environment even in the urban neighbourhoods which is now available in the large urban open spaces such as parks alone. This further helps to reduce the UHI in the city which in reduce the energy consumption in the buildings.

ABSTRACT

Reducing the CO2 emission by 80% from 1990 level by 2050 is a challenging operation for the UK. This challenge has embarked the whole nation in a national exercise that involves professionals in all sectors, corporations, SMEs, families and individuals. The nation meets every day with new tasks, initiatives and incentives designed to meet that target. The built environment is one aspect of this multi-faceted exercise and within the built environment itself many aspects are being tackled. This paper evaluates the current legislations, initiatives and incentives introduced in the UK to reduce the energy demand in the Built Environment and how they contribute to meeting the UK's international obligation in cutting CO2 emission.

Incentives such as feeding tariff for renewable energy, Green Deal for upgrading buildings and many other initiatives; have been withdrawn, revised or replaced after their excessive success or unexpected failure. These actions reflect the lack of clear plan and strategy. This paper won't examine the reasons of these success or failures but will use these disruptions as a call for the establishment of serious tools and mechanisms as a platform for discussion in mitigating climate change. Although the theme of this conference is dedicated to developing world, we believe that exchanging our experiences will benefit developing countries in avoiding our mistakes and follow successful steps. There is certainly no benefit in re-experiencing same failures as the world is embarked in the same climate change mitigating exercise.

INTRODUCTION

The climate change is monitored very closely by the IPCC (Intergovernmental Panel on Climate Change), whose main task is to review and assess scientific and socioeconomic data produced globally in order to understand climate change and in particular the effect of human activity on climate change (Ipcc.). Although there is evidence of the changes in global climate in the last 10.000 years, IPCC's reports show a significant rate of increase since 1750. A date that coincides with the industrial revolution (Pearson & Foxon, 2012) which has involved intensive use of fossil fuel to run ambitious industrial ideas and increase productivity (Antràs & Voth, 2003). Since then, an ever increasing large-scale production to satisfy booming economies and people's desire to maintain a comfortable level of living standard has worsen the situation of the planet's climate.

The global warming has entered the public domain after serious research undertaken in the 1950s when scientists began assessing the CO2 effect on climate change worldwide. The sad news resulted in the whole world engaging in long debates on how best to mitigate climate change. These debates took place between governments as well as nongovernmental organisations and resulted in solutions that were interpreted by each participating country, in different ways. The goal was to reach an optimum level of CO2 emission in the atmosphere while keeping industrial and socio-economical activities moving forward to meet people's needs and expectations in a sustainable manner (Momtaz, 1996).

The aim of this paper is to present the various initiatives introduced in the UK to mitigate the effects of the built environement on climate change as well as to evaluate their effectiveness. This investigation will show that some of these initiatives are rushed which is evidenced by the fact that many of them were withdrawn or revised shortly after being introduced.

THE UK AND ITS COMMITMENT IN MITIGATING CLIMATE CHANGE

The UK as many nations started organising itself to deal with climate change throughout conventions, agendas, road maps and declarations. Le country took swift actions and made significant commitments in response to these climate change (Department of energy and climate change. May 2014).

We have to bear in mind that, despite the CO2 emission worldwide being multiplied by three since 1990, the UK are still referring to the 1990 levels in their commitment to reduce the CO2 emission by 80% by 2050. Nonetheless, even such commitments require legal and technical instruments to be honoured.

In the Built Environment, various instruments have been created to reach that goal; these instruments varied from legislations to personal initiatives where the awareness was a major driver in finding alternative solutions to tackle climate change.

THE UK MAJOR ENGAGEMENT ACTIONS IN MITIATING CLIMATE CHANGE

The UK signed international agreements and reflected on them nationally put in place policies to reduce greenhouse gas emissions relatively early as part of the international efforts to limit global warming and other effects of human induced climate change. It now has a range of measures and targets in place, underpinned by statute, to achieve the reductions and in this regard has been one of the leaders internationally. As stated by the CCCEP (Centre for Climate Change Economics and Policy): "CO2 emissions are the main focus of climate change mitigation policies in the UK as they account for around 80% of total greenhouse gas emissions".

However whilst the UK may claim, with some legitimacy, to have been at the forefront of measures and policies to tackle climate change it is less clear how effective those measures and policies have been, or indeed what the likelihood is of achieving the ambitious target of an 80% reduction in carbon emissions by 2050.

According to The Energy Saving Trust, in order to 'achieve these goals the UK needs radical change' (Energy saving trust, 2014). A report on the UK's climate change policy, in 2011, by the CCCEP concluded that 'a step-change in the pace of emission reductions is required to put the UK on the path towards its ambitious 2050 target' (Climate change policy in the United Kingdom, 2014).

Since the UK government passed the Climate Change Act in 2008 to impact positively on climate change, this long term legally binding framework requires the reduction of the UK annual carbon emissions to 154.2 million tonnes of CO2 by 2050.

To reach such level of CO2 reduction, the British Governments introduced a number of regulations and incentives at various levels. These regulations were not necessarily based on a quantitative analysis and scheduled intermediate aims based on capabilities to meet the set target. Selected regulations and incentives are shown next and vary between successful unchanged regulations to multi-updated incentives.

UK ACTIONS TOWARDS REDUCING CO2 IN BUILDINGS AND THEIR REVISIONS

1. The introduction of the Energy Performance of Buildings Directive (EPBD) in 2003 which influenced the construction industry and building renovation. However, this measure can be challenging given that the buildings' actors need to look for different means to reduce the building energy consumption and require the exploration of a huge number of possible combinations of energy-saving measures. (Hamdy, Hasan, & Siren, 2013). A recast took place in 2010 followed in 2013 by a proposal from the Scottish Government to consult on the implementation. A new change took place in 2013 as a result and the green Deal took place (Scottish Government).

   The Government introduced SAP (Standard Assessment Procedure), a method which aims to calculate and assess the overall energy use of buildings. Although this method of assessment didn't go through revisions and changes, its formulation was not practical for all buildings. This method was criticised at various levels, it still has its importance in energy use assessment of dwelling, but still controversial (Kelly, Crawford-Brown, & Pollitt, 2012). SAP calculation is a requirement to demonstrate compliance with the energy performance requirements of Part L of the Building Regulations, as well as used to demonstrate achievement of the required performance levels for sustainability benchmarks such as the Code for Sustainable Homes.

2. Building Regulations Part L (Conservation of Fuel and Power). Provides guidance on the means to comply with the energy efficiency requirements of the Building Regulations. It deals with a number of areas including insulation requirements, heating and air permeability etc. but also sets out the requirements for SAP calculations and Carbon Emissions Targets for dwellings (Planning portal, 2014). The reinforcement of the existing Building Regulation in its Part L dedicated to the energy performance. This continuously updated regulation has seen a huge step forward in regards to the minimum energy performance requirement of new buildings and refurbished existing buildings. The requirements, expressed in U-Val, are not generic to the whole building but very specific to the building's components such as the roof, wall, windows and floor.

3. The Building Regulations co-exist with other standards and recommendations that largely relate to best practice (Department for building innovation and skills, 2014), for example BREEAM and the Code for Sustainable Homes. BREEAM is an environmental assessment method and rating system for buildings which, amongst other key areas of environmental impact, addresses energy demand, consumption and CO2 emissions by promoting designs that minimise demand and consumption in buildings thus reducing carbon emissions. These instruments have been in place early enough to influence the building sector by reaching the whole building sector industry and achieve thereafter part of the goal.

4. The Code for Sustainable Homes is in effect the domestic version of BREEAM and there remains to date a mandatory requirement for new homes to be rated against the Code. However in an effort to reduce 'red tape' in the housing construction industry the government has confirmed, in March 2014, that it will be 'winding down' the Code and consolidating some of its requirements in the Building Regulations (Sustainable construction legislation, regulation and drivers, 2014).

5. The Feed-In-Tariff was announced in 2008 and introduced in 2010 to replace the UK Government grants as the main financial incentive to encourage uptake of renewable electricity generating technologies. Less than a year into the scheme, the new coalition Government announced that support for large-scale photovoltaic installations would be cut. From August 2011 the rate for installations changed. In October 2011a second review of the Feed in Tariffs for low carbon electricity generation was announced and was supposed to take an effect from 12th December 2011. In its second year, the government announced further cuts to the FIT scheme. On 5th March the tariff was cut done. This cut was originally scheduled for 12th December 2011 but was delayed. The latest cut came into effect on 1st November and this rate was set to remain until 1st February 2013). Another drop in the FIT is to take place in January 2015 to £0.13 that is a 1/3 of its original incentive of £0.43. This can't come from a strategic approach infortunatly.

6. Energy Performance Certificates (EPC) is a Post construction monitoring tool, reporting on energy efficiency of building of small scale. The buildings are then classified into categories from A to G where A indicates the best rating. EPCs are mandatory for the sale and letting of properties but they provide only theoretical ratings on energy performance based on the design and construction in conjunction with assumed patterns of use and occupation. Such theoretical assessment doesn't convey a full understanding of buildings and a more measurable approach are required to really have a clear perception of these buildings. Further collaboration between energy supply companies to provide buildings' energy consumption might give a better understanding on where these building stands in regards to their CO2 emission but not on their heating need therefore separated meter for heating and cooking where possible will narrow the potential misleading analyses given by the EPC.

7. The Display Energy Certificate (DEC) (Display energy certificates, 2014) is more of a permanent document to display. They are far more informative with regards to energy performance as they are based on actual consumption but despite the fact that there is evidence that their use can help achieve substantial reductions in energy use they are currently only a requirement for buildings that are over 500m^2 and occupied by the public sector (Fuerst & McAllister, 2011). There is more of a psychological influence on occupants to save energy but might not be effective in long term if actions are not taken forward.

8. The compulsory inspection of equipments, such as boilers, to insure their performance. This is an important measure given that 57% of energy use in the UK goes towards space heating. However, the guidelines did not insist on the best performance at this stage but a new future enforcement is due to take effect where buildings will be assessed to that level. As a consequence, many landlords might find themselves not able to rent out their properties if they don't meet certain levels of performance. (Hamilton, Steadman, Bruhns, Summerfield, & Lowe, 2013). This level of performance, although known, is still unclear on how to be reach in efficient way.

9. The Green Deal was included in the Energy Act 2011 and came into force in 2012. In 2014 a second green deal would be launched, as grants rather than the loans which underpinned the original Green Deal scheme.
   The initial Green Deal didn't take into account a socio economical and behaviour of home buyers since the deal consisted on a loan to be granted and remain with the property rather than with the initial owner, hence its failure. The Green Deal is a government initiative to try and incentivise building owners and occupiers to invest in improving the energy efficiency of existing properties by offering 'green finance' for the installation of energy efficiency measures. Taken at face value a scheme that offers the chance to fund improvements to the energy efficiency of property with the promise that the savings will outweigh the cost of the finance (the so-called 'Golden Rule') appears attractive and an effective way of targeting a big contributor, housing, of carbon emissions.

   The reality has been somewhat different with doubts over value for money (uncompetitive interest rates for the loans offered) as well as little, and often conflicting, evidence to support the government's assertion that the investment is financially worthwhile (for the occupier). Uptake to date has been very low and the initiative is plagued by the perception that neither energy companies nor the government are committed to the scheme.

   The Green Deal is an attempt to deal with the retrofit of energy efficiency measures in existing homes which is clearly is a key area to target but its apparent failure suggests the strategy is not working in its current form.

10. The GCB was set up to provide leadership to the sector on reducing carbon emissions and capitalising on low carbon growth opportunities, as well as monitoring the implementation of, actions in the Low Carbon Construction Action Plan. It was announced in February 2014 that the Green Construction Board (GCB) will continue its work on reducing carbon emissions for a further two years. The focus of the GCB over the next two years will be working towards delivering the 'ambition of a 50% reduction of greenhouse gas emissions by 2025'. It will be interesting to see what recommendations are made to achieve the 'ambition target' of 2025 that will act as benchmark for the 2050 commitment.

The above list can be extended to other actions and strategies however the message is conveyed through these actions and showing the coutry's 'rush' to demonstrate many actions towards 2050 target. Although all actions are positive in their contents, the wider vision doesn't seem to be that positive. The fact that these actions were addressed short after their applications and this reflects a quick response and therefore a close monitoring of the outcomes. Were these actions put in place for just testes? Something we won't know from diferent governements in place since?

BUILT ENVIRONMENT AND CLIMATE CHANGE

The Royal Institute of British Architects (RIBA) describes the UK government's overall strategy as 'encouraging organisations to reduce their emissions and embrace opportunities through setting regulations, establishing market-based mechanisms, providing incentives and ensuring the provision of information, advice and support'. It [the government] hopes that in doing this it will 'help to stimulate development of low carbon solutions and services and promote their uptake within the UK' (Willars, 2014).

The UK Green Building Council quotes: Construction and Sustainable Development report that states that 'energy from fossil fuels consumed in the construction and operation of buildings accounts for approximately half of the UK's emissions of carbon dioxide' and 'housing alone generates 27% of UK emissions, of which 73% is used for space and water heating' (Constructing Excellence, 2008). This means that space and water heating in UK homes is responsible for nearly 20% of the UK's carbon emissions.

Further evidence is found in the UK Government Department for Business Innovation and Skills 2010 report that estimated the amount of CO2 emissions that the construction industry can influence. It considered the life cycle of buildings from design, through operation to refurbishment/ demolition. It concluded that the industry could influence almost 47% of all the UK's emissions and in-use building emissions accounted for 80% of this figure (Department for building innovation and skills, 2014). Therefore building emissions in-use alone is estimated to account for over 37% of all of the UK's CO2 emissions.

It is not disputed that the built environment and the construction industry are major contributors to the UK's carbon emissions and therefore required to play a significant role in actions and strategies to meet the reduction targets. In the UK the means of doing this is largely through the Building Regulations. The Building Regulations are the statutory instruments that are used to try and ensure that legislated policies are acted upon.

The UK has highly ambitious targets for 'zero carbon' standards but it remains unclear as to exactly what the definition of 'zero carbon' is or how it will be reached. The Code was introduced in 2006 to help achieve the pledge that all new homes would be 'zero carbon' from 2016 but its 'winding down' is part of a wider review and plans to 'rationalise all building regulations and national and local housing standards' (UK Green Building Council, 2014). The UK Green Building Council claims that not only was the 2016 Zero Carbon target instrumental in achieving improved environmental standards and innovation in building (UK green building council, new built.2014), but also that the changes now being made will 'almost certainly result in poorer quality homes, built to lower environmental and social standards' (UK green building council-government shake-up of housing regulations likely to cause confusion, affect quality and slow down delivery warns UK-GBC, 2014).

Inevitably, opinions differ on the motivations and likely impact on sustainability of the decision to phase out the Code. The decision is based on a desire to reduce 'red tape', and in the process help to invigorate the housing construction industry. This raises an interesting point that is a basic problem for governments in tackling carbon reductions. One of the biggest reductions in carbon emissions recently followed the 2007 recession and downturn in the economy and conversely a growing economy sees an increase in output and carbon emissions. A challenge for government is to stimulate and grow economies without sacrificing climate change targets. It begs the question of whether governments can be relied upon to balance long term climate change policies over other issues such as economic growth.

One of the key issues of this study is the energy performance gap: that is the difference between the designed performance and the actual in-use performance with regards to energy efficiency and consequently operational carbon emissions. It is interesting to note that the mandatory requirements for assessing energy performance prior to construction are based on theoretical performance and that the reporting on the energy efficiency of the vast majority of buildings once completed and in use is also based on theoretical assumptions rather than actual performance. A 2012 report that analysed actual energy use in commercial properties found 'little or no correlation between EPC ratings and actual energy performance' (Jones Lang Lasalle & Better Buildings Partnership, 2014).

THE ECONOMICAL IMPACT OF MITIGATING CLIMATE CHANGE

The move to the low carbon economy cannot be without an impact as stated by Sir Nicolas Stern, who highlighted, in a world renowned report, the dramatic consequences of not acting and insisting that the economical impact of not acting is worse than acting: "The costs of stabilising the climate are significant but manageable; delay would be dangerous and much more costly." (STERN, 2007). We should emphasise that the economical aspect of mitigating the climate change was of concern at an early stage of the climate change debate. Although nations have different financial capabilities, they, nonetheless, face the same challenge. Such financial disparities were addressed in later climate change discussions and encouraging solutions where found to make it less challenging for developing countries. This was introduced in the form of CO2 trading mechanisms involving developed and developing nations as stated by the United Nation Framework Convention on Climate Change (UNFCCC) 2014).

DISCUSSION AND CONCLUSION

The concerns raised in this paper appear to be fairly consistent in saying that:

- There is a lack of clear understanding of the mechanisms and their capabilities in mitigating climate change in the UK. The withdrawn of certain initiatives based on their excessive success such as FIT was not particularly welcomed.
- Current legislation and strategies are insufficient, inconsistent and unclear from the operational perspective.
- The rate of progress needs to change radically if the UK is to have any chance of meeting its legally binding commitments by 2050. Meeting the target in advance is also problematic since this will be achieved against other needed development in the country.

In consideration of current observations and research it seems that some of the key areas of focus in order to achieve the government targets of CO2 reduction that require further investigation are:

1. Making DECs mandatory for all buildings so that the actual performance is measured rather than theoretical (predicted). DECs are also accompanied by an advisory report that identifies measures to improve the buildings' energy rating as currently there is no obligation to act on the advice in the report.
2. Legislation tends to focus primarily on new build properties. The biggest single contributor to carbon emissions from the built environment and construction is operational carbon from residential property (space and water heating) and the vast majority of dwellings (around 80%) that will be in use in 2050 have already been built. Therefore retrofit should be the main focus to reduce in-use operational carbon emissions.
3. The way the building occupiers behave and use their buildings is hugely significant in terms of energy consumption (and therefore carbon emissions), yet existing assessment methods such as SAP ratings and EPCs are not able to account for the complexities and variations that accurately reflect how significant occupant's behaviour is.
4. The government needs to increase its efforts to incentivise people and organisations to want to make their buildings more energy efficient. A small percentage will pursue a low or zero carbon building because of an ideology or ethos but the majority will respond more to legislation and/ or financial incentives.
5. The revisions of many initiatives including legislations and incentives the UK saw in the last decade reflects a clear uncertainty in regards to the effectiveness of what is made in place to mitigate climate change.
6. There is still a lack of strategy to quantify and measure the potential outcomes of these initiatives hence their suspension or revision.
7. There is not enough measuring of the actual performance and too great an emphasis is placed on the theoretical or predicted performance based on design assumptions.
8. Not enough is done by the government to make it easy and cost effective for building owners and occupiers to implement energy efficiency measures in existing buildings with an over reliance on 'encouragement' and 'hope' that the market will develop low carbon solutions that are taken up to 'solve' the problem.

It is understandable that a start needed to happen to mitigate climate change but the lack of expertise worldwide has led to a period of trial and error. This period lasted for more than it should and the time has come for actions based on strategies and undertaken by experts in consultation with all stakeholders. Actions should be seen in a wider context and overseen by multidisciplinary teams to anticipate dysfunctions that can happen along the way as was stated in this paper.

This period of trial and error was certainly costly, time and cost wise. This lost won't be passed on to other nations who joined lately the mitigating climate change actions. PLEA is certainly the hub where experiences are exchanged to move on from trials actions to planned strategies.

ABSTRACT

This is a presentation showing the procedures and results obtained from the analysis of the energy transmitted in walls and roofs of the selected homes in the south zone of the state of Tamaulipas, one of the five zones established in the "Development and validating of a methodology to estimate the impacts in the saving of energy for the use of passive-constructive systems in the edification for different climates in México" project, which third stage of execution's objective consisted in making use of the Ener- Habitat software, developed during the project's second phase. This research was sponsored by the Energy Sector Sustainability Fund SENER - CONACYT S0019 - 2009-01 call log under the project No. 118665. With this software the comparative energy expenses of four constructive systems for walls and three constructive systems for roofs were determined. With the acquired information and through the use of the methodology developed to estimate the impacts on energy saving, the energetic price of each of the constructive systems was evaluated. With the acquired results it was determined which were the walls and roofs of less energy expense for the study zone.

INTRODUCTION

It is essential in locations which have high solar insolation and large temperature variations through the day to evaluate the thermal performance of building systems. This emphasizes G. Barrios, P. Elias, G. Huelsz and J. Rojas (2010) who state that "in climates where solar radiation is significant and the daily temperature swing is important, as in most of Mexico, the heat transferred through walls and roofs must be analyzed as a function of time. For these climates, the steady state heat transfer model from a period of time can lead to the improper selection of materials".

The objective of this project is to provide guidance for the selection of suitable constructive systems for the warm-humid climate of the southern part of the state of Tamaulipas to help improve the thermal comfort inside the home without using air-conditioning systems.

The study was divided into three parts:

A. Apply the methodology established in the project protocol .

B. Analyze the results derived from the Ener - Habitat program[1] construction systems of the

[1] For further information consult: http://www.enerhabitat.unam.mx/Cie2/

Author A is a Professor and researcher in the Centro de Proyectos Medioambientales in the FADU, UAT, Tampico, México. Author B is a Professor and researcher in the FADU, UAT, Tampico, México; Author C is a Professor and research in the Centro de Investigaciones Aplicadas in the FADU, UAT, Tampico, México.

selected walls and roofs, comparing energy costs.

C. Get the conclusions of the investigation in the study area.

This also implied a review of climatic factors existing in the study area formed by the municipalities of Tampico, Madero and Altamira, prevailing therein a warm-humid climate with average summer temperatures of 29°C in summer and 21°C in winter. The variations of weather through the year fluctuate in summer ± 10°C and in winter ± 8°C.

METHODOLOGY

As part of the established objective, the following steps to define the selection of constructive systems for the warm-humid climate of the study zone were generated.

A. Twenty five housing buildings were selected in the south zone of Tamaulipas for investigation.

B. A data sheet designed to provide the information of each of these homes on their behavior with regard to the thermal comfort inside, provided the m2 of property, the square meters of construction, typology, orientation, vegetation and exterior colors.

C. Determine which passive systems impact on each housing building.

D. Analyze the constructive systems of walls and roofs using the software. Ener-Habitat solves the time dependent one dimensional heat transfer equation using the sol-air temperature at the exterior. At the inside, the indoor air temperature can be assumed constant (air-conditioned) or as a function of the heat transferred through the constructive system (free running).

E. Compare, using the Ener- Habitat software, the two most widely used construction systems in the area which transmit less energy for walls and roofs.

F. Suggest other systems of walls and roofs in different layers, so as to establish the best benefit cost.

G. Different layers of walls and roofs were proposed which were analysed for their energy-cost with the information provided by the Ener-Habitat software.

H. Determine which were the final layers of walls and roofs of lower expense and energy-cost of the climatic zone of study.

RESULTS

With the information gathered in the data sheets of the 25 homes tested, it was determined how passive systems impacted in each of these homes .

It was shown on a study which were the constructive materials for walls and roofs more widely used. This information was used to feed the Ener-Habitat software which steps are:

I. Select the construction system (wall or roof). Determine whether the layers are homogeneous or not and understanding that homogeneous are those with a single material and no air gaps.

II. The following information is selected from the database:

   a) The city where the calculation will be made: in this case Tampico.
   b) The time period analyzed: annual or a specific month.

c) Use of air-conditioning: yes or no.

d) Select the tipe of construction element: roof or wall.

e) Number of building elements to compare: 1 to 5.

III. Determine the amount of building elements to be analyzed, for all the following (Image 3):

a) Orientation: north, south, east, west, other.

b) Tilt angle: 0º to 90º.

IV. The layers of the construction system from 1 to 7 are introduced to be analyzed

V. Determine the absorptance, the thickness and the material of the outer layer of this system. And subsequently, determine the thickness and the material of the following layers. Because the time dependent heat transfer equations are solved, being the thermal properties needed for the evaluation the thermal conductivity, the density and heat capacity, as well as the width of each layer.

VI. Finally, after entering all the data, the software shows the results from the Ener-Habitat through tables and graphics .

Image 1. Selection of layer material.

The calculation of the energy transferred to the two different wall construction systems to compare the walls and roofs of the building envelope used in the area of Tampico was made considering that all the walls are west facing. This was done in order to compare them regardless of orientation.

In Table 1, the two types of walls most used in the zone are shown. Percentages of the construction systems used in homes as well as the transmitted energy values are included. Each system has two extreme values of transmitted power; the minimum value corresponds to the wall that transfers the least amount of energy and the maximum value corresponds to the wall that transfers more energy, classified within the same type.

Furthermore, the values of energy transmitted in the same type of construction system presented in Table 1 are associated with walls with clear exterior colors, which have low solar absorptance (A). Without air conditioning, it is observed that the energy transmitted by the walls with no homogeneous layer (wall of hollow concrete block) is 2.56Wh/m^2 day. This allows us to affirm that the walls with no homogeneous layers and more space between their inner sides are more suitable for homes without air-conditioning operating in southern Tamaulipas.

The calculation of energy transmitted in the walls north, south, east and west to find the best orientation and also using white colors with absorptance 0.1 was found to be the most used in the building systems in the area.

The most energy transmitted is from the wall facing west with an average of 4.80Wh/m2 per day and the wall with less energy is facing east with an average of 3.62Wh/m2 per day and therefore being the best orientation for the zone.

Table 1. Result rates of transmitted energy in the wall construction systems.
Source: Created by researches with Ener-Habitat (2012).

Wall construction system	Label	% Construction systems	Without air conditioning Energy transmitted warmest month (Wh/m2 day)
Hollow concrete block 10cm	BH_acay_10	36.0	19.12
Hollow concrete block 15cm	BH_acay_15	64.0	2.56
Total non homogeneous construction systems		100	
Total housing represented		1325	

The best wall construction systems without air conditioning is using hollow blocks of 15cm with 2.56Wh/m^2 per day, in second place, with a bigger difference, is using hollow blocks of 10cm with 19.12Wh/m^2 per day.

The wall construction system non homogeneous to analyze the effect of color is shown in Table 2.

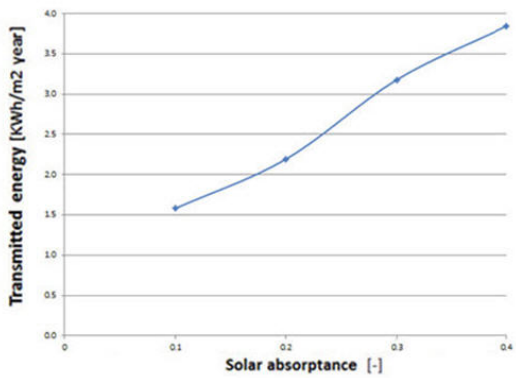
Table 2. Specification wall construction system used to study the effect of color.

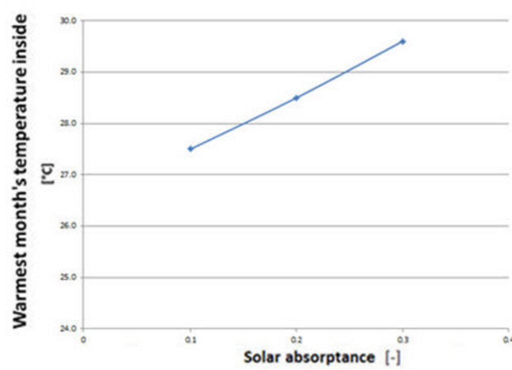
Construction system components (outer layer → inner layer)	**Thickness (cm)**
Sand-cement mortar	1.50
Hollow concrete block	15.00
Plaster	1.50

With the Ener-Habitat software solar absorptance varied from 0.1 to 0.7 without air conditioning during the critical summer month of August. The transmitted energy increases linearly with solar absorptance 0.4kWh/m2 per year for each 0.1 of solar absorptance, is shows in graghic 2.

The average interior temperature in the warmest month also increases linearly with the increase of solar absorptance as shown in figure 3. For A = 0.1 the average temperature is 27.5ºC, while for A = 0.3 is 29.6ºC. In this case, the increase is 1ºC for every 0.1 increase in solar absorptance. For this reason light colors are recommended in the outside of the walls, especially the west and eastern walls, which receive more solar radiation is shows in graghic 3.

The evaluation of energy cost, using the Ener- Habitat software, was conducted using horizontal roofs. Two types of homogeneous roofs were used, concrete ribs and polystyrene blocks of 10cm and 15 cm. The systems were evaluated without air conditioning.





Graph 2. Transmitted energy as a function of solar absorptance on the wall. Graph 3. Indoor-air-average temperature as a function of solar absorptance on the wall.

Table 3 shows the percentages of each type of construction systems used in homes as well as the transmitted energy values. The best rated roof construction system shows that the transmitted energy is of 8.55 Wh/m^2 per day. ||

Roff construction systems	Label	% Construction system	Without air condition Energy transmitted warmest month (Wh/m2 day)
Concrete rib slab and polystyrene block 10cm	NeCa_cfy_10	16.0	9.31
Concrete rib slab and polystyrene block 15cm	NeCa_cfy_15	84.0	8.55
Total non homogeneous roof construction systems		100	
Total housing represented		1325	

Table 3. Result Rates of transmitted energy in roof constructive system.
Source: Created by researchers with Ener- Habitat software (2012).

To calculate the cost-benefit of wall construction systems, three systems were used: the first system is a brick wall with an exterior and interior finish of sand-cement mortar of 1.5cm, the outer surface being white with a solar absorptance of 0.1; the second being a wall of compressed earth block 14cm thick, with an interior and exterior finish of sand-lime mortar 1.5cm with solar absorptance of 0.10; which mechanical behavior is shown in table 4. The third is a set of five layers, two layers of compressed earth block joined by a sand-lime mortar being the same used for the interior and exterior layers.

Dry condition		Humid condition	
% Dry cement	Resistance Kg/cm	% Humid cement	Resistance Kg/cm
6%	41.40	6%	41.40
8%	77.72	8%	44.63
10%	120.74	10%	44.63

Tabla 4. Mechanical behavior, compressed earth block.
Fuente: Roux (2010).

The analysis for the proposed wall construction system is to compare the cost-benefit factor that obtained from the product of the energy (E) for the cost (C) of the 3 proposed systems, taking care that the standard cost (Cu) is not too high.

Table 5 shows that "Wall One" transmits more energy (E=1.20) than the "Basic Wall", its cost is equal to the "Basis Wall" (C01.0), so that a cost- benefit factor is E*C=1.20. "Wall Two" transmits a fraction of energy E= 0.70, and has less cost than the "Basic Wall" (C=0.70) and the cost- benefit factor is E*C=0.49. "Wall Three" transmits less energy than the "Basic Wall" (E=0.10), the standard cost is C=1.10 and its cost- benefit factor is E*C=0.11.

"Wall 3" is the one with the lowest cost-benefit factor E*C = 0.11 and this cost is even higher than the basic system. Note that this type of construction system with double compressed earth block 32cm thick is not currently on the market in the area.

For the proposed roof construction system, the same methodology for walls is used.

"Roof One" is a conventional slab of reinforced concrete; while "Roof Two" has in addition a layer of polyurethane foam of 2.5cm of thickness. The two systems have an exterior finish of white acrylic waterproofing (absorptance of 0.20) and an internal plaster finish.

Wall construction systems	**α [-]**	**Layers**	**e [m]**	**Eu [Wh/m^2 day]**	**Cu [\$/m^2]**	**E* [-]**	**C* [-]**	**E*C* [-]**
Basic Wall	0.1	sand-cement mortar	0.015		85.8			
		hollow concrete block	0.150		151.6			
		sand-cement mortar	0.015		85.8			
Total basic wall			0.150	2.056	484.0	1.00	1.00	1.00
Wall One	0.1	sand-cement mortar	0.015		85.8			
		brick	0.160		143.0			
		sand-cement mortar	0.015		85.8			
Total Wall One			0.170	3.035	314.5	1.20	1.00	1.154
Wall Two	0.1	sand-lime mortar	0.015		40.0			
		compressed-earth block	0.140		140.0			
		sand-lime mortar	0.015		40.0			
Total Wall Two			0.170	1.90	220.0	0.70	0.70	0.50
Wall Three	0.1	sand-lime mortar	0.015		40.0			
		compressed-earth block	0.140		125.0			
		sand-lime mortar	0.010		40.0			
		compressed-earth block	0.140		125.0			

		sand-lime mortar	0.015		40.0			
Total Wall Three			0.320	0.375	370.0	0.10	1.10	0.168

Table 5. Comparison of wall construction systems in Tampico.
Source: Created by researchers (2013).

Table 6 shows that "Roof One" transmits more than twice the energy value of the "Basic Roof", with E = 2.4 which has a standard cost of C = 0.9 and a cost-benefit factor E * C = 2.16. "Roof Two" transmits a normalized energy E = 0.1, and has a cost of C = 1.0 as the "Basic Roof" with a cost-benefit factor E * C = 0.10.

Roof construction system	α [-]	Layers	e [m]	Eu [Wh/m^2 day]	Cu [\$/m^2]	E* [-]	C* [-]	E*C* [-]
Basic Roof	0.10	acrylic waterproofing	0.001		70.0

CONCLUSIONS

The thermal performance of a house depends on many variables; most of them derive from the architectural design, especially, the morphology rather than the materials and construction systems; however the knowledge and use of thermophysical properties of materials is an aspect that can more easily be subjected to regulation. Some decisions regarding the selection of materials can contribute to the better performance of the building, particularly if the materials are appropriate to the environmental conditions of a region.

The study in the area has shown in its initial stages that the construction processes used for architectural housing envelop are not the most appropriate. So to continue analyzing and comparing these processes, it has been established that in the case of the walls, the compressed-earth block has a better thermal performance than the traditional hollow-concrete block used for building walls. For roofs, the results of the analysis showed that the lightened layers (polystyrene foam and reinforced concrete) are less efficient than the reinforced concrete with polystyrene foam.

For the south zone of Tamaulipas, where a warm humid climate prevails, the construction systems recommended without air conditioning are:

For walls, a double compressed earth block with a thickness of 29 cm and an outside and inside finish of sand-lime mortar 1.5cm thick using white exterior colors and a solar absorptance of 0.1 are proposed. The energy transferred from this construction system is 0.10 used and its cost is 76 % of the value of the most used in the zone, with a value of the cost -benefit factor of E*C=0.11

For roofs, a reinforced concrete slab of 12 cm with a layer of polyurethane foam 2.5cm on the top and a finish of acrylic waterproofing 1cm thick using white colors with a solar absorptance of 0.10 and in the interior a plaster of 1cm thick is proposed. The energy transferred from this construction system is 0.1% of the value of the most widely used in the area with a cost-benefit factor of E*C=0.10.

For the south zone of Tamaulipas, where a warm-humid climate prevails, the dwellers usually have mechanical ventilation, like air-conditioning, to improve the thermal confort.

The study showed that the construction systems proposed and mentioned above were efficient for thermal confort even without using air conditioning.

ABSTRACT

The quality of urban life and urban experience is being compromised regularly in urban areas; one primary aspect being continuous urban climate degradation because of concentrated anthropogenic intervention in natural climate. As a result of rapid urban sprawl, drastic modification of the natural setup are common all around; like transformation of surface cover, alteration of watersheds and natural drainage, devastative destruction of natural flora and fauna, which in turn deteriorates the overall urban experience. On the other hand, urbanization is the necessity to sustain the economic growth and overall prosperity of the population in the present global scenario. Maintaining the quality of urban experience is one of the toughest challenges to the planners, urban designers and architects.

The researchers are investigating on the impacts of modified urban climate in terms of degraded air quality, thermal discomfort, unbalanced hydrological cycle, and various socio economic impacts as a result of the same. Urban physics is increasingly gaining importance in the research world as a tool to mitigate the urban climate and improve the overall living experience in urban areas. Urban physics is basically an inter-disciplinary approach combining physics, environmental chemistry, aerodynamics, climatology, mathematics and statistics, and most importantly urban morphology. But the real-life application of the knowledge acquired is limited. The pattern of urbanization and the main trend of building our cities remained primarily unchanged.

This paper will focus on different types of researches carried out so far in this Urban Physics domain, and their findings. This state of the art review will also provide a scope for the present authors to identify application potential of different researches in real life scenario. This can bring out scope for further research extensions on the basis of gaps found in research findings.

INTRODUCTION

The planning and designing of urban areas has taken a radical paradigm shift in the last few decades in the developed nations regarding the environmental sustainability. The change transcends from the early energy efficient buildings to the present net positive energy, intelligent buildings, which is really a big step towards the mitigation of the problem of climate change issues and global warming. The awareness of the people, encouragement from the government and social motivators played a great role to bring the wind of change.

The 20th century tendency of "design whatever the client wants, mostly on the basis of cost or aesthetics" (Butler, 2008) is an anomaly and hardly ever leaves much impact in our 'ecological age' (Head, 2008). Presently most of the buildings and urban settlements are designed in a much sustainable way remembering their context and subsequent environmental impact. But, climate-responsive design is becoming more and more difficult due to rapidly changing urban climate and the buildings are depending more and more on artificial cooling, mechanical ventilation and artificial lighting even at daytime. This problem becomes more traumatic in the urban areas of developing nations because of their high density and higher insolation which is further deteriorated due to tremendous population pressure, lack of financial support, political ill-will and ignorance of common mass to retrofit the urban growth pattern for a more positive outcome. The deteriorating urban climate casts doubt on the efficiency of traditional Indian design philosophy of open buildings with fuzzy demarcation between the inside and the out.

This rapid urbanization demands sprawl of the city boundaries and densification of the urban tissues as well. The latter frequently results in the erection of tall structures along narrow streets and complete eradication of green spaces. As a result of the altered climatic balance, the air temperature, humidity, air pollutants and concentration of Suspended Particulate Matters (SPM) in air rises, worsening the quality of life in urban areas by the decreased thermal comfort, acute air pollution, frequent urban floods and increased energy consumption.

In order to apprehend all the problems of urban areas, it is essential to look into the physical properties of the various elements of urban climate. Urban physics is the engineering discipline that establishes the interrelationship of the transfer of heat, wind flow, moisture, pollutants, light and sound in urban areas to have a better understanding on urban climate. The aim of the study of urban physics is to provide an outdoor and indoor built environment that is healthy and comfortable taking into account of existing and future economical, ecological and climatic constraints.

Presently most of the researches in urban physics focus on environmental degradation in urban areas taking into account the Urban Heat Island, evapotranspiration, wind driven rain, pollutant dispersion, wind turbulence etc. Techniques like advance measurement of climatic parameters in boundary layer, sophisticated modelling tools based on Computational Fluid Dynamics (CFD) and wind tunnel simulations are combined together to obtain knowledge about heat, moisture and air flow starting from individual building scale to neighbourhood and entire city scale. The study of urban physics is helping the researchers a lot to understand the urban climate and finding out solution for better urban experience.

OVERVIEW OF URBAN PROBLEMS

Urban areas are plagued with various issues like outdoor thermal discomfort, extreme air Pollution, Urban flood, Low water table, loss of natural vegetation etc. these are basically a result of the interaction between some more fundamental inherent and external factors. If these fundamental issues are understood first, it will be easier to formulate some streamlined mitigation strategies in order to make cities a better place for living. Issues related to the design of urban areas like the materials used to cover the surfaces, placement of plazas and courts, alignment of trees and vegetation etc. play a vital role in urban thermal dynamics. Based on the principles of urban physics high performance computers analyze huge data sets collected by the instruments and help to understand various responsible factors and the interrelationship between them. The most important issues and their impact on urban climate are described below stating their causal relationship with other factors.

Transformation of Urban Surface:

The urbanization of the natural landscape through the replacement of vegetation with roads, bridges, houses, and commercial buildings has dramatically altered the temperature profile of cities. In fact, even within a city, different zones have different temperature profiles, dependent on their surroundings, type of surfaces, and characteristics of ground cover. Urban areas are characterized by dry, impervious surfaces, such as conventional roads, roofs, sidewalks, and parking areas. As cities grow, more greenery is vanished, and more surfaces are either paved or covered with buildings. The transformation in ground cover consequences in less shade and evapo-transpiration to keep urban areas cool. Lesser evapo-transpiration from paved and built up areas contributes to the rise of ground and air temperatures. These transformations affect the natural hydrological cycle within the urban area, leading to extreme surface runoff, reduced baseflows and infiltration, greater amounts of non-point source pollution when compared to areas of a more rural nature, and especially forested areas.

The surface transformation brings in consequential changes in urban hydrologic cycle that contributes to greater localized flooding potential, water bodies that harbour more nutrients and other chemicals, resulting in a greater growth of algae and reduced diversity of fish and wildlife, and a general overall decline in the aesthetics of urban water resources.

Formation of Urban Heat Islands:

In most cities, urban air temperatures are generally greater than their corresponding rural counterparts. This occurrence, the urban heat island (UHI), has been known since the turn of this century and has been well documented (T.J. Chandler, 1960), (T.R. Oke, 1987), (T.R. Oke, 1988). The fluxes of heat, moisture, and momentum are significantly altered by the urban landscape and the contrast between the urban and 'undisturbed' climates is further enhanced by the input of anthropogenic heat, moisture, and pollutants into the atmosphere. It has been observed that the heat island intensities can go up to 10^0C in Indian cities (Pune) (Santamouris, 2001). The probable causes of the formation of UHI as suggested by oke (1982) are as follows:

i. Trapped short and long radiation between the buildings.
ii. Reduced Sky View Factor (SVF) resulting in decreased long wave radiative heat loss
iii. Increased heat storage in urban construction materials
iv. Abundant anthropogenic sources of heat and moisture from fuel combustion
v. Reduced evapo-transpiration
vi. Reduced wind speed resulting in reduced convective heat removal

Though UHIs are not always unfavorable for cold climatic regions (Erell et al., 2011), it substantially increases the cooling load in warm climate and causes serious effects on inhabitants regarding the comfort and health issues. The increased urban temperature not only creates acute heat stress, but it also leads to psychological and behavioural changes along with the reduction of human physical and mental performance which leads to lesser productivity (Evans, 1982).

Increased Energy Demand:-Increased energy demand costs the consumers and municipalities more energy related expenses to maintain the desired comfort levels. The heating and cooling load of a building depends on the climate to which the building is exposed. Buildings located in the same area can have entirely dissimilar energy consumption pattern due to altered local microclimates. High ambient temperature increases the cooling load and energy consumption as well. It has been stated that for US cities the peak electricity loads increase by 1.5−2 % for a temperature increase of 1 ◦F (Akbari et al. 1992). A number of studies has been carried out using urban physics to look into the effects of urban heat island on various cities like Athens (Santamouris et al.2001), London (Kolokotroni et al. 2010) (Kolokotroni et al. 2006), Kassel (Schneider & Maas, 2010), Tokyo (Hirano &Ohashi, 2009) etc. All studies indicate a substantial impact of the increased urban temperature on the energy consumption of buildings.

Wind movement:

Wind movement in urban areas is much restricted due to the high building density. It results in low air exchange and lower the potential of air circulation in and around the buildings (Hirano &Ohashi, 2009) (Ghiaus et al. 2010).

Convective heat transfer and evapo-transpiration is also affected by lower wind speed. This reduced heat exchange results in excess heat storage in the urban built environment and raises the temperature of urban microclimate which again increases the cooling demand of indoor spaces. As a result of the entrapped solar radiation, the building skin temperature is always higher than the ambient air temperature (Allegrini et al. 2011).

Air Pollution: -

Generation of more electricity by power plants leads to higher emissions of sulfur dioxide, nitrous oxide, carbon monoxide, and suspended particulate matters, along with carbon dioxide. Development of urban heat islands often escalates the formation of photochemical smog, as ozone precursors like nitrous oxides (NOx) and volatile organic compounds (VOCs) reacts photochemically to form ground level ozone.

As the intrinsic characteristics of the natural landcover is transformed in the urbanization process, the energy exchange which takes place within the boundary layer are highly affected. Transformation of the natural ground cover influences the local (microscale), mesoscale, and the macroscale climate and disrupts the natural route of energy flow through the land, atmospheric and water cycles.

Planning Issues:

A number of planning related issues are responsible for continuous degradation of urban climate. In most of the cities, urban growth happens in a haphazard way without proper planning. Though the urban development guidelines tell some sort of indirect guidelines, the planners and urban designers often neglect the issues. In most of the cases they only visualize the space but fail to apprehend impact of the proposed development after their construction on urban climate. The climatic data that are taken into account, mostly collected by the weather stations which are placed at a much higher height. The actual ground level climatic parameter and the impact of local anthropogenic factors like mutual shading and reflected heat from surroundings, very often remain unnoticed.

Absence of mandatory energy efficiency codes and the resulting energy wastage from buildings also play a vital role in deterioration of urban climate. Building energy efficiency policies and programs are mostly in an active design stage with limited implementation to date. Decision-making authority at the national level is spread between several agencies and program design and implementation responsibilities are spread across a large number of state and municipal agencies, resulting in a diversity of implementation regimes and little coordination. This micro level reduction in energy use can cumulatively make a great impact on improvement of urban climate.

The role of urban physics in better appreciation of the problems of urban climate is indisputable. A lot of researchers are working in this field presently in order to solve the problems generated by rapid urbanization in various parts in the world. For an in depth appraisal of urban climate in urban neighbourhoods and street canyons, the combined effect of solar radiation, wind flow and evapotranspiration is studied. Modelling and simulation of various cases are performed using computational fluid dynamics (CFD), Radiation simulation and whole building simulation tools. Wind tunnel simulations are often carried out to validate the CFD simulation. By varying the various parameters of the model (like building density, green plot ratio etc.) the impact on microclimatic variables like outdoor temperature, wind speed etc. are observed and optimum solution can be proposed.

APPLICATION OF URBAN PHYSICS

Urban physics not only helps a lot to identify the problems of urban areas but also has the capability to suggest the optimum solutions of the problems.

A substantial amount research has been done to reduce the detrimental impact of urban climate change which suggests various measures like the use of evaporative cooling from ground level (Kruger and Pearlmutter, 2008) and rooftop water bodies (Runsheng et al.,2003; Tiwari et al.,1982) or make use of evapo-transpiration from wetted ground. Alternatively the design of the buildings with lesser exposed flat surfaces to control the direct solar access and aerodynamic design of the building can facilitate wind movement in and around it to improve the urban microclimate.

Considering the context of cities where the high humidity level, acute shortage of land is a burning issue, the solutions mentioned above are not feasible. As of today, most of the buildings in cities of the developing nations are built without any professional input and custom made passive design solution for every single building is a farfetched dream. Rather the protection of existing landscape by facilitating urban forestry, increasing the surface albedo by applying reflective materials especially on horizontal surface and plantation of shade providing trees along the road and around the buildings seem to be a more implementable solution. Among all known strategies of urban climate mitigation, a few, befitting the present context are discussed below.

Implementation of Urban Green Infrastructure:

‘Green infrastructure’ (GI) is a term used to delineate a network of greenways, parks, and untransformed open spaces, which are basic modules of urban environments (Benedict and McMahon 2006). (Kambites and Owen 2006, 484) specified that green infrastructure denotes “connected networks of multifunctional, predominately unbuilt, space that supports both ecological and social activities and processes”. These systems provide assorted psychological, economic, social, and environmental benefits to urban individuals and communities (Forest Research 2010); (Manning 2011), and are essential in city planning and design (Walmsley 2006). Green infrastructure focuses on strategic planning to identify and protect wetlands, forests, and other natural components that deliver crucial ecosystem services.

GI includes the community “greening,” in which trees and plants are used tactically for stormwater management and other functions in urban areas. Urban greening ranges from planting streetside trees, installation of high albedo surfaces and rain gardens to installation of green roofs and planters on high-rise building balconies. Urban greening is very important to mitigate the extremities of urban climate and it provides several types of additional benefits to the urban community including richer biodiversity, pleasant visual experience, reduction of stormwater runoff and more groundwater recharge.

Green roofs:

Installetion of green roof can passively cool the air above it and the indoor space below, (Köhler, 2004) (Teemusk and Mander, 2009) reduces the stormwater runoff, tackles air pollution by absorbing the pollutants and Suspended Particulate Matters (SPMs) and so on. The higher reflectivity of the foliage of the trees compared to common roof materials results in lesser absorption of radiated heat. Their higher emissivity also facilitate long-wave radiation and so radiant cooling (Gaffin et al., 2005) (Gaffin et al., 2006).Green-roof shades the roof slab by obstructing solar radiation. It offers thermal insulation to obstruct heat absorbed at the upper surface toward the roof slab (Lazzarin et al., 2005) (Getter et al., 2011).

Use of High Albedo Surface:

Roofs and pavements constitute around 60% of urban surfaces in many urban areas (Akbari et al., 2003) (Rose et al., 2003) (Akbari and Rose 2001). It is also demonstrated in many studies that an increase of roof reflectivity from 10-20% to 60% can generate energy savings excess of 20% in many cities. Increase of albedo of roofs and pavements can improve the air quality and reduce the summertime temperature in urban areas (Taha 2001) (Taha et al. 2000) (Rosenfeld et al. 1998). Due to the increased reflectance of urban surfaces some amount of incoming solar radiation can be reflected back and can counter global warming also (Kaarsberg and Akbari, 2006).but this strategy can only work in the case where the solar radiation is reflected back to the space and not entrapped between the building due to multiple reflections.

Promotion of Urban Forestry:

Urban forests can ameliorate the urban climate by restricting direct solar radiation, facilitating wind movement, removing SPMs and pollutants by the means of bioretention. It can lower the overall temperature of the surrounding by at least 2 ^{0}C-8 ^{0}C by the means of increased evapo-transpiration (Oke, T.R., 1987), (Taha et al, 1989). The shade provided by urban trees can be the single most important parameter to increase the overall thermal comfort as the direct solar radiation has the maximum impact on the surface energy balance (Taylor and Guthrie, 2008). The most favourable design solution is a layout where the buildings and trees together mutually shade the open spaces and roads (Emmanuel and Johansson, 2006), (Erell, 2008).

Policy Level Mitigation Strategies

Planning policies, guidelines and development control regulations actually determines the urban geometry. Though there is a subtle linkage between policy framing and urban physics, appropriate planning and development control regulations can facilitate the solutions that came out from simulation of various city models. At the same time, proper implementation of those guidelines should also be ensured.

Urban geometry has a strong influence on urban climate and the comfort level. It has been observed that a compact urban form with very deep street canyons and lower sky view factor (SVF) can create lower temperature (Cool Island) providing shade to the pedestrians in hot dry climate (Pearlmutter et.al. 1999) (Givoni,1998). On the contrary, dispersed urban forms create an extremely uncomfortable environment in the summer. So urban physics can indirectly guide the framing of building bylaws of a city depending upon its climate.

From the above discussion it is understood that urban physics not only gives the researchers an in depth knowledge of the problems regarding urban climate but also helps to find out the solutions for the same. The advancements in this field of research will certainly help to build better cities with better living experience.

INTEGRATION IN URBAN DESIGN

The comfort level of cities are highly compromised due to their high pollution level, formation of UHI, and reduced thermal comfort. Framing the Urban design guidelines according to the findings of the researches following the principles of urban physics can can lead to the optimum urban setup. Taking the case of a city in warm humid climate, it can be observed that the stagnant air mass inside the city helps to form UHI, rises the humidity level and concentrating the pollutants and SPMs which altogether deteriorates the urban experience. But improvement of wind movement inside the city can substantially improve the scenario. Strategic placement of the tall buildings in the urban fabric can extensively improve the wind flow in the city. But placing the tall building in a dense pattern restricting the wind penetration inside the city is not recommend in this particular case. So setting the building bylaws in favour of higher FAR and lower ground coverage in some strategic plots and designing the urban area in accordance with it can be very helpful to improve the outdoor comfort and reduce the outdoor temperature which results in substantial energy savings.

But this same urban setup can become incompatible in the case of cold and windy cities. The opposite approach, i.e. clustering of tall building in the path of prevailing wind restricting the wind flow can reduce the pedestrian level wind movement to a comfortable level and prevent the conduction heat loss from building skin. Appropriate and contextual urban design guidelines understanding the principle of urban physics can thus improve the urban experience and reduce the energy demand as well.

In the case of a number of tropical and subtropical coastal cities, moist air comes from the seaside.

The hot urban area underneath heats up the moist air and it rapidly goes up followed by sudden cooling and formation of dense clouds. But the wind drives the clouds on the other side and heavy rainfall happens in the opposite side of the city of the direction of that incoming moist air from the sea. This unequal heavy sudden rainfall results in unprecedented high intensity urban flooding in those cities. Cities like Kolkata, Mumbai, Puri, Kochi, Surat are some common example of this incident in India. The urban poor or those who live in slums are mainly affected by urban flood especially in cities like Kolkata and Mumbai where the slums are located in low lying ecologically fragile areas

There is a need to access the probability and extents of occurrences of these incidents and design the urban area accordingly facilitating prolonged runoff time using urban green infrastructure, more permeable surfaces, more urban greenery and improving the efficiency of stormwater drainage. This can reduce the chances of vulnerability of the services and the inhabitants as well. Therefore many of the urban design principles for sustainable and climate resilient development of the cities require the inputs from urban physics for betterment of their performance.

THE INDIAN SCENARIO

Since the economic reforms started in 1991, Indian economy is growing at a fast pace. Due to migration from rural to urban areas, India's urban population is expected to reach 472 million in 2020 and 611 million in 2030 compared to 325 million in 2005 reaching a share of 41% of the total population resulting in urban sprawl and densification (MGI 2010). To accommodate the migrating population, the construction industry is also growing at a fast rate contributing an average 6.5% of GDP (JLLM 2007).

Indian cities grow in a ridiculous way by inclusion of urban fringes in the municipal areas. When a city starts to grow, the land price of its surrounding village areas go up and development of the rural areas start according to the rules and regulation of the rural areas having narrow roads and lack of public amenities. It does not support any future improvement due to high built up areas and virtually no open space. When these peri-urban settlements are included in the urban municipal areas, the problem increases many fold due to the further increased population pressure. These areas may be retrofitted with some basic services and amenities, but the situation remains the same. These densely packed buildings (mostly without mandatory open spaces) creates a havoc impact on the urban climate because of complete extinction of greenery, extensive hard paved surfaces and the least space for wind movement.

In most of the cases, Indian cities only have municipal building byelaws which only deals with one individual building but they do not have any comprehensive strategy or guidelines for developing the public spaces considering the outdoor comfort and convenience in the urban realm. The existing building bylaws are often disobeyed which creates problems in wind movement, water percolation etc. Even the buildings in the National Capital Territory of New Delhi, comply with building codes less than 35% of the time (WB & IFC, 2009). Considering the unsustainable growth of the urban areas in India, a number of policies are introduced to facilitate the energy efficiency and green building as a control and regulatory measures including appliance ratings and certifications. But almost all the measures deal with an individual building. No visionary guideline has not been developed considering a neighbourhood level or city level.

Though in March 2011, BEE asked for the compulsory enactment of ECBC at the local level in eight states starting in 2012: Delhi, Maharashtra, Uttar Pradesh, Haryana, Tamil Nadu, Andhra Pradesh, Karnataka, and West Bengal (PTI, 2011).

The data on existing building stock in India are incomplete and estimates about the total floor space, number of units and typology of building (commercial, residential or industrial) vary considerably. With this limitation, the following facts and figures should be viewed as approximation. The total building stock in India has experienced an annual average growth of 6% between 1990 and 2005 resulting the doubling of floor space from 4 to 8 billion m2. From 2005 to 2030, the average growth is expected to be 6.6% resulting 22 billion m2 in 2020 and 41 billion m2 in 2030. The growth pattern represents that almost 70% of the buildings that will exist in 2030 have not been built yet which actually leaves a window of opportunity to make substantial improvement of urban climate. (The World Bank, 2010). There is an urgent need to develop an urban development guidelines with a strong emphasis on the mitigation strategies of climatological and environmental impacts of urban development.

It is an agreed upon fact that Indian cities need much more attention for their extreme and as well as diverse character and as most of the future cities are yet to be built, there is a great scope of implementation of urban physics in designing Indian cities. Though a lot of researches has been carried out but the real life implementation of urban physics in urban design is yet to gain its momentum in the subcontinent.

CONCLUSION

The amelioration strategies discussed above came only through the research of urban physics and gives a direction to improve the experience of urban areas and explore new areas for improvement. It is evident that most cities suffer due to their air quality (pollution), thermophysical quality (thermal comfort) and water related issues (urban flood, low water table, etc.) (Campbell-Lendrum & Corvalan, 2007). In most of the case they are linked with one another in the urban ecosystem. So, the architects, urban designers and planners need to use urban physics to understand their interrelation for a practically implementable, streamlined and unified approach to start the development of mitigation strategies to deal with the unintended urban climate change.

The development route of world civilization till date has made it very clear that the population growth and urbanization will continue at a very rapid pace. Development of a number of new cities and expansion of the existing ones is a necessity. Therefore, there is an urgent need to develop new sets of urban design guidelines that comply with the research outcomes of urban physics to ensure that the upcoming buildings and the corresponding urban areas go along with today’s most efficient, climate resilient design and planning strategies.

Though the subject, urban physics, comes with a world of opportunities, it has some downside too. The correlation between various factors of urban climate, huge data sets and highly complex mathematical calculation demands profound knowledge of the subject and substantial amount of computational resource to run the simulations. Supply of resources and availability of experienced professionals and a streamlined networking among all the stakeholders is necessary for its success.

Though urban physics mainly deals with a group of buildings, neighbourhoods, urban canyons etc. special emphasis has to be given on the design of individual buildings also as they cumulatively contribute to the overall urban experience. Considering the common trend of having very less building designs with professional inputs in most of the urban areas, the situation is going to deteriorate much more in the foreseeable future. It is very important to get the urban fabric right so that every single building have the capability to extract the maximum environmental potential with or without professional interventions echoing the ethos of traditional Indian design with a fuzzy demarcation of indoor and outdoor.

ABSTRACT

One of the characteristics of passive low energy architecture is the dependence of its facades on solar access. However this aspect is little considered by law or in the practice of real estate development. On the one hand, urban space configurations such as streets are defined in planning guidance by law to safeguard the common good, but on the other, real estate activity puts pressures on land and creates large buildings occupying maximum plot ratio. This is particularly the case in developing societies and emerging economies. One of the direct effects of this process is solar obstructions on the urban space, i.e. facades, ground and sky. This means that indirect passive low energy opportunities which affect the possibility to capture energy for passive or active systems are lost with new high-rise developments creating unequitable environments. Therefore, the design of urban space which considers solar access to facades becomes an important issue as a means to avoid these problems.

This paper seeks to explore designs which permit solar access within the context of urban practice which permits large building volumes. Here different street configurations are examined to evaluate to what extend it is possible to balance solar access and plot ratio criteria in planning guidelines. This investigation examines four urban space configurations from lower to higher density to discover the range in which both criteria present compatibility. Two cities located at two different latitudes are compared to assess solar irradiation availability on the surfaces of facades, the ground, the roof and the urban space. A simulation was carried out on winter and summer solstice with 2 urban orientations: east-west and north-south axis. Results show an inflexion point in the curve of irradiance according to geometrical profile. These findings help to orientate planning guidelines in the consideration of passive low energy architecture to promote a more sustainable habitat in developing societies.

INTRODUCTION

Contemporary cities in the context of emerging economies tend to experience growth both outwards on the periphery and upwards in high density central areas with planning guidelines trying to control development. Whether in horizontal or vertical expansion the built environment is shaped by economic forces that try to maximize plot ratio and building floor-space. One of the effects of these developments are towering high rise blocks which shadowed streets and surroundings impacting on solar access for urban spaces, facades and buildings in cities as shown in **Figure 1.**

On the other hand the Chilean urban regulations try to order urban morphology and spatial arrangements through morphological constraints such as; distance to boundary (“rasante”), plot ratio,

Cárdenas is Associate Professor in the Department of Urbanism, Faculty of Architecture and Urbanism, University of Chile, Santiago, Chile. Vasquez is Instructor in the Faculty of Architecture, Design and Urban Studies, Pontificia Universidad Católica, Santiago, Chile. Turnbull is Instructor in the Department of Architecture, Faculty of Architecture and Urbanism, University of Chile, Santiago, Chile.

built floor coefficient, shadows above plot, amongst others. These parameters are useful to shape urban form for individual buildings on a single plot but not necessarily achieve a coherent morphology at city-block level. The emphasis on individual buildings in the urban regulations results in the poor design of three dimensional spatial surroundings. Regulations determine parameters which are concerned with architectural built form which theoretically allow the access of sunlight but in practice shadows are really only taken into account as a spatial limit to the height of buildings rather than any concern for energy use in passive and low energy architecture.

(a)

(b)

Nonetheless, from a solar perspective planning guidance should consider the shading effects of buildings on their surroundings because this has an impact on the opportunity of daylighting and passive or active heating. Equity is put at risk when solar obstructions from high buildings fall on a neighborhood regardless of a minimum solar access to sunlight or daylight. The question is how to protect solar resources for every neighbour within cities? This is particularly important in cities which belong to the world's 'sun belt' which have extremely high irradiance and opportunities to benefit from this resource, such as in the case of Chilean cities. As an example the southern German city of Freiburg is known as the "solar city" with enormous solar PV cells and solar thermal investment integrated to the architecture. It is located at latitude 45°N which is considerably further north and therefore receives less radiation, than Chile's southerly cities, for example Puerto Montt at latitude 41°S. Therefore there is enough radiation to justify exploring solar options in Chilean cities not only in the north but also in the southern territory. Therefore it is argued that urban planning instruments should recognise the potential of solar access throughout the whole of Chile whilst considering the different contexts which may create different opportunities.

International institutions have stated that traditional approaches to urban planning have failed to promote equitable, efficient and sustainable human settlements for addressing twenty first century cities in developing countries (UNHS, 2009). However, there are many authors studying specific issue such as solar access on buildings and cities to deal with energy and spatial conditions to save urban morphology. (Capeluto, 2001; Košir et al., 2014; Lau et al.., 2011; Benoit, 2012)

The general objective of this paper is to explore urban design which allows solar access within the context of urban development which permits large building volumes regardless of energy capture on urban surroundings. Cross-section of streets with different configurations (width/height ratio) are examined to evaluate to what extend it is possible to balance solar access and plot ratio criteria in urban planning guidelines.

Amado et al (2013) state that solar urban planning is a complex process that requires interplay between many factors related to urban form and solar energy inputs. The authors use a parametric approach to quantify solar energy from photovoltaic systems in the urban context (Amado, 2013). They argue that solar power plays a strategic role in improving the energy efficiency of cities because it could be used to generate clean energy for consumption and perhaps match demand. Both these functions are key indicators to understand the balance of energy performance in city neighbourhoods.

In the city of Oeiras, Portugal, an algorithm has been developed to estimate the annual energy production for PV systems. This has been applied to specific urban configurations such as the cellular unit called the "warped parallel". Three factors were used to classify the city into different cellular units;

year/period of construction, population density and representative morphological patterns. The element of ‘roof surface’ was the mean element used to study the PV solar electricity potential. Here they compared energy demand and solar supply in the urban system with existing typologies of building block and street pattern. This appears to be a useful tool for consolidated urban areas but the question arises as how to plan the future urban configuration with a huge diverse morphological pattern.

With this in mind, we propose that a simple cross section analysis might support planning guidance in the future to control height of buildings considering both interests of maximizing urban densities and providing solar access to neighbouring buildings.

Current controls and guidance on urban morphology include “Site Layout Planning” of the Building Research Establishment (BRE) of Great Britain which has been in use since 1991 (Littlefair, 2011). This document advocates access to skylight and sunlight because these contribute to building energy efficiency. Daylight will reduce the need for electric light, while solar gain can help meet heating requirements in winter.

Additionally ‘Development Advice Notes’ exist at local municipal level in the UK to help applicants in submitting their planning applications. For example, Stirling Council in Scotland has produced a document to give general advice on daylight, sunlight and privacy on new development or extensions. Here they look for a balance between expectations of the homeowners and the effect of that development on the locality. The discretion of the Council is relevant to give permission for any changes in the built environment and daylight in this case is a guiding principle rather than sunlight.

These guidelines are set out to minimize the overshadowing of neighbouring properties for the majority of the day where the design should confine shadow projection to the applicant´s own land. The factors considered in the design are height, distance to boundary, size of plot, orientation and topography on plan. A “degree approach” refers to the angle allows daylight at the “centre of the closest ground floor habitable room window of neighbouring properties” (Stirling Council, 2002).

Finally, urban canyon has been analyzed as an element used to characterize the street in relation to the climate, meteorology and urban design by many authors (Oke, 1986; Mills, 1993; Pearlmutter et al., 1999; Venegas y Maceo, 2012; Andreou, 2014; Botillo et al., 2014). In this paper urban canyon was chosen to create a conceptual model for studying available solar direct radiation.

RESEARCH METHODOLOGY

In order to analyse effects of different urban configurations on solar access a parametric approach was applied. To achieve this objective a digital model was constructed considering a typical cross section of a street found in central areas of the city as shown in **Figure 2**. Two parameters were tested: irradiation (Wh/m2) and ratio height/width (1:1, 1:3, 1:5, and 1:7) where the heights of buildings were changed while maintaining a constant street width as shown in **Figure 3** for each city and **Table 1.** This model was chosen because it represents urban spatial configuration that involves a topological relationship between facades and urban space. This means that analysis is not only of single buildings, as is traditional, but of two buildings which interact with the urban spaces and hence the human habitat.

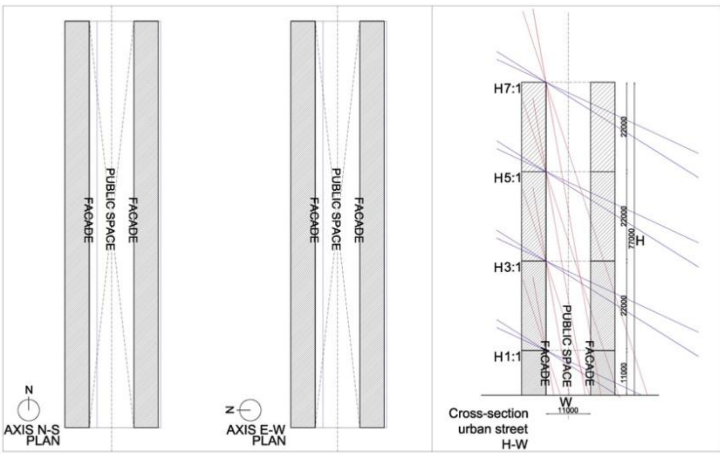

Figure 2 A cross section model of urban street canyon

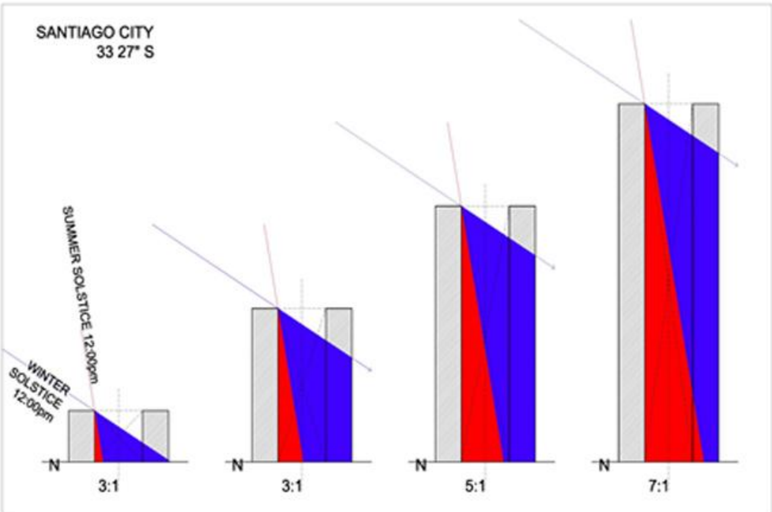
Table 1. Parameters of the model based on Cross section of streets

Width of street between official line	ID	Height of building (N° of floor)	Proportion of urban space (W/H)	Factor of constructibility (ratio: floor surface / site surface)
11	A	4	1:1	0.99
11	B	12	3:1	1.98
11	C	20	5:1	3.96
11	D	28	7:1	7.92

Two cities which have witnessed rapid growth and urbanization located in different latitudes and climates were selected to examine incident radiation on facades and urban space. To achieve this, the same cross section model was analyzed to compare how spatial configuration works in different climates. Four configurations were chosen according to proportion of urban space and two street axis orientations: North-South and East-West. The criterion for urban spatial configuration was a growing density from a lower to a higher extent to discover the range in which both objectives present compatibility: solar access and density. The questions were; To what extend it is possible to raise the height of buildings and have available solar radiation? and, How to balance both objectives to get a maximum solar energy on facades and a maximum high rise buildings?



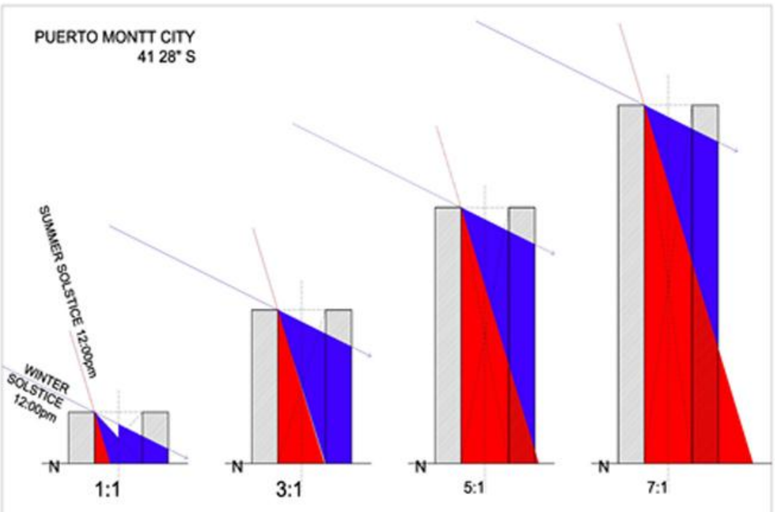


Figure 3 Urban spatial configuration proposed for analyses pointing out solstice angle.

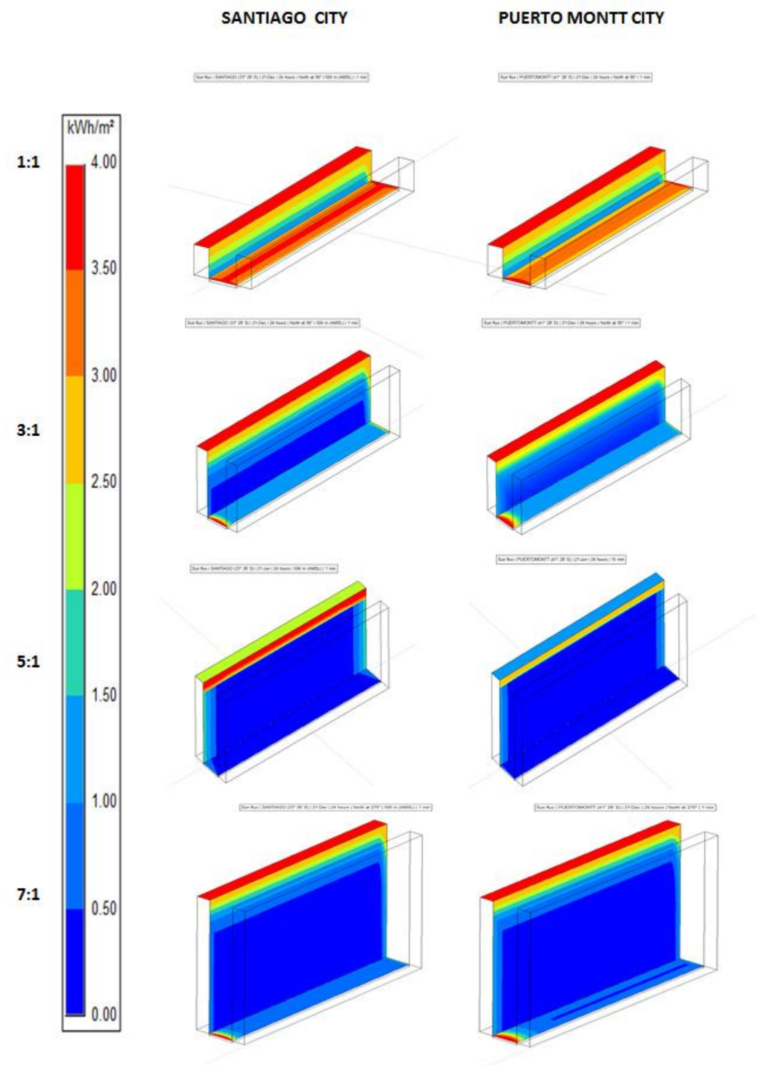

Figure 4 Simulation of solar radiation on cross-section of urban street

RESULTS AND CONCLUSIONS

First of all energy simulation has carried out by using Heliodon ™ software to measure irradiation on facades and urban space assembled on two axis: North-South (N-S) and East-West (E-W). Total direct radiation incidence on both facades in front of the urban canyon was calculated which was divided by available surface on building in square meters to give the average energy. Masking has been considered in calculations during one whole day: summer and winter solstice, as shown in **Figure 4**. The same method was used for ground as horizontal data and all those values were registered in **Table 2**. In **Figure 5** the chart shows curves energy performance according to proportion of street expressed through ratio H/W (height/width) such as 1:1, 3:1, 5:1, and 7:1.

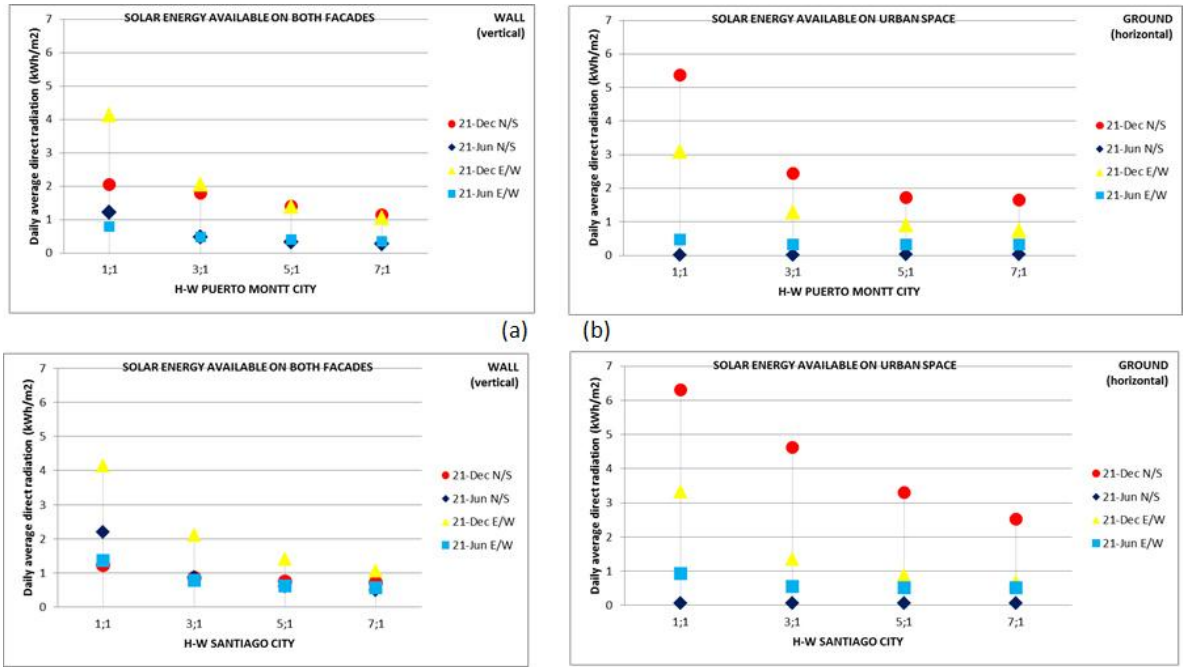

Figure 5. Solar irradiation available on facades and urban space considering mask from buildings in front during solstice and growing density.

Results from **Figure 5** show an inflexion point of facades curve at 3:1 proportion of the canyon in both cities of Santiago and Puerto Montt. After that radiation curves continue to slowly descend as density increases (higher buildings). Energy available on facades also changes according to the orientation of street axis and climate. If direct radiation is compared between the two cities the maximum values are observed in East-West facades during summer solstice (21 Dec). Similar values are observed in East-West facades during winter solstice as well (21 Jun). However values (kWh/m2) in North-South facades present differences in both cities whether summer or winter solstice. For instance, Puerto Montt registers almost twice the amount of solar energy values in summer and same situation as in Santiago but in winter. A conclusion might be that North-South facades within an urban canyon are relevant to assembled grid on urban design project and hence planning guidance.

In **Figure 5** (a) it is also observed that the proportion of urban canyon becomes another relevant parameter for similar values. Given 3:1 in winter solstice in Santiago city is of a similar energy value to 1:1 in winter solstice in Puerto Montt city. So a conclusion for planning guidance is high rise buildings should be allowed in latitude closer to the equator (Santiago) rather than far from them (Puerto Montt). If the width of street is enlarged it would capture solar energy. A balance between solar gains in front urban facades is possible when a proportional magnitude of streets is managed by town planners at local government level.

Following this conclusion it is relevant to find out that some different orientations and different solstices in the same city of Santiago deliver equivalent solar direct radiation on facades. Values obtained from East West facades in winter are equivalent to North-South facades in summer solstice. By contrast, in the city of Puerto Montt different orientation in the same climate delivers equivalent values. Therefore a conclusion is that each city has equivalent values combining orientation of the street and weather (solstice). These findings might be useful for urban planning guidance which wants to consider solar energy as input for the architectural envelope in the urban context rather limited to the isolated conditions of laboratory simulation.

In **Figure 5** (b) solar irradiation on urban spaces presents a higher value in Santiago than in Puerto Montt as expected, at the summer solstice there is a 1kWh/m2 difference in value. However values tend to be similar when approaching winter with a similar curve at the solstice of June 21th. An inflexion point occurred at the 3:1 proportion of urban space in both cities. The north-south axis presents more dispersion in respect to the east-west. The proportion of 7:1 in Santiago is equivalent to 3:1 in Puerto Montt therefore high-rise building might be managed to have a similar potential of solar access.

Finally a comparison of irradiation performance on facades and ground surface regarding the proportion of urban space has been analysed with simulation modeling. Solar energy performance changes significantly if facades or ground surfaces are analyzed considering masking. A balance between both initial objectives, highlighted at the beginning as solar access and urban density, is possible to achieve when analysing values from simulation as this paper demonstrated. Decision making might be taken by local planners through physical parameters such as proportion of street canyon. It is interesting to discover that similar solar energy values can be obtained depending on the height of buildings in two cities with different latitudes. More specifically, it is possible to manage the proportion of urban space through finding out the relationship between ground width and building height. These parameters would help urban design and planning guidance at local government.

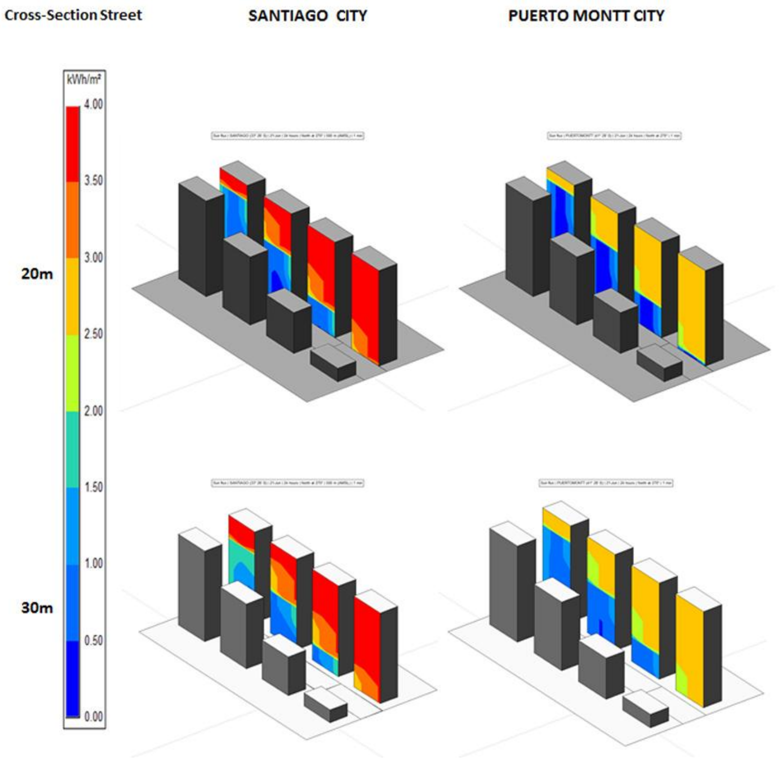

Figure 6 New arrangement buildings are placed on land plots varying the width of the street.

To evaluate more complex changes in building geometry the model is rebuilt with different heights for both cities during the day of least favorable solar radiation, the Winter solstice (June 21). In this new arrangement buildings of different heights are placed on land plots as an alternative to the continuous urban canyon and this time varying the width of the street. **Figure 6** shows a simulation of solar flux intensity (kWh/m2) falling on the façade of a building on a street of 20m (top) and 30m (bottom). An inverse relationship was discovered; as the width of the street becomes greater the direct solar radiation available on the north façade facing a solar obstruction is slightly lower for Santiago. However the model for Puerto Montt shows a direct relationship; as the width of the street increases the direct solar radiation available on the north façade increases. Since Puerto Montt is at a lower latitude than Santiago it could be inferred that in high latitude cities, increasing the width of the street optimizes solar energy in northern facades, but in cities of a lower latitude this spatial parameter works the opposite way.

ABSTRACT

Vernacular architecture is characterised by a type of formal expression that has been developed in response to a number of factors – climatic, lithologic, cultural and economic – characterising the local area or region. In its various forms, a range of techniques has been employed in different regions to mitigate the effects of climate. Despite the fact that Portugal is a small country, it has a territory full of contrasts, which gave origin to many different architectural manifestations. The approaches adopted in the design and construction of vernacular buildings have the potential for further development and could be adapted in response to contemporary needs. In the future, a blend of tradition and modernity should be aimed at in order to develop a new form of aesthetics and functional construction. Portuguese vernacular architecture is associated with a fund of valuable knowledge that should be studied and aligned with the principles of sustainability. In this paper, is presented the climatic contrast between the northern and southern parts of Portugal and the relation with the purpose of different passive solar techniques used in vernacular architecture to provide comfort. The focus is on the effectiveness of passive cooling techniques (e.g. high thermal inertia, the use of light colours and patios), and the findings of a case study in which the thermal performance during the summer of a vernacular residential building located in the south of Portugal are presented. In the context of the current global drive for clean energy and sustainable buildings, much can be learned from a review of past experience in order to provide an understanding of such forms of construction, which are an intrinsic feature of specific places and have evolved over time in the face of a lack of resources.

INTRODUCTION

Nowadays, sustainability and energy efficiency are inevitable discussion topics for building industry. This industry is one of the largest raw materials and energy-consuming sectors of the economy and responsible for almost a third of all carbon emissions (Ürge-Vorsatz, Danny Harvey, Mirasgedis, & Levine, 2007). In order to address this problem various bodies have set medium and long-term targets for improving efficiency in construction, such the European Union that has outlined a path of 70% of reuse/recycling/recovery of construction and demolition waste by 2020 (European Comission, 2012) and an 80-95% reduction in CO_2 emissions by 2050 (EEA, 2012).

Jorge Fernandes is a PhD student in the Centre for Territory, Environment and Construction (CTAC), University of Minho, Guimarães, Portugal. Ricardo Mateus is an Assistant Professor at the Department of Civil Engineering, University of Minho, Portugal. Luís Bragança is a Professor at the Department of Civil Engineering, University of Minho, Portugal. José Correia da Silva is an Assistant Professor at the Department of Rural Engineering, University of Évora, Portugal. Sandra Silva is an Assistant Professor at the Department of Civil Engineering, University of Minho, Portugal.

In order to achieve the above-mentioned objectives, there is an urgent need to rethink the ways of building. In a era of globalization that led to the homogenization of the different ways to build, according to some authors we should reflect on past experience, since traditional buildings are an example of a more sustainable construction and so they could have an important role to play in the future of construction (Foruzanmehr & Vellinga, 2011; Oliver, 2006). Intrinsically bound up with the local conditions, vernacular architecture could contribute towards reducing waste and energy consumption through the use of passive solar design, traditional techniques and local materials, which were developed in accordance with a specific territory and climate (Fernandes, Mateus, & Bragança, 2013; Kimura, 1994; Singh, Mahapatra, & Atreya, 2011).

This paper is focused on energy efficiency (other sustainability categories are not discussed), since this issue is particularly relevant in the contribution of vernacular architecture towards sustainable building. This is because vernacular buildings gave prime importance to passive climate control for ensuring indoor conditions of comfort. Additionally, the strategies used to mitigate the effects of climate are usually low-tech and not very dependent on non-renewable energy, while they do not require special technical equipment, which makes them suitable for contemporary construction, especially passive building design. In this sense it is important to highlight that a passive houses provide the lowest contribution in terms of such equipment as far as LCA results are concerned, mainly due to the fact that there is little need for conventional ventilation and air-conditioning equipment (HVAC) (Passer, Kreiner, & Maydl, 2012).

Although "Energy" is just one of the sustainability categories, several comparative studies (Forsberg & von Malmborg, 2004; Haapio & Viitaniemi, 2008) about Building Sustainability Assessment (BSA) tools have shown that energy efficiency is a relevant aspect of the overall sustainability of a building. For example, according to the Portuguese assessment and rating system (SBTool^{PT}), the "Energy Efficiency" category has the highest weighting (32%) in the assessment of environmental performance and the third highest weighting in the assessment of the global sustainability of a building (Mateus & Bragança, 2011). Energy consumption is also a key issue in terms of the environmental life-cycle impacts of buildings, mainly during the operation stage, and is related to the provision of healthy and comfortable conditions for occupants (Passer et al., 2012)

Nevertheless, some studies have been carried on the passive strategies used in Portuguese vernacular architecture, the state of the art is that there are no results available from *in situ* measurements that can demonstrate the contribution of these different approaches to improve energy efficiency. Therefore, this paper attempts to provide a contribution in this field by presenting both: an overview of the climatic contrast between the northern and southern parts of Portugal and its influence on the type of approaches adopted by vernacular architecture; their potential contribution to passive building design; and the results of a study on the effects of passive cooling strategies on the control of indoor temperature and humidity of a building during summer.

THE CONTRIBUTION OF VERNACULAR TECHNIQUES TOWARDS ENERGY EFFICIENCY

In the past, due to the lack of advanced technological systems for the maximization of comfort, buildings were built using passive systems. While simple and clever, these were based only on the available endogenous resources and on a range of criteria such as: geographical characteristics; insolation; orientation; geometry; form; and materials, among others (Coch, 1998; Oliveira & Galhano, 1992).

The relationship between the built environment and the natural environment is well described by the Roman mythological concept of the *Genius Loci* and has primal importance on buildings' conception and thermal performance. The significant differences between the way house-construction developed in northern Africa and northern Europe, for example, demonstrates that this was not a random process; similarly, in Portugal, there is a considerably difference between the houses from north and south.

Several quantitative studies on the thermal performance of vernacular buildings conducted in different parts of the world have shown that vernacular buildings achieved acceptable comfort standards throughout much of the year just using passive strategies, in some cases indoor temperatures remaining almost constant (Cardinale, Rospi, & Stefanizzi, 2013; Martín, Mazarrón, & Cañas, 2010; Shanthi Priya, Sundarraja, Radhakrishnan, & Vijayalakshmi, 2012; Singh, Mahapatra, & Atreya, 2010). The results support the idea that passive strategies are in many cases feasible for use in contemporary buildings and that they could contribute to reduce buildings's energy demands for HVAC.

VERNACULAR ARCHITECTURE IN NORTHERN AND SOUTHERN PORTUGAL: STRATEGIES TO SUIT THE CLIMATE

Vernacular architecture in Portugal, as in other countries all over the world, is influenced to a great extent by geographical location. Climate and other geographical features account for differences between the various types of vernacular constructions found in the different regions of this country.

Continental Portugal is located between latitudes 37º and 42ºN in the transitional region between the sub-tropical anticyclone zone and sub-polar depression zone. Beside latitude, the most important features affecting the climate of the territory are orography and the influence of the Atlantic Ocean (Santos, Forbes, & Moita, 2002). With regard to relief, the highest peaks rise to a height of 1,000m to 1,500m, except for the Estrela Mountains, whose highest point is just under 2,000m.

Even though it is a small country, Portugal is a territory of contrasts. In spite of the fact that the variation in climate factors be rather small, it is sufficient to justify significant variations in air temperature and precipitation, such as (Santos et al., 2002):

- Air temperature – in winter the average minimum temperature varies between 2ºC in the mountainous interior zone and 12ºC in the south zone of Algarve; in summer Summer: the mean maximum temperature vary between 16ºC in Serra da Estrela and 34ºC in inner central region and eastern Alentejo.
- Precipitation – in the highlands of the northwest region the mean annual accumulated precipitation is above 3000 mm, one of the wettest zones in Europe; in southern coast and in the eastern part of the territory: the average amount of rainfall is in the order of just 500 mm; southern interior has a Mediterranean climate, well known for its vulnerability to climate variability, namely to droughts and desertification.

To suit different climate conditions Portuguese vernacular architecture developed specific mitigation strategies. In a general form, as shown in Figure 1, it is possible to verify that in the northern part of the country the adopted strategies aim to increase heat gains and to reduce indoor heat losses during winter, while in the south the strategies are more focused on passive cooling during summer.

In order to respond to cold winters, reducing heat losses and taking advantage of solar radiation, vernacular builings from the north frequently used thatched roofs – due to their insulating properties – to reduce heat losses, and south-facing balconies to take advantage of solar radiation. The glazed-balconies are a feature of the architectonic identity of the Beira Alta region and, due to the advantages they bring many are still in use today. They are usually facing between south and west so that they receive the highest number of hours of sunshine and a high level of radiation during the winter, while affording the best shelter from the prevailing winds, as shown in Figure 1 (a). The use of this kind of structures is feasible in refurbishment projects with energy efficiency purposes, as demonstrated at the Residential complex in Dornbirn, Austria, where residents' heating bills have been significantly reduced (Küess, Koller, & Hammerer, 2011).

In the south of the country, in order to minimise heat gain, several techniques were developed, such as (Figure 1 (b)): reducing the size of doors and windows; the use of a high thermal inertia building systems; the use of courtyards (patios); and the use of light colours in order to reflect the excess solar radiation. The effect of these passive cooling strategies on the thermal performance of buildings is described in the case study in the following section.

The abovementioned strategies are relevant to the debate on energy efficiency in buildings because they are aimed at reducing energy consumption and increase the comfort level for occupants by passive means. Despite the advantages of the presented passive strategies, for the Portuguese context there is a lack of quantitative data on the effectiveness of these approaches on the thermal performance of vernacular buildings in different climate zones. Nevertheless, the interpretation of the results of studies conducted in other European countries points to some techniques of Portuguese vernacular architecture being effective and having the potential for use in contemporary buildings.

PASSIVE COOLING STRATEGIES EFFECT IN THERMAL PERFORMANCE OF A CASE STUDY

Aim and description of the case study

The study presented in this paper is aimed at a quantitative analysis of the contribution of passive cooling strategies, a vernacular approach used mainly in the south of Portugal (Figure 1), in the control of indoor temperature and humidity during the summer to achieve comfort conditions.

The case-study is situated in the historic city centre of Évora, a city located in southern interior Portugal (latitude 38º34’N, longitude 7º54’W). The climate in Évora is Mediterranean temperate (Csa – according to the Köppen climate classification), with hot and dry summers and high temperatures during July and August (with maximum temperatures of 30°C to 40°C, occasionally reaching 45°C) (AEMET & IM, 2011). In July and August severe drought is normal and rainfall is rare, with an average total precipitation of 8,6 and 6,6 mm, respectively (AEMET & IM, 2011).

The monitored building has an L shape, with the façades facing the courtyard oriented to SE and SW, as shown in Figure 2a-b. The courtyard has plenty of vegetation and in which two trees offer considerable shade for the building. The building has two storeys and a total area of approximately 900m^2: the ground floor houses the kitchen, a bedroom, and various storage spaces; on the upper floor there are living rooms and other bedrooms.

The *in situ* measurements were carried out in the ground floor (Figure 2a), which have the following construction features: traditional brick vaulted ceilings, ceramic tile finished floors, lime mortar finished walls and single glazed wooden windows. The average wall thickness of the building is about 100 cm. It was not possible to rigorously determine the composition of the walls but, so taking into consideration that this kind of buildings were usually built with rammed earth or massive brick masonry, it was estimated that the heat transfer coefficient (U-value) is of about 1,00 W/m2.ºC. The floor area of the monitored spaces is approximately of: kitchen – 33m^2; bedroom - 17m^2; courtyard - 600m^2.

Methodology and equipments

The effect of passive cooling strategies in the control of the indoor temperature and humidity of the building was quantified through *in situ* experimental measurements. Two physical parameters were quantified: air temperature (ºC) and relative humidity (RH %). For this purpose, were used three equipment with an internal sensor to measure temperature and relative humidity of the air. It has a measuring range between -35 to 70ºC and an accuracy of ±0.9ºC. Readings recorded can be downloaded to a PC.

Field measurement involved the positioning of units inside and outside the house: one in the courtyard and two inside, in the ground floor: one in the room adjacent to the courtyard (the kitchen) and the other in the bedroom (Figure 2a). Data was recorded continuously over the period from 17th to 26th July 2007; data from the different sensors was recorded at 30-minute intervals. Secondary data for the study was collected at the Geophysics Centre of Évora for the same time period.

Figure 2 a) Ground floor plan showing the position of measuring instruments; b) View of the courtyard (*patio*).

Analysis of results

Indoor air temperature, both in kitchen and bedroom, varied slightly, remaining nearly constant, while in the courtyard there were great fluctuations in air temperature throughout the day (Figure 3). The high thermal inertia of the building is the most probably reason for this, but the presence of abundant vegetation in the courtyard also contributed towards reducing direct heat gain through the envelope by providing shade. In order to provide an understanding of the effectiveness of different passive cooling techniques used in the building, these results were compared with the data recorded in the city centre during the same period. This showed not only the importance of the thermal inertia for reducing variations in indoor temperature but also the role of the courtyard in substantially reducing air temperature around the building. An analysis of recorded data shows that air temperatures in the courtyard always remained lower than those recorded for the city centre, especially during peak periods of heat, with a maximum difference of around 9ºC, as shown in Figure 3. It may also be concluded that this vernacular approach also allows for a delay of approximately 90 to 150 minutes between the moment at which the temperature in the courtyard starts to rise and that at which peak temperatures are reached in the city centre. An analysis of the chart in Figure 3 shows that during daytime, in the city centre, outdoor relative humidity reaches a minimum of about 20% whereas the maximum temperature is nearly 40ºC. For the same period, in the courtyard, minimum relative humidity is nearly 30% and the maximum temperature is about 30ºC. A possible reason to explain the lower air temperature in the courtyard is that the existing vegetation does not allows that this area contributes for the local heat-island effect (Figure 2b). Additionally, both the abundance of vegetation and the presence of a water fountain contribute to the evaporative cooling of the courtyard, thus raising the relative humidity and diminishing the air temperature. Another plausible reason for this difference is that cool humid air, which is consequently dense, remains in the courtyard during the early hours of the morning, until is warmed by the sun. In this confined space, the air takes longer to gain heat than the air in the city centre, thus its temperature remains lower and its relative humidity higher than the air in the city centre during warm periods.

Indoor relative humidity shows slight fluctuations throughout the day with an average of around 50%, the most suitable level for human health and comfort (Morton, 2008). This difference between indoor and outdoor relative humidity can be explained by the use of materials that contribute to the regulation of indoor humidity. Indoor wall surfaces and ceilings are covered with lime plaster, with a thickness of about 3cm. This material regulates the quality of the indoor environment, as it is not only permeable to water vapour but also contributes towards moisture buffering (Berge, 2009), i.e. it moderates changes in relative humidity by absorbing moisture from the surrounding air and, when the air is less humid, giving off absorbed moisture.

In what concerns the assessment of the thermal comfort conditions indoors, was applied an adaptive model of thermal comfort, since this is the most adequate model for naturally conditioned areas, and used a psychrometric chart representing Évora's climate conditions and the adaptive comfort range for July. Due to high fluctuations in outdoor temperature and humidity between night and day, the thermal conditions for each indoor space were represented separately for day and nigh. Analysing the results it is possible to conclude that both kitchen and bedroom spaces have thermal conditions within the limits of the adaptive thermal comfort range for summer in the majority of the days without any mechanical cooling system, as shown in Figure 4. Only the bedroom did not reach the comfort conditions in two days. However, is very close to the comfort limit.

study, applying the Adaptive Comfort Model in ASHRAE 55 (2010) (Chart adapted from: "Climate Consultant 5.5," 2014)

DISCUSSION AND CONCLUSIONS

Vernacular architecture is the paradigm of the interaction between architecture and climatic conditions. The techniques presented in this paper, due to their simplicity and pragmatism, have great potential for use both in the design of refurbishment projects and the construction of new buildings. For example, the passive cooling strategies employed in the south of the country, as shown in the case study in Évora, are simple to implement and can improve indoor comfort conditions in buildings during the summer season. Our findings show a difference of 7ºC and 16ºC between indoor temperatures and the peak outdoor temperatures (recorded in the courtyard and in the city centre, respectively) and the psychrometric chart showed indoor spaces within the thermal comfort limits during all the monitoring period, which means that such a vernacular approach has great potential for decreasing energy consumption by means of active cooling systems. These results are achieved by combining several passive-cooling strategies, such as: whitewashed walls; small exterior doors/windows; high thermal inertia walls; and courtyards or *patios*. In these strategies, the two last have considerable influence in indoor climate. The courtyard revealed to have a large influence on the creation of a microclimate near the building, with air temperatures remaining lower than those recorded for the city centre, with a maximum difference of around 9ºC. It is likely that these features affect the thermal performance of the building during the winter. However, taking into consideration the regional climate classification considered in the Portuguese Regulation for Energy Performance of Buildings (DL118/2013, 2013), the most difficult issue to solve in this region is the hot summer period.

With an opposite purpose, the balconies in Beira Alta provide an efficient mean of increasing solar gains and preventing heat loss, are easy to install and play an important role in minimising heating requirements. It may also be concluded that these strategies are perfectly adapted to the local area in which they were developed and there is no negative aesthetic impact on buildings.

Vernacular knowledge on passive strategies is relevant when current buildings are known to have a high level of energy consumption for providing air conditioning. It is imperative that priority is given to building design that adopts passive methods for controlling the indoor climate, limiting mechanical systems no more than a backup role, to be used only when the passive strategies are not sufficient for meeting the comfort needs of occupants. This paper assesses in holistic terms this architectural manifestation in the light of current knowledge in order to seek scientific justification for the principles of vernacular architecture and validate and promote its use in the future. However, there are limitations to this study and some aspects are only discussed qualitatively. Further studies are required to provide quantitative assessments in order to generate specific scientific information about the thermal performance of vernacular buildings in Portugal. More accurate information about the contribution of passive vernacular solar strategies would be useful for architects and engineers concerned with climate-responsive and energy efficient buildings and therefore could provide a contribution to the sustainability of buildings.

The influence of culture on energy consumption in Aboriginal housing in arid regions of Australia

Timothy O'Rourke
The University of Queensland
t.orourke@uq.edu.au

ABSTRACT

This paper examines both the technical and sociocultural aspects of Aboriginal housing in hot dry climates, posing the question: can domestic living patterns and preferences be harnessed to reduce domestic energy consumption? The colonial history of housing Aboriginal people in Australia is rife with precedents that are unsuccessful on multiple levels. Research has highlighted the frequent mismatch between modern housing types and the sociocultural traditions of Aboriginal households. In arid and semi-arid regions, the majority of Aboriginal housing is poorly designed for the climate, yet this aspect of shelter has received limited scholarly attention. The design of bioclimatic houses that support cultural patterns is still an architectural challenge, complicated by diverse historical and economic conditions. Additionally, the increasing cost of energy causes economic stresses for public housing occupants. Current climate change models for Australian arid regions predict increasing temperatures and less predictable rainfall patterns, which provide further challenges for low-energy housing design. Using recent survey data on Aboriginal housing in Northwest Queensland, this paper examines the design implications of using both sociocultural and technical factors to improve living environments and reduce energy consumption. The integrated design of buildings in landscaped yards can both mitigate overheating and support socio-cultural practices that affect overall residential energy consumption. Despite a general consensus on the significance of external living environments in the literature, there is lack of evidence from research that measures culturally derived adaptive strategies to reduce residential energy consumption in Aboriginal housing.

INTRODUCTION

In the arid and semi-arid regions of Australia, a large proportion of the Aboriginal population face problems associated with socio-economic disadvantage, the high cost of domestic electricity supply, high energy demand, and predicted changes to the climate. These problems are compounded by housing and yards that are poorly designed for the current climatic conditions. In the remote regions, within the last century, the transition to sedentary Western style housing has disrupted and transformed social and cultural practices related to Aboriginal domestic living patterns. Since the 1970s, when housing Aboriginal people became a political concern for Australian governments, researchers have documented the dilemmas and difficulties of designing culturally appropriate housing (Heppell 1979; Memmott 2004; Reser 1979; Ross 1987). This area, and Aboriginal housing generally, remains under-researched (Long, Memmott & Selig 2007), partly due to the diversity of Aboriginal groups, demographic change and significant socio-cultural changes influenced by multiple factors.

Only recently has research attended to questions of thermal performance of Aboriginal housing and energy use, partly as a result to climate change studies (Duel et al. 2006; Martel et al. 2012; Horne et al. 2013). There is a need for further studies that purse an integrated approach to research that attempts to measure housing quality and performance, and record and analyze behaviours that affect energy use. This aligns in one of the gaps in data identified by the IPCC (2014:67), which recognized the need for "Improved and more comprehensive databases on real, measured building energy use, and capturing behaviour and lifestyles are necessary to develop exemplary practices from niches to standard."

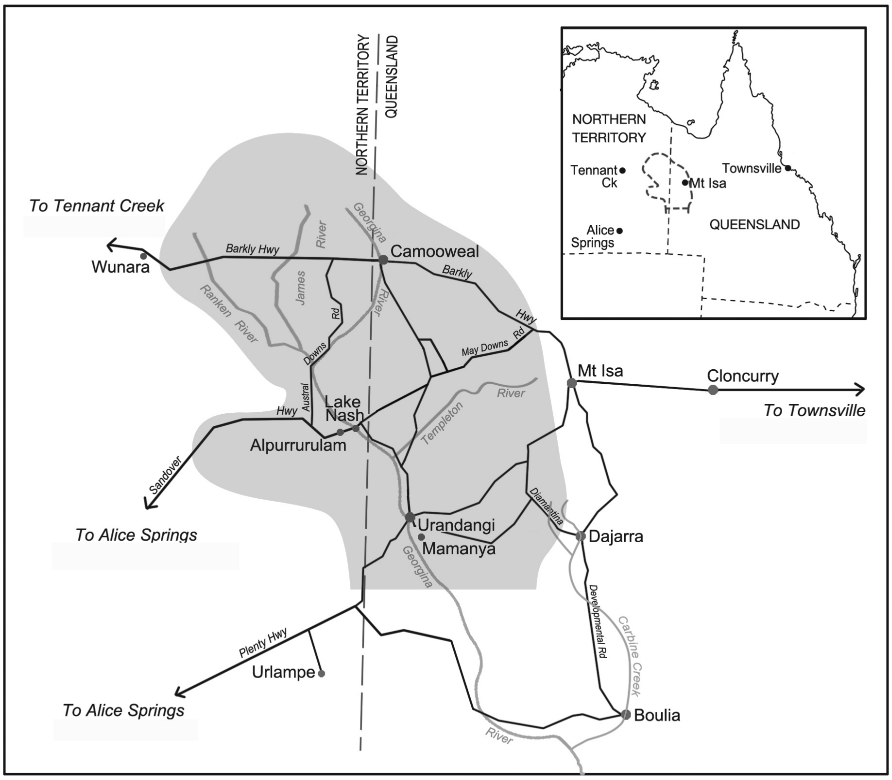

Figure 1. Map of the upper Georgina River Region showing settlements Dajarra, Urandangi, Camooweal and Wunara examined in the research on climate change.

Using data from different sources, this paper examines the potential for synergies between low-energy housing design and Aboriginal cultural practices. It also identifies behaviours and external factors that challenge sustainable domestic architecture in remote semi-arid and arid regions. This raises the primary question: once identified, can socio-cultural patterns and preferences be used in design strategies for low-energy domestic living environments? This question is particularly pressing given the added challenge of climate change in the arid regions of Australia, where new approaches to housing design are necessary for mitigation strategies in both Aboriginal and mainstream housing (Wang et al. 2011).

METHODS

This papers draws on research that examined climate change Aboriginal people and in the Georgina River Basin, a semi-arid region in northwestern Queensland, extending across the Northern Territory boarder (Figure 1.). In 2011 and 2012, an interdisciplinary study of Aboriginal adaptation to climate change was conducted in four towns in the region (Memmott et al. 2013). Surveys were used to ask 32 questions (quantitative and qualitative) about the informant's experience and use of the built environment and utilities. This included housing, domestic behaviour patterns and preferences, water supply and electricity, with some questions related to climate. These data and observations of Aboriginal houses and yards are compared with the literature on Aboriginal housing design, complemented by evidence from architectural practitioners working in the field. Data on the planning, construction and performance of Aboriginal housing in remote areas draws on post-occupancy evaluations, housing assessments and the collective observations and records of an interdisciplinary research centre with four decades of experience in the field. A number of researchers have conducted research in the upper Georgina River Region for over a decade with a particular focus on the built environment and the delivery of services (Long & Memmott 2007; O'Rourke 2011). In the small town of Dajarra, Long (2005) documented socio-cultural practices in an extended ethnographic study of Aboriginal people's living environments in the settlement.

CLIMATE AND HOUSE CONSTRUCTION

The upper Georgina River Region is characterized by a hot dry climate with mild winters, although toward the north of region the summers are more humid. The rainfall varies across the region, with a general decrease in precipitation moving south away from the influence of the northern summer monsoon: from wet summer/dry winter (mean annual rainfall of 401 mm in Cammoweal) to an arid climate (264 mm/annum in Bouila). Landscapes are predominantly grasslands in the north with deserts in the south. In Cammoweal, the annual mean maximum temperature is 32℃ and in mean minimum is 17.6°C.

Climate change models for the region predict temperatures to increase in arid regions with a greater frequency of extreme heat events (CSIRO 2007). A recent review of the Australian climate data (CSIRO 2014) describes a significant warming trend across the arid and semi-arid regions of the continent. This includes increases in the duration, frequency and intensity of heatwaves since 1950. Seven of the ten warmest years on record have occurred since 1998. In 2013, the region experienced its warmest spring on record. Overheating is the main challenge with housing in the region, with mean maximum temperatures averaging around 38℃ across the four summer months. Winter temperatures require heating for thermal comfort, and Aboriginal people in the arid regions are sometimes more concerned about cold conditions that hot weather (Thorne et al. 2013).

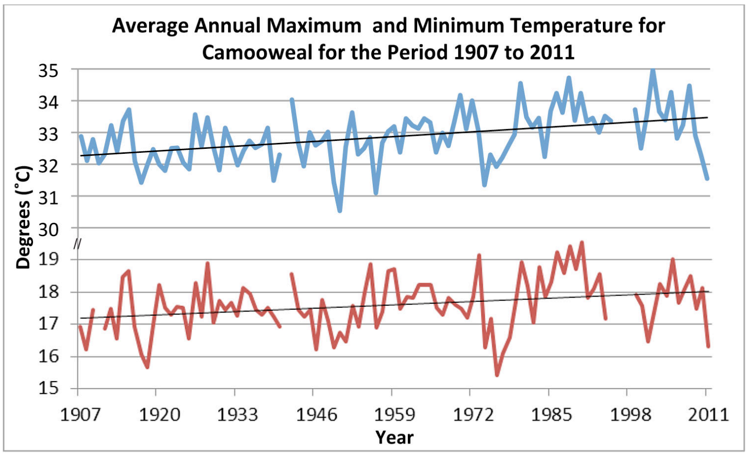

Figure 2. Climate profile for Camooweal. (Source Memmott et al. 2013)

In his analysis of the regional climate and housing design, Szokolay (1990) advised that cross-ventilation cannot be relied on for cooling; insulated thermal mass walls are able to exploit the relatively high diurnal variation with nocturnal ventilation, and benefits from either passive or mechanical evaporative cooling. He also recommended slab-on-ground construction with full shading of walls all-year-round. Deep verandahs are generally recommended for cultural reasons, although fixed shading can limit the use of thermal mass for heating in the regions with colder winters (Duel et al. 2006:45). Recent studies (Wang et al. 2010, 2011) of heating and cooling energy requirements for residential buildings across different Australian climatic zones predict that, under current models, climate change will significantly increase the cooling loads in arid zone housing.

In our survey of housing in four settlements in the Georgina River region, 72% of the participants (N=68) agreed that their house was too hot in summer and similar numbers agreed that their houses were too cold in winter. Over 70% used air conditioning to 'get through summer', although the preference to live in an air-conditioned house was less than 50%. In Dajarra, about one third of the houses had evaporative air conditioners and one third had refrigerated air-conditioners—all were retrofitted to the housing. The state-wide use of residential refrigerated and evaporative air conditioners has increased significantly in the past 20 years, with only one third of Queensland households not using air conditioners in 2009 (ABS 2010).

ENERGY PRICE AND POVERTY

Electrical energy is the primary source of domestic energy in the study region with all but a few houses connected to a distribution network. Between 2003 and 2013 in Australia, household electricity costs increased on average by 72% in real terms (Swobada 2014). The increase in the study region was 73%, with additional price increases of 20.4% in 2013-2014 and 13.6 % announced in May 2014 (AER 2013:131). This increasing cost in electricity supply has placed considerable financial burden on Aboriginal households in the remote regions where low rates of employment limit disposable income. In a 2008 survey, expenditure on electricity in Dajarra ranged from AUS $2, 400 to $6,000 per annum for Aboriginal households of varying size in one settlement (O'Rourke 2011). For many Aboriginal people occupying remote public housing, price rises in electricity increase vulnerability to climatic extremes, and particularly during heatwaves (PWC 2012).

In remote settlements, Aboriginal people have increased dependency on electrical energy although surveys of housing show that refrigerators, air-conditioners and electric heaters are at the lower end of energy efficiency. In our survey, 55% worried about paying bills and the same number of participants had changed the way they used household appliances to reduce electricity usage. A significant number (37%) had changed the way they lived in their house and yard due to extreme weather events.

HOUSING BACKGROUND

The change from mobile hunter-gather patterns of dwelling to more sedentary living conditions in remote regions of Australia varied with the history and circumstances of the colonial frontier. Aboriginal dwelling practices follow three historical phases that were often overlapping and uneven across the last 150 years: 1. In traditional or pre-colonial campsites a repertoire of shelters largely related to seasons were structured around spatial practices: windbreak and shade structures were used for most of year, with thatched domical dwellings used during cold and wet weather; 2. Adaptation of building traditions to more sedentary settlements often on the margins of colonial towns, pastoral properties, and government or missionary reserves; and, 3. The first substantive investment in state-supplied Aboriginal housing began in the late 1960s.

Although the involvement of architects in housing was initially promising in the 1970s (Heppell & Wigley 1981), direct participation in design has been marginal. In remote settlements, the housing stock varies in age and type, ranging from transportable homes, prefabricated housing, to a variety of mainstream housing, often standardized designs. A substantial proportion of Aboriginal housing in remote areas is of poor quality and requires either significant upgrade or replacement (Hall & Berry 2006; Pholeros et al. 1993). Remoteness—defined by distance to a service centre—is a significant factor in the design, delivery and maintenance of housing (Hall & Berry 2006:100). Transportation to remote or settlements limits construction choices and the cost of both labour and building materials escalates with distance from major coastal cities. A correlation between remoteness and continuities of pre-colonial Aboriginal socio-cultural practices adds to complexity of housing design in remote settlements.

Memmott (2003) identified three approaches to Aboriginal housing design that vary in their primary objectives: culturally appropriate factors, design for environmental health, and building procurement and delivery methods. These overlap but design for environmental health has had the largest influence on design standards (FACSIA 2007). There are notable exceptions of housing that provides architecture responsive to socio-cultural practices in remote regions of Australia (Dillon & Savage 2003; Memmott 2001, 2004). But within the literature, low-energy housing, for either socio-economic reasons or concerns about climate change, has received less emphasis than housing for cultural or health factors. There are few empirical studies of the thermal performance or energy use in Aboriginal housing: Duel et al. (2006) modeled thermal comfort of standardized designs in desert communities and Martel and Horne (2013) examined house designs in hot/humid area of northern Australia.

Settlement morphology and conventional housing in arid regions of Australia are not derived from historical or vernacular building traditions suited to hot/dry climates. Residential building types are largely detached suburban housing (variations on the bungalow), which continue to establish patterns and expectations for mainstream residential buildings. Courtyard type housing, for example, has few precedents in arid Australia for either Aboriginal or mainstream housing. Two examples by architects in the 1970s failed for a number of cultural and functional reasons (Heppell 1979; Heppell & Wigley 1981:157). Remote Aboriginal clients are wary of experimental housing design and preferences for conservative, mainstream architecture can conflictwith preferred living patterns (Memmott 2003).

SOCIO-CULTURAL FACTORS AND IMPLICATIONS FOR HOUSING ENERGY USE.

Research and evaluation of both mainstream and self-constructed Aboriginal housing has identified a range of behaviours and social practices that are relatively consistent across remote settlements in semi-arid regions (Memmott 2003). We need to be cautious about accepting generalizations for diverse groups and changing demographic profiles, but the following factors either directly or indirectly influence residential energy use.

Mobility and the use of houses

High intraregional mobility is a consistent and common practice of people Aboriginal in remote and regional areas across the country and this factor directly affects the occupation of housing with implications for domestic energy use. Research on mobility in three towns in the study region in 2006 found that about one third of Aboriginal households contained visitors, a proportion consistent with other studies (Long & Memmott 2007:3). Cultural and social factors (the maintenance of kinship relationships) and service needs are main reasons for the high mobility.

Across Australia, Aboriginal household numbers are significantly higher than the mainstream household. High household numbers are related to general housing shortage in remote areas, population growth, socioeconomic disadvantage and cultural preferences (Memmott et al. 2012). High mobility also causes household numbers to fluctuate. There is a growing literature on overcrowding Aboriginal households yet there is little direct evidence of the relationship between numbers and energy use. High and fluctuating household numbers present challenges to designers and need to be considered in the assumptions required for thermal modeling of Aboriginal housing.

Unconventional use of housing by Aboriginal people is common in remote and urban settlements. Living rooms are used at night for sleeping (Long2005:223) and bedrooms can be occupied by relatively large numbers (2013). Social and technological change has also increased energy intensive activities such as television and computers, particularly for younger generations, yet the effects on housing use is underexplored. Surveillance of the community and environment was a determinant in the architecture and spatial arrangement of traditional camps yet it is common for windows to be closed and heavily screened. This may relate to privacy but in remote communities the practice may also relate to a fear of the supernatural and sorcery (Dillon & Savage 2003). In areas where this practice is prevalent, the use of windows for either diurnal or nocturnal ventilation needs to be reconsidered—occlusion of windows renders them ineffective for either daylighting or venitation (per. comm. Finn Pederson 2014).

External living

The literature on Aboriginal housing indicates a strong preference living outdoors during the day, and sleeping outside the house has shown to be been common in remote settlements (Long 2005; Memmott 2003; Musharbash 2008; Pholeros et al. 1993). Both socio-cultural practices and thermal comfort influence these behaviours. In summer, shaded areas outside the house, mostly from trees but also purpose built shade structures, are used in preference to the house interior (Dillon & Savage 2003). External living environments, which include verandahs, also enable social and environmental surveillance, including the monitoring of weather and seasonal indices.

In remote areas, adapted forms of pre-colonial shelter types continue to be constructed in yards to support socio-cultural practices. Variations on the windbreak are used extensively in yards and often associated with fires for warmth or cooking purposes: firewood piles are common in yards in the study area with the elderly often supplied by family. In the study region, and arid-zone settlements generally, traditional thatching materials are used on shade structures, but certified uses of such materials are limited.

Figure 3. Housing in Dajarra that show little modification of the yard and a self-constructed windbreak used for cooking and other activities. June 2013. (Photographs author).

Aboriginal residents use conventional (mainstream) internal kitchens but a range of traditional cooking activities occur outside the house in open fires and wood-fueled stoves (Long 2005). Long has traced the continuity of these traditions in the study area, recording the additions and alterations to rental housing to make external cooking areas. Thermal comfort was an additional reason for external cooking. In survey questions about adapting to increasing energy costs (Memmot et al. 2013), almost of quarter of respondents preferred to cook outside on wood fires.

Design guides (FACSIA 2007) and good architectural practice (Dillon & Savage 2003) recognize the use of external living environments but exemplars of yard design are rare and not recorded in the study region. Our research shows that gardening practices vary and landscaping around housing for shade depends on the householder. In Dajarra, comparisons of aerial photographs show an increase in vegetation cover over the last three decades. Garden irrigation is also used for evaporative cooling effects in summer but garden maintenance results in very high residential water use in settlements with unreliable water supplies (O’Rourke 20110).

With limited empirical data, it is difficult to gauge whether outdoor living activities are diminishing as people adapt more to houses and become accustomed to air-conditioning. In survey questions on adaptation of living environments to increasing hot weather, the most common answer was to use trees and landscaping. A recent post occupancy evaluation of Aboriginal housing in Alice Springs (CAT 2013), suggested that improvements to yards were more desirable for tenants than alterations to the house. Although the potential of landscape elements to improve thermal performance of residential buildings has long been recognized in arid region design in Australia (Aitchison 1962), there is a wide gap in studies of the actual and potential contribution of microclimates to low-energy housing, particularly in the reduction of cooling loads. Selection, testing and evaluation of xerophytic plants are also necessary given climate change and problems with water supply in arid regions.

With the high cost of construction, landscaping of yards is rarely delivered in remote public housing projects. Cost, household mobility and resources limit ability of the tenants to improve landscapes around remote public housing. Despite these impediments, a range of gardening practices can be identified in the study region. Design improvements to residential landscapes benefit from the participation of household, in both maintenance and involvement in the design process.

CONCLUSION

Studies in the Georgina River Region found that vulnerability to climate change was related to poor quality housing and increasing energy prices. Low-energy housing is required for socio-economic reasons and the viability of remote Aboriginal settlements, in addition to low carbon imperatives. In the semi-arid and arid regions of Australia, modeling software demonstrates that both existing and new residential buildings will need substantial changes to building envelopes to achieve existing levels of thermal comfort without large increases in energy intensity (Wang et al. 2011). Harvey's review of low-energy buildings (2013:303) suggests that high performance housing requires "significant additional investment costs, with simple payback times of 20–30 years or more." His survey shows that high levels of skill, from integrated design processes to construction, can produce economical low-energy buildings.

Although integrated design and technologies can inform approaches to Aboriginal housing, the literature emphasizes knowledge of domestic social and cultural behaviours as a prerequisite for cross-cultural design. Limited but relatively consistent evidence presented in this paper suggests that certain socio-cultural practices provide a level of passive thermal comfort. This is particularly the case with the use of external living environments. These practices present opportunities for synergies between behaviour and passive or low-energy design. Landscape design for residential microclimates in the arid region supports current cultural practices and has potential to reduce the energy intensity of housing. In contrast, mainstream housing, reliant on air-conditioning, can work to undermine domestic cultural practices that are inherently sustainable.

It is a challenge for researchers to devise methods to record behaviours and preferred practices that influence the use of housing and yards over different seasons in remote areas. This does require an ethnographic strand to the research. In different settings, social and cultural change affects the currency and relevance of existing data. Data is also deficient in the measurement of energy use and the thermal performance of existing housing and yards as well as data on new approaches to design of both the internal and external living environments in arid regions.

ABSTRACT

Mediterranean architecture is characterised by the presence of transitional spaces in which thermal conditions are intermediate between the inside and the outside ones. It is important to analyse these spaces because they act as climatic moderators with a strong social role at the micro scale level.

This study focuses on a particular type of transitional space that morphologically is located at the border of a building, usually called porch. The geometry of this space influences the effect of solar radiation as a source of heat in the space and for the building facing on it. However, their potential in terms of thermal comfort especially in summer season is in contrast with the need of solar gains in winter, daylighting and visual contact to the outside. The importance of integrating these aspects is generally underestimated by designers.

Aim of this study is to define the potential of environmental control of these transitional spaces and, in particular, how they can balance the requirement of a shaded area and the need of natural lighting inside the building. The effects of a porch orientation and proportions are analysed to compare how different configurations modify the transitional space performaces. These evaluations are performed with simple tools, which take into account the impact of direct and diffuse solar radiation.

The analysis is still in progress but the most important finding of this paper is to present a method of evaluation that enables the architect to do early stage considerations according to the user requirements and the external constraints of the context.

INTRODUCTION

Mediterranean architecture is characterized by a great diffusion of transitional spaces (called also intermediate or semi-open spaces) that have intermediate thermal conditions between the indoor and outdoor environment. Historically their role as climatic moderators makes them an extension of living space and a place that favour social relations.

These spaces have always existed in different countries with specific features according to the culture and the climate. The benefits they provide make them interesting to investigate.

Intermediate spaces were largely used in the history of the Mediterranean countries where they originated and developed different configurations as porches, patios, loggias etc. especially in the

Author A is a PhD candidate in Building Technology and Environmental Design, Politecnico di Milano, Italy
Author B and C are professors in the Department of Architecture and Urban Studies, Politecnico di Milano, Italy

northern latitudes where the climate is more temperate and variable through the year (presence of hot summers, cold winters and middle seasons). These intermediate conditions imply the necessity of adapting the building to variable external dynamic stresses, combining the necessity of summer cooling and winter heating. For these reasons, transitional spaces are considered very important passive strategies, especially for their role in moderating the effect of direct solar radiation at a microscale level.

Since a complex network of different public spaces constitutes the structure of Mediterranean cities, the presence of intermediate spaces such as covered streets creates semi-public environments that act as unifying elements and promote a gradual transition between areas with different functions and levels of privacy. The potentially comfortable area they provide makes possible to experience protected zones where to sit, relax and enjoy the surroundings.

They are still built today but often using new materials and formal solutions with the only aim of enhancing the building exterior appearance. In fact, the advent of mechanical systems to control climate in modern buildings led to a standardized architecture with little use of passive strategies. Thus, the results often demonstrate a lack of environmental consciousness. This paper tries to clarify the environmental impact of these traditional forms and explains a method that enables the architect to do first conscious design considerations balancing the different needs required by a specific project.

TRANSITIONAL SPACES

Although transitional spaces have always played a significant role in moderating climate, it’s difficult to completely define their use because of their nature of being always “in between” different conditions (external/internal, public/private etc.). However, they can be classified in categories depending on their relation to the building.

From literature review (Chun et al., 2004; Coch, 2008; Maragno, 2010) there are: the “central type” totally enclosed by building’s walls and opened to the sky such as courtyards, patios and atria and the “perimeter type” covered and located at the border of a building such as porches, loggias and balconies.

Their value in climatic control is recognized from the Greek and Roman architecture mostly because they provide protection from undesired sun radiation, wind and rain, creating habitable semi-open spaces. The two types are sometimes integrated or used in a sequence increasing their value. For example, the Roman “domus”, the most typical Mediterranean residential housing type, is constituted by these different types of space: the impluvium and the court (central) and the peristilium (perimeter).

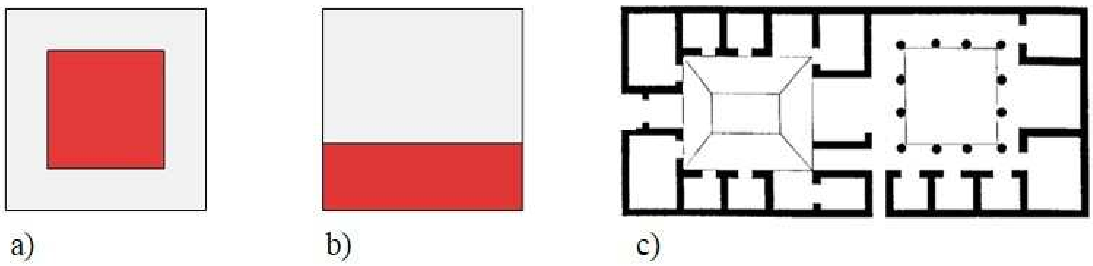

Figure 1 (a) "central type", (b) “perimeter type” and (c) the Roman “domus”.

The advent of the glass in the modern architecture made possible the transformation of these two traditional types of transitional spaces in real “thermal buffer spaces”: the central type became an atrium and the perimeter type a greenhouse. The glazed solution increases the thermal effect but loses partially the relation to the outside that remains only visual. This is an example of how the new technology transforms traditional architectural elements in a way that potentially increases the climatic control but more specific knowledge and a more conscious design is required to avoid undesiderated effects of overheating.

The shading effect

This work is based on the hypothesis that the microclimatic characteristics of transitional spaces influence people's behaviour and their propensity to use such spaces (Dessì, 2007). The qualities of these spaces are visible at a micro-urban level because they create microclimatic environments that enhance activities and provide social interaction. They can be seen as a comfortable extension of the private living space and a passive strategy of building envelope protection in overheated period. Their "ability" to protect from external environmental factors like sun, wind, rain and the amount of natural light inside the building depends on their configurations (horizontal and vertical limits) and on the materials that constitute them.

Although it is demonstrated that the presence of shaded spaces reduces the temperature fluctuation producing a more liveable environment (Chun et al., 2004), current comfort standards are not appropriate to evaluate well-being conditions in spaces that are neither interior nor exterior.

In this sense, it is necessary to assume a different approach to demonstrate their effectiveness. According to Potvin (2000), the presence of urban transitional spaces as porches provide a progressive adaptation of the body to a new environment. Even though this phenomenon cannot be clearly evauated, there are researches that deeply investigate the perceived thermal comfort related to the psychological effects (Nikolopoulou and Steemers, 2003). In transitional spaces, the adaptive behaviour of people is demonstrated by the positive feeling resulting from the experience of passing through gradual conditions between the interior and the exterior. Moreover, the vision of a shaded space that anticipates the coolness sensation is a form of thermal "gestalt" which defines the richness of sensations that associate the multisensory perception to the metabolic and behavioural mechanisms of thermal regulations.

Thus, not only the physical effect of shading, but also psychological aspects related to multisensory experience are important issues that induce social use of transitional spaces.

THE PORCH AS A TRADITIONAL CLIMATIC MODERATOR

This research focuses on a particular transitional space usually called "porch" in Mediterranean countries. It is a "perimeter type" that in another part of the world has different cultural or climatic values. In traditional Japanese house where it is named "engawa", it is a house extension that creates a continuum with the interior, while in tropical countries it has a stronger climatic impact and it is called "verandah" (Maragno, 2010).

In temperate countries, the porch is present both in its introvert and extrovert expression, along the streets and inside the courtyards. It has its origins in classical civilizations but its configuration has changed through the history to meet specific functional and aesthetic requirements.

The term "porch" derives from the Latin word "porticus" referring to a covered, columned space facing to a religious or civil building. On one side with a very symbolic value in relation to the concept of access to the sacred area of the temple, while in its public meaning with the name of "stoà" as place of philosophical, political and commercial meeting. In the private roman house the "peristyle" defined a certain internal realm around a courtyard. During medieval times it has been used in the monastic architecture inside cloisters as a space for meditation, than in the Renaissance it was a recurrent element in palaces courtyards or at upper floors named "loggia". In modern architecture, it appears in the form of modular balcony or delimited by Le Corbusier "pilotis". Today the porches are built with new technologies and materials often with bad results in terms of climatic control, as previously mentioned.

The morphology of a porch is defined trough spatial characteristics that are useful also to analyse other configurations of "perimeter spaces". These spatial characteristics are: the "degree of enclosure" (enclosed or attached) in the building volume, the "proportions" respect to the façade (punctual or linear) and the "level" at which is located (ground or upper floor).

According to these variables, the porch can be defined as "enclosed", positioned at the ground level and "linear" since normally its length is much more than the other dimensions.

The position on ground floor makes the porch a space with a strong link with the surrounding open space with a pontential high level of social interaction and, for this reason, the permeability of the open side (e.g. distance between columns if any, presence of shading elements etc.) acquires great importance. Then the characteristic of being “enclosed” means that the upper horizontal limit is not exposed to the solar radiation but it only makes shade. Finally, the fact that the porch is linear allows its analysis in section, considering only the depth and the height: if it has the proportions of a corridor, it is only a space of circulation while if it is wider it can become a place for static activities.

In the perspective of a new project or a renewal, each of these variables assumes the role of a design strategy with a functional, environmental and aesthetic impact.

Environmental potential

Especially in temperate latitudes, the porch has a great climatic importance because of its good response to the variability of the climate: it protects from direct sunlight in summer but allows sun penetration in winter.

From a thermal point of view it enlarges the perimeter “potentially passive zone” (Baker and Steemers 2000) of the building in which the climate can be moderated without mechanical control systems. In relation to natural light, the porch works as an “intermediate light space” which permits the entry of daylight in the adjacent building through wall openings. Thus if it is designed so as not to reduce too much the daylight availability, it can provide a decreased and less contrasting light level to the interior zones facing the porch.

The effectiveness of a porch in relation to thermal and visual comfort depends primarily on its geometrical configuration, the orientation and the materials that constitutes its limits.

The solar radiation is the most critical environmental factor because it needs a contradictory architectural response according to the season and to its direct and diffuse components. Preventing direct sunlight creating shadows means to reduce also the infrared re-emitted radiation. Diffuse radiation is reduced as well affecting the daylight levels inside. The reduction of direct sunlight has positive effects because it increases illuminance uniformity and reduces contrasts preventing glare. It also creates pleasant effects of “penumbra” but you have to be careful in order not to go below the threshold of visibility. It’s worth noting that the amount of daylight inside should be considered togheter with the wall openings size and position.

All these issues refer to the importance of integrating different (and sometimes contrasting) environmental aspects in the design process in order to balance the effects primarily in relation to the user needs.

METHODOLOGY TO EVALUATE THE ENVIRONMENTAL CONTROL OF A PORCH

Many works have contributed to the quantitative evaluation of daylighting and sunlight control with energy simulations but few researches have explored the combined visual and thermal aspects related to solar radiation. The aim of this work is to propose a methodology based on an integrated approach that takes into account the requirements of a shaded area with the need of daylighting inside the building. In this way, architects can be helped to solve the problem of associating aesthetic qualities to environmental issues and functional needs.

Evaluation process

In order to evaluate the environmental potential of a transitional space configured as a porch (as described before) it is important to individuate the main parameters which represent its behaviour at micro-urban level.

A configuration comprehends the building surfaces that define the limits of the porch and the urban surrounding space. It is defined in terms of latitude, orientation, proportions and materials. In a preliminary design stage, the geometric parameters are more important than the material’s effect. Later, to have a more detailed analysis, it is useful to introduce the physical properties of the materials. The key issue is to balance the requirement of shading with the need of opening to the sky. Thus the first step is to evaluate solar accessibility in different seasons. The influence of external obstructions is assessed in terms of "aspect ratio" (H/W, the height of the building to the width of the open space) during the winter solstice when the sun is lower in the sky and the direct radiation is desiderable. It is possibile to define the two opposite urban scenes in relation to the solar access: a street canyon completely shaded or a wide open space (as a square) without influence of obstructions.

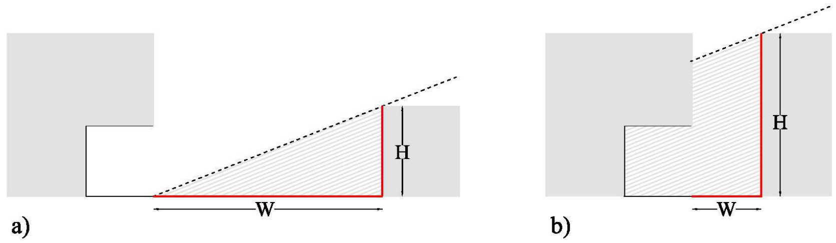

Figure 2. Solar accessibility in winter solstice at 45°N latitude in two urban contexts with the aspect ratio of a square (a) or of a street canyon (b)

On solar access and urban geometry, Oke observes that an "H/W of approximatively 0.6 seems to be a suitable upper limit to maintain solar access in a city at a latitude if 45°N" (Oke, 1988). The need of opening to the sky is not only related to the thermal aspect but also to the daylight issue. In previous studies (Littlefair, 2001) it is suggested a spacing angle for temperate climate, that is nearly 35°. In fact, a transitional space in a street canyon tend to lower the sky component of daylight but at the same time the reflective properties of materials could increase illuminance levels due to the diffuse light reflection within the canyon.

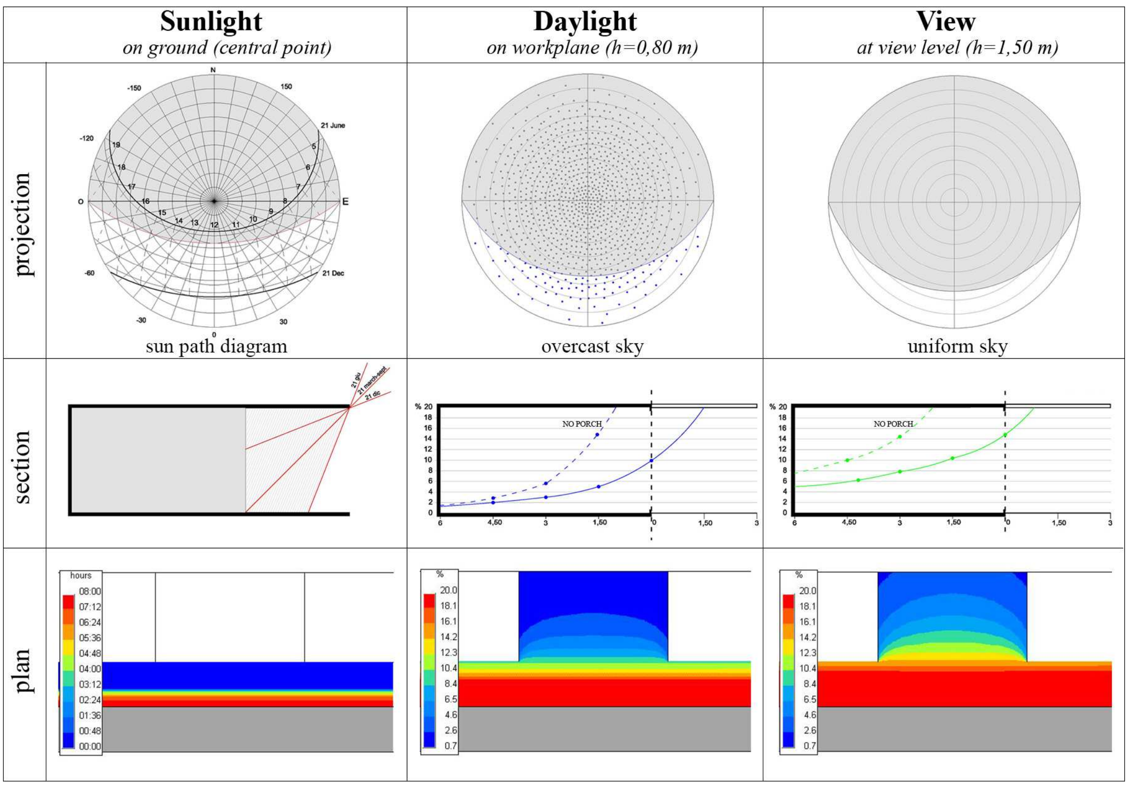

Figure 3. Evaluations and related representations. (e.g. H/D=1 and facade completely glazed)

After the context analysis, the evaluation should focuses on the geometrical effect of the porch defined in terms of aspect ratio H/D, since it is assumed of infinite length (Fig. 4). The prediction of the sunlight and daylight distribution in the transitional space and in the adjacent interior rooms can be performed using different procedures (e.g. algorithms, nomographs, prediction tools, scale model-measurements and simulation programmes).

A simple graphic way to assess the direct sunlight impact in a point consists in overlaying a sun path diagram of the selected latitude to an obstruction mask properly oriented in a plane projection of the sky vault. Thus, it is immediately visible if the point meets the requirement of being shadowed in summer and not in winter. The unobstructed part of the mask gives also information on visual comfort (changing the reference point height above the ground), evaluating two aspects. On one side, it provides directly the percentage of visible sky from that point as Sky Factor (SF) measured considering a uniform distribution of the sky vault. This parameter is related to the pleasant effect of having a visual link to the esterior and for this reason it is interesting to evaluate it at the eye level of a standing person (1,50 m). On the other side, overlaying a dot chart representing the illuminance distribution of an overcast sky (worst-case scenario) it is evaluated the Daylight Factor (DF, the ratio of interior horizontal illumination to exterior unobstructed horizontal illumination) as a first approximation. In fact, actually, the number of dots in the opening area represent the sky component of the DF, the illuminance received directly from the sky (neglecting in this first stage the reflected light from surrounding surfaces). In this way, for Mediterranean countries, sometimes the amount of natural light can be underestimated because in the southern latitudes there is a high frequency of clear sky conditions and that increases the contribution of radiation reflected from ground. In our case, considering the northern Mediterranean areas with temperate climate (latitude of about 45°N) it is reasonable to consider an overcast sky (in a first stage). Moreover, there are many design parameters, such as surfaces reflectances, window shape and size, and optical properties of the glazing that are unknown by the designer at the early design stages. For reference, a room that has a DF of less than 2% is considered poorly lit while rooms with DF between 2% and 5% are considered ideal for activities that commonly occur indoors.

Using different representation techniques, it is possible to have a more comprehensive description of the parameters values in the space. Especially at the early stages it is very useful for a designer to have simoultaneous views (plan, section etc.) of the same object (Fig. 3).

In this study the parameters described are calculated with the help of Heliodon 2 (Beckers, 2009), a simple simulation software that allows faster evaluations and multiple view of the same geometry. Other more sophisticated tools (e.g. Radiance) enable more precise assessments but they are much more complex to use and the computation takes longer time, thus they may be of help in a further step of the design process to verify the choiches made.

The study model

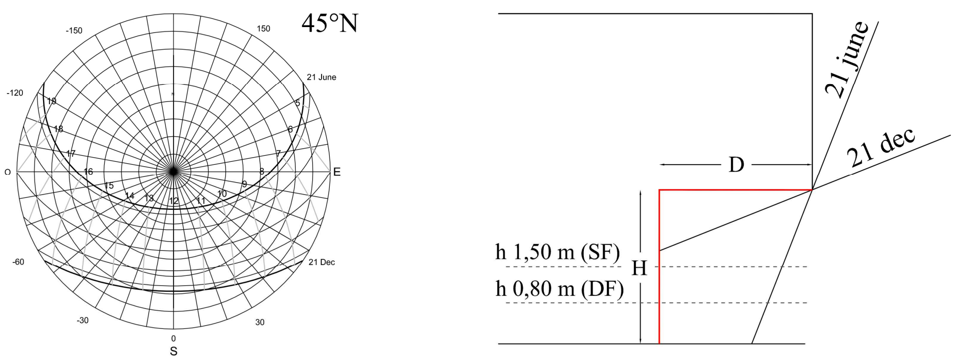

Figure 4. Configuration of the study model.

The effect of proportions and orientation of the porch on the luminous and thermal performaces is evaluated through a study model (Fig. 4) considered representative of possible real cases. The model is located at a 45°N latitude, in an urban context in which external obstructions does not affect solar accessibility (Fig. 2, case a).

It is tested in different hours of the day and in the two seasons with conflicting requirements (summer and winter). The proportions tested are based on the observation of different existing porches and ranges from 0,5 to 2 H/D.

The evaluations are performed using indexes that allow comparisons among different configurations. The percentage of shaded area in summer is evaluated on the ground surface (on the 21st of June at noon) as Shading Factor, while the ratio of sunlite area in winter winter (on the 21st of December at noon) is assessed on the building wall as Sun Factor. The Daylight Factor (actually its sky component as previously explained) is evaluated at a work plane height (0,80 m) while the Sky Factor at the eye level of a standing person (1,50 m).

The building wall is the critical limit on which to evaluate the porch and the effect on the interior space depends on the porch's geometry and the wall configuration, in particular in terms of both windows size and position in the wall.

Results

Regarding the porch orientation: the more the angle deviates from the east-west axis the more the porch becomes useless for all tested proportions. If the porch is very deep (H/D < 0,5) there is a lack of daylight inside and at least 50% loss of solar gains in winter. This first observation highlights the importance of integrating different aspects in the evaluation process.

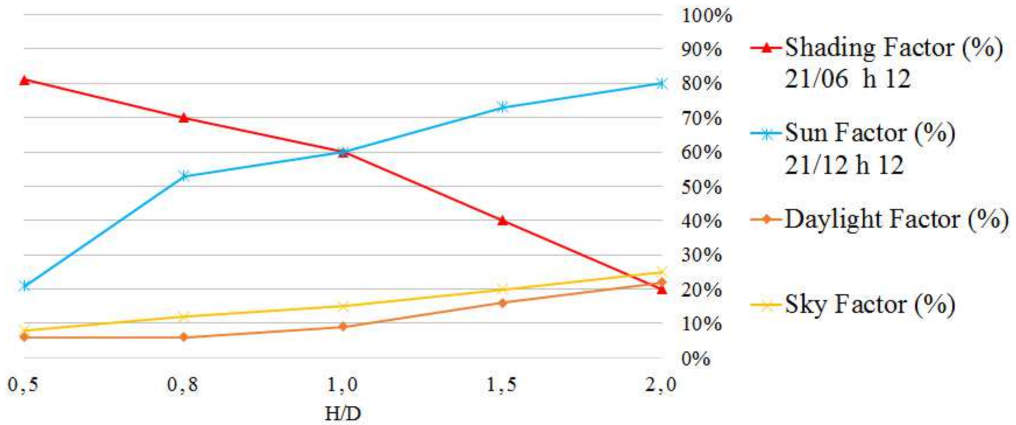

Figure 5. Effect of different aspect ratio on thermal and visual parameters.

Fig. 5 shows the comparison between different aspects ratio integrating the thermal and luminous aspect. Therefore, DF and SF are considered as punctual values on the building façade, the physical boundary that separates the inside to the outside.

Observing the graph, it seems that the aspect ratio of 1 offers the best balance between protection and openness to the sky, with the same percentage of shaded ground in summer and wall exposure to solar gains in winter, with a medium value of daylight and view factor on the building envelope. On the contrary, the extreme cases show that: if the deptht is double than the height the only benefit is to have a wide shaded space in summer, while if the porch is too narrow it does not provide a usable space and it is only a solar protection for the building envelope. Of course, as it mentioned before, these analysis do not pretend to give accurate results but they are first evaluations to be integrated with other design features.

CONCLUSION AND FUTURE DEVELOPMENTS

The partial findings presented in this paper are part of a wider research that investigates transitional spaces in relation to human well being with the aim of providing guidelines for an architect in the early design stages. In particular, the importance of the porch as a climatic moderator in temperate Mediterranean latitudes has been clarified. Since environmental potential is well exploited only if it anticipates the human expectations, the method presented makes the effort to integrate different and sometimes contrasting needs especially in terms of daylight and sunlight.

Further evaluations can be performed taking in account other design features. In particular, the material effect is to be investigated: on one side in terms of exterior finishing, taking in account the surfaces' multi-reflectances for a more precise assessment of the illuminace levels and eventually the occurance of glare; on the other side the thermal effect due to riemission of long-wave radiation.

All the design choices modify the building exterior appearance with consequent effects on multisensory perception and on the integration within the surrounding context, especially in the case of building renewal or in an extremely dense urban context. Resolving all of these questions is a complex issue; therefore, the priorities of a project should be defined in relation to the specific user needs and balanced with the external costraints in order to reach a satisfactory compromise.

ABSTRACT

This study unveils PCK house by revealing its sustainable architectural features in both cross-cultural and climatic adaptation aspects. The Kelantan Peranakan Chinese (KPC) are a group of Chinese-Malay-Siamese mixed-race community living in the state of Kelantan, Malaysia bordered with south Thailand, a Malay-Muslim majority region. The KPC's ancestors were Chinese from Min Nan, the southern Fujian province who migrated to and settled down in Kelantan in the last 300 years. Throughout these periods, KPC have socio-culturally assimilated into Malay-Thai native identity and adapted into the local tropical environment. One of the most noticeable features of these cross-cultural and cross-regional climatic adjustments is their unique domestic architecture. Ritually, the layout of a KPC house strictly inherits the basic Chinese domestic house planning, where the ancestral hall is positioned in the central and both sides of the hall are bedrooms. Externally, the style of the KPC house resembles typical Malay-Thai timber stilt houses. These amalgamations are required in order for KPC to fulfill their spiritual needs, and at the same time to harmoniously sustain in a new socio-cultural and nature environment. This study unveils the KPC's creativity in modifying the architecture of their domestic house by regulating certain socio-cultural and ritual-religious variables to suit local climate and contexts. The purpose is, certainly, towards creating a more socially and environmentally sustainable residence. The methodology of this study is based on contents analyses of five measured drawings and observations on more than 400 visited houses. Simple temperature, humidity and illuminance measurements have been taken to provide some quantifiable figures. These analyses suggest that in adapting into a new local context, KPC are more concerned on how to achieve and maintain their ritual needs and identity over climatic aspects.

INTRODUCTION

In the quest of energy conservation and visioning the low carbon developments, investigation on how vernacular houses sustain naturally by their passive energy mechanism is getting more attention in environmental science researches recent years. Undeniably, vernacular architecture has been highly cited by scholars as one of the established archetypes evolving over the time through the processes of intertwining and adapting nature and socio-cultural aspects. The purpose is to achieve a balance living condition for humans to sustain harmoniously in their domestic sphere and surrounding contexts.

Vernacular house is the metaphor of these nature and socio-cultural symbiosis reflecting on its house form, spatial layout, site planning, material selection, etc. In searching for the lessons of sustainability aspects of vernacular architecture, however, most researchers focus on quantifiable climatic aspects than human or socio-cultural aspects. Albeit climatic architecture features are important supportive mechanisms to help providing climatically comfortable living to the residents, it is not always the main choice for vernacular houses where socio-cultural contexts, inherited rituals and identity aspects may play decisive factors over the climatic aspects.

So far, most environmental researches on vernacular architecture focus on homogeneous setting. The outcomes might not offer diverse and alternative lessons which are very useful in hypothesising the way of sustaining the growing plural and cross-cultural living environment in today's world. Hybrid vernacular architecture, or fusion of two or more cultures, perhaps is one of the best subjects to be examined. KPC's vernacular architecture offers great research exploration on how cross-cultural and cross-regional climatic adaptations could happen, particularly when involving different socio-cultural and environmental contexts; for example adapting sub-tropical climate into tropical climate or from a Min Nan Chinese culture into Muslim-majority context. The study shows the KPC are adaptable to their external architecture identity by adapting local influences in materials, design elements, and styles in order to sustain ecologically in the new environment. However, these amalgamations do not prevent their strong instinct to inherit their Chinese cultural identity, ritual and spiritual needs by remaining the Chinese architectural principal in spatial organizations in their house layouts by scarifying some climatic quality aspects.

The methodology of this study is based on contents analyses and observations on five measured drawings from KALAM (Center for the Study of Built Environment in the Malay World), UTM, and more than 400 identified houses from five fieldworks. In the aspects of climatic adaptations and socio-cultural assimilations, analyses are made from the comparisons between KPC houses and their vernacular houses in Min Nan, China as well as Malay houses in Kelantan. In the aspect of climatic adaptations, aspect of ventilation, lighting, materials, etc. are discussed and supported by some simple quantifiable measurements. Socio-cultural amalgamations such as factors which influence the adaptations and changes in KPC architecture were gathered through observations, interviews and literature reviews.

GEOGRAPHY AND CLIMATE

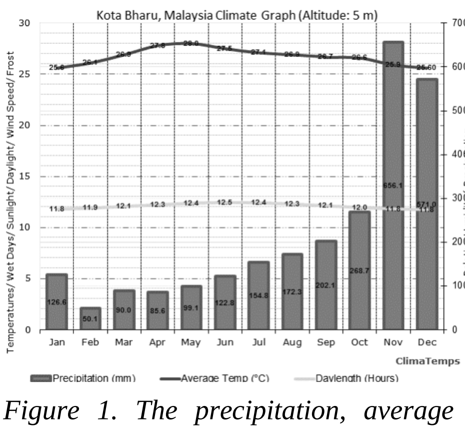

Figure 1. The precipitation, average temperature and daylength in Kota Bharu. Source: http://www.malaysia.climatemps.com/.

The Peninsula Malaysia, strategically located between West and East Asia, has been an important melting pot of commercial and cultural exchange since six hundred years ago. Today the diverse multi-racial demographic, comprising 60% Malays, 27% Chinese, 10% Indians and others, in the Peninsula is the result of these historical consequences. Kelantan, the most north-eastern state of Malay Peninsula, shares its border with Southern Thailand. Covering the area of 15,099 km2, Kelantan is the sixth biggest state in Malaysia. With a population of 1.5million, the density of the state is about 100 where the concentration of population can be found in Kelantan Plain, a fertile agriculture plain dominated by the main river system, Kelantan River, and other smaller river systems.

Generally, the climate of Malaysia is tropical rainforest, having hot and humid ambience and no distinct rain and dry seasons year round. With the latitude and longitude slightly north from the equator 5.2500 ° N, 102.0000 ° E, Kelantan has clearer dry and wet seasons compared to southern part of Peninsula Malaysia. The wettest period is from end of October to early January when the Northeast Monsoon brings heavy rain to the state, whereas the driest period is from February to May. The average yearly rainfall and temperature in Kota Bharu, the state capital, is about 2600mm and 26.7 ℃.

HISTORY

Figure 2. The former Pattani Region. Kelantan (no.8) shares border with southern Thailand.

Facing the South China Sea, the Northeast Monsoon does not only bring heavy downpours to Kelantan, but historically it had been shipping the Chinese immigrants to the east coast of Peninsula Malaysia. The coming of the Chinese into the Southeast Asia can be traced back to 3rd century A.D. There are very rare academic records on the history of the Kelantan Chinese in the early period, but the existence of a 300-year old Chinese temple at Kampung Tok' kong proves that a small group of Chinese had already established their community in Kelantan in 18th century.

The early Chinese immigrants who landed in Kelantan were mainly from Min Nan, Fujian province, China. Most of them settled down in rural areas along Kelantan rivers' basins to find livelihood. Their comings were much earlier and small in numbers compared to those Chinese immigrants who migrated massively into the British Malaya in 19th to 20th century. Due to separation by the central mountain range and limited infrastructures, social contacts and economic exchanges between Kelantan Chinese and Chinese from other Malayan states have been scant. Having long been away and disconnected from their Chinese roots has resulted in that the Kelantan Chinese gradually assimilated to the natives' way of life by acquiring local Malay language as their mother tongue, adapting to local food, costume and others. One of the most obvious assimilated features is their fusion domestic house which shows interesting cross-cultural and cross-regional climatic adaptations. This community is widely known as *Cina Kampung* or village Chinese by the local Malay and Siamese natives, but the community prefer to be called as Kelantan Peranakan Chinese (KPC), means local born Chinese or the Peranakan in short.

KELANTAN PERANAKAN CHINESE VILLAGES AND STILT HOUSES

Figure 3 Location of KPC villages. Most of the villages are located along the river basins of Sungai Kelantan and other smaller river systems.

Almost all KPC villages can be found along the fertile river basins of Kelantan, Pengkalan Datu and Kemasin rivers. Alike native Malay and Siamese traditional villages, their houses are usually located near to the source of their livelihoods such as paddy fields and rivers (Chen, 1998). River fish provides important source of protein to the KPC. Besides, rivers were the main highway for the KPC to communicate from one village to another and ferry their livestock, goods and crops to towns for trades. Although the rivers have not been actively used as in former days, the rivers are an important symbol of how the community sustained their living in the new environment. This could be deduced from the practical way on how most of the KPC orientated their houses facing the rivers, significant to their source of livelihood, economy, transport and communication. Traditionally, the orientation of Chinese house is facing south (坐北朝南) following the Chinese geomancy principals, while to climatically avoid cold northern winds during the winter months. Nevertheless, extreme weather is not part of issues in the hot-humid climate of Kelantan and the principal of orientating the house facing south is impractical for KPC to conduct their daily activities with rivers.

Most KPC houses are sparsely located from each other on linear grid pattern by facing rivers or roads. The KPC village pattern is obviously disparate from Min Nan traditional village pattern, as Min

Nan villages are arranged in cluster group patterns. Two reasons could be hypothesized; least concern of security and climate in Kelantan. In Min Nan, traditional houses are closely grouped together to form a big cluster. The purpose is to create a strong surveillance network to defend the villages from bandit attacks. Secondly is to keep the villages warm during colder months. Since security is not part of the concerns in Kelantan, KPC houses are not densely planned or arranged in cluster manner, which allows greater wind velocity and penetrations to help discharge contained humidity. Besides, the practice of opening new lands after the existing villages have reached certain levels help to maintain the villages in low density, which is critical to help KPC village to sustain its micro-climatic aspects. To maintain the social networking and kinships, normally the new villages are opened opposite the rivers or adjacent to the existing villages. Therefore, many KPC villages can be found located side by side or facing each other along the rivers in Kelantan. Due to small number of population, KPC villages' public facilities such as schools, markets, public spaces, etc. are shared with surrounding Malay and Siamese native villages. Sharing these facilities enhances the interactions between the natives and the KPC, which it is very important for the KPC to mutually and socio-culturally sustain as a minority in the natives' socio-cultural landscape.

THE HOUSE UNIT

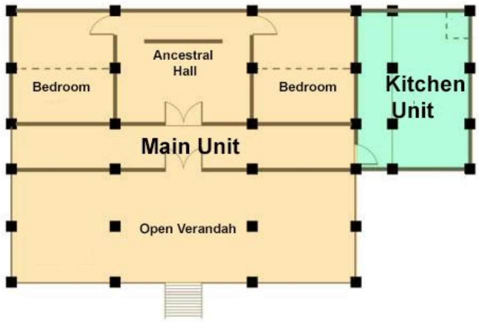

Figure 4 (left) The KPC house plan comprises two units: main unit and kitchen unit. Figure 5 (right) shows the façade of KPC house with large curvy roof to help discharge rain water and reduce the velocity of strong wind.

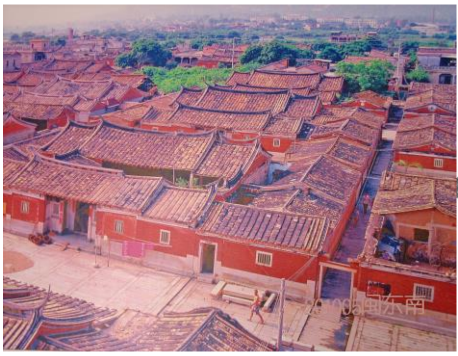
Basically, a KPC house consists of two units, which are the main house (unit) and kitchen house (unit). The main unit has an ancestral hall and bedrooms. The kitchen unit is where kitchen, dining area and bathroom are located. Similarly to a Malay house, a KPC house also comprises of *rumah ibu* (main house) *and rumah dapur* (kitchen unit). In Min Nan, China, the house unit can be repeated and expanded to form a big enclosed complex to accommodate bigger family members of few generations. From climatic point of view, the enclosed complex is not suitable in hot-humid climate where accumulating humid and high air temperature will make residents feel uncomfortable. In Malay village, extended families normally will establish their own houses adjacent to or in the nearby areas to their parent houses. Several Malay houses form a family cluster and several family clusters form a Malay village. This trend also applies to the KPC house where a village normally comprises of several family clusters. Besides, the reason why the KPC and Malay houses are small may be due to the limited spans of timber material. Most of KPC house structure is about 9 x 6 m (main unit). Technically, it might be difficult for timber structure to hold a large span without established construction skills. Another interesting sustainable feature of Malay and KPC houses is these houses can be dismantled and reinstalled from one location to another location.

The House

Western scholar Kohl (1984), who studied on the development of Chinese architecture in West Malaysia and Singapore, observed that the Chinese community is pretty practical in dealing with their domestic houses, signifying that "*satisfied with their fitness of purpose, serviceability and aesthetics, the Chinese have not altered their architecture forms, with architecture becoming more a rule of thumb than 'art'* *after the Tang dynasty*." Even the Chinese immigrants who have settled down in foreign lands for few hundred years would stick with the basic house plans. This is suggested by Chua (1997), stating that the principal of Chinese house is *"not only cut across time, but also 'survived transplantation' from its origin to a new environment."* This principle has been reflected in KPC house.



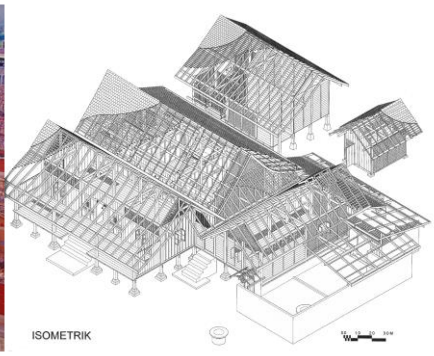


Figure 6 (left) Min Nan house can be repeated and expanded to allocate few generations of family members Figure 7 (right) KPC house can be expanded,or dismantled and relocated to other locations.

The KPC house basically can be divided into three parts: the body, lower floor, and roof. The body is the main house where rooms are located. The lower floor is the area below the elevated timber floor of the main house. The roof is the upper level of the main house. This configuration provides a natural mechanism for KPC house to adapt into its environment.

The Body

As mentioned above, in term of spatial arrangement, Chinese domestic houses are rarely seen having much of regional differences. The internal layout of the Chinese house strictly follows the Chinese architectural concept of "one bright, two darks." (一明两暗). The bright zone is where the ancestral hall is located in the middle of the house facing the main door. The dark zones are the bedrooms located at both left and right sides of the ancestral hall.

Figure 8 (left) Inside the main door is the private domain, where the ancestral hall is located. Figure 9 (center) Ancestral hall is rarely opened to visitors, therefore there are considerations in its ventilation and lighting design, as sacredness and privacy are more important than environmental aspects. Figure 10 (right) KPC have assimilated to native behavior by utilizing the elevated timber floors in their daily activities. KPC have got rid the culture of using furniture. Source: Berita Harian, 4 April 2011.

To achieve brightness in the ancestral hall, two small windows can be found at two sides of the main door of the ancestral hall. Above the main door are timber lattices to allow further penetration of light and air into the hall. Sometimes, small openings covered by transparent glasses can be found on the roof over the ancestral hall to enhance the brightness of the hall. According to the Chinese architectural principal, the dark zones are the bedrooms located at both left and right sides of the ancestral hall. Normally in the bedroom, no window is placed on the wall facing the front part of the house. Only a small window can be found at the side wall of each bedroom. Therefore, the bedrooms are darker than the ancestral hall. Usually, native Malay and KPC houses have low lighting ambience in indoor spaces. According to the simple indoor lighting measurements on a KPC house (refer Graph 1), most of the internal rooms hardly receive 100 lux. However, it creates a more relaxing indoor atmosphere for occupants to rest since most of the daily works are conducted outside of the house or in the kitchen. However, the method of using smaller windows is not due to native influences but the KPC's intention to maintain the origin identity of the Min Nan architecture. The purpose of smaller windows in Min Nan house functions for security reasons and minimizes the effect of northern cold wind. Nevertheless, the atmosphere of Min Nan house is much brighter than KPC house because there is a big central courtyard in the enclosed compound of Min Nan house. In KPC house, in the quest of achieving its ritual needs and architectural identity, the spatial arrangement of “one bright, two darks” with minimum opening makes the indoor lighting extremely low. The long and large overhung roof at veranda further reduces the light penetration into the house. This situation is worsened by the main door and windows of the ancestral hall being closed in the most of the time. The rational of this incomprehensible practice perhaps is due to the feeling of insecurity and sensitivity being in the majority Muslim social setting. As Teo (2003) suggested, the attitude of the KPC is vividly reflected in their way of life where they practice native behaviour (local costume, culinary, sociolinguistic, etc.) in the frontage, while keeping their own Chinese religion and ritual in the backstage, which are usually contained in their own houses and domestic spheres. It shows that maintaining good ethnic relationships and sustaining a mutual-respect living environment with the local natives are given the priority by the KPC and the external factors such as climate and thermal comforts are relegated as secondary aspects.

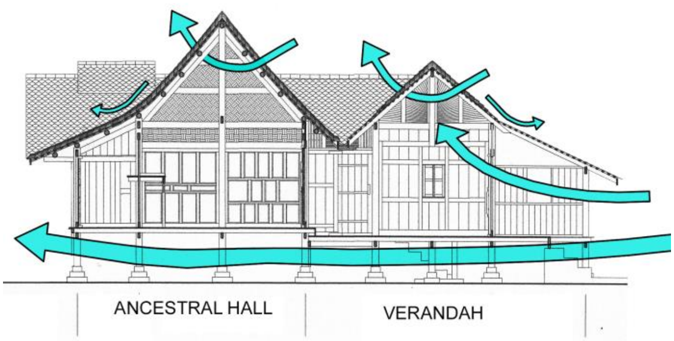

Figure 11 Cross ventilation helps to reduce humidity. Source: KALAM, UTM.

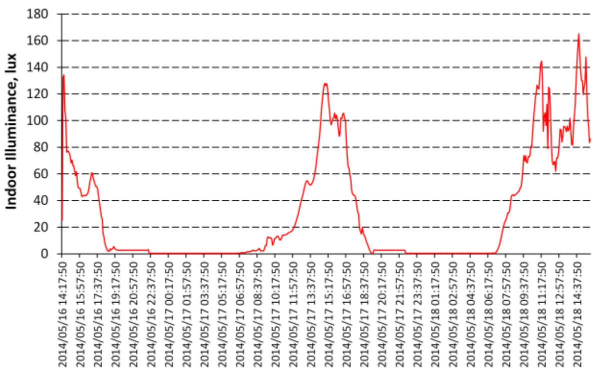
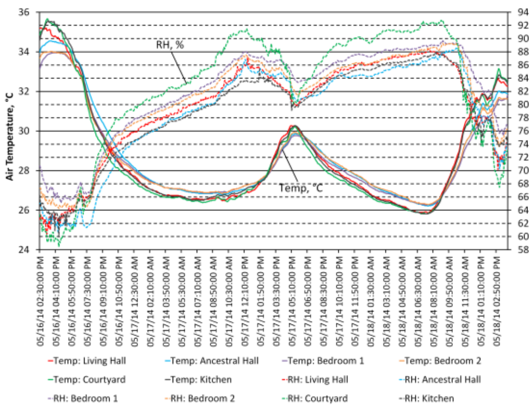
Indoor ventilation and lighting are interrelated. Both are determined by the size and position of openings. Cross ventilation, particularly at body level, is critically important to achieve thermal comfort in hot-humid climates. The airflow will evaporate heat from the human skin allowing the occupants to feel cooler (Lim, 1987). In a Malay house, even though the indoor spaces are considered private to family members, usually windows and doors are open widely to allow natural ventilation occur. Furthermore, the concept of open plan where there is less or no partition is used to divide indoor spaces allows greater cross ventilation to happen in Malay house. In contrast, the concept of indoor space in KPC house is obviously more private, perhaps sacred, than that of Malay house. As mentioned previously, the main door and windows of the ancestral hall are remained closed to prevent direct contact of passer-by to the ancestral hall. Besides, the internal spaces, bedrooms and the ancestral hall are divided by walls which will definitely slow down or block the wind entering the house. However, the problem of limited body level ventilation in the indoor spaces is reduced by roof level ventilation. The steep pitch roofs provide higher roof attics which allow accumulated indoor hot temperature release at the roof level and keep the lower part of rooms cooler. However, this is not sufficient to reduce the indoor air temperature to comfort level.





Graph 1 (left) and 2(right): Sample air temperature and daylight measurements taken from a KPC house (Chan Awang's house, Kampung Sering). The house has an extended living room in front of the ancestral hall. The thermal comfort temperature ranged from 23.5 - 28.5 deg C with neutral temperature (feel neither cold nor hot) = 26 deg C. Generally, all the spaces yielded temperature higher than the comfort zone starting from 11.00am to 11.30pm (except day 2, it was a raining day). For daylight, the living hall only yielded > 100 lux during 1030am to 330pm on the 1st and 3rd day (except second day).

Although the indoor air temperature and lighting are poor, KPC rarely use indoor spaces at daytime. KPC men preferred spending their daytime and doing domestic tasks in the open veranda, while women and children spend most of their time in the dining area and kitchen where Ratio Humidity (RH%) and air temperature are relatively lower due to better openings. Guests are usually entertained in the open veranda area, and the indoor spaces are only generally being used at night when the air temperature and RH% decrease to the comfort level. The roof level's fenestrations and the thin clay roof tiles easily release hot heat, making the indoor area comfortable to relax at night. This suggests that in maintaining the ancestral ritual and identity, KPC choose not to change their spatial layouts and opening for better lighting and indoor temperature but choose to change their living behaviour by assimilating native's way of life and alter its domestic architecture.

The Lower Floor and Roof

Figure 12 Plaited bamboo walls are used to discharge hot air. Figure 13 shows the deep roof which helps to reduce the glare and provide more shade to the house.

Either on lower plains or higher ground, KPC houses are usually elevated on timber stilts, like those of Malay, Siamese and many Southeast Asian traditional houses. Formerly, the underneath of elevated floor was used for storage and to rear domestic livestock. This space allows for a buffer zone between elevated timber floor and the ground. This gap prevents the humidity and moistures from the ground sip into timber and damage its strength and make the residents feel uncomfortable when touching or sitting on it. The elevated floors are very important for the KPC, since most of their daily household activities such as eating, sitting, relaxing, and sleeping are conducted on the elevated timber floors. This shows that KPC has changed their Chinese way of life from using furniture to sitting on the floor as Malay native. From the climatic aspects, the higher the house is elevated, the greater wind velocity can penetrate into the house. This helps to reduce the KPC house's RH level.

Once, the roof of KPC house was made from thatch. Since 1960s, the roofs have been covered by a type of clay roof called *atap Singgora*, imported from Songkhla, Thailand (Winzeler. 1985). The roof is pretty thin and easily broken but it looks closer to the roof tiles in Min Nan house. Like those of Kelantan Malay house, the roof tiles are loosely hanged on the batten to allow breeze to slip inside the house, compared to Min Nan houses whose roof tiles are cemented onto each other to prevent blowing up by typhoons. The curvy tapering roof form is the most expressive part of the KPC house. It symbolizes the Chinese Min Nan architecture identity and their origin. The typical Min Nan house's roof curves into two directions – the ridge and hip rafter, making the roof having greater velocity to discharge water and redirect wind; particularly during the typhoon seasons. In response to higher precipitation average 2600mm in Kelantan, the KPC design the roof steeper in the angle at about 45 degrees. The purpose is to discharge the rain water more smoothly, particularly during the heavy downpour in monsoon seasons from November to January. The pitch of the Min Nan house roof is at about 30 degrees, making the depth of roof lower than that of KPC house. With shallower roof depth, Min Nan house is able to allow greater daylight penetrating into the building and to make the building interiorly and exteriorly brighter. In contrast, the KPC house has steeper pitch and longer roof overhang to shade excessive sunshine. Therefore, the proportion of the roof is much greater than the body of the house, which provides deeper shades to the open veranda. It also helps to reduce excessive glare. The effect of glare provides some security protection to the house owners, particularly in sunny days where one at the veranda can easily recognise any passer-by, but the passer-by having difficulty to figure out whether anyone is inside the house due to glare effect.

CONCLUSION

Having been migrated from sub-tropical region of south China into the tropical region of Malaysia, KPC have to judge what aspects that they can retain and what aspects they should adjust, accept and change in order to sustain environmentally and socio-culturally with the new native environment. These negotiations are illustrated in their domestic house design. Most obviously, KPC ancestors had chosen to follow the local Malay and Siamese natives in using local natural material to build their homes. The lightweight natural material with low thermal capacity such as wood and bamboo provide the house better thermal comfort in tropical climate, besides being visually and contextually harmoniously with the native villages' surrounding environment. To get rid the problem of contained humidity in tropical climate, KPC houses are kept in small units, with the houses being sparsely arranged and the floors are elevated. The purpose is to allow better wind velocity to penetrate into the house compounds and units for reducing the level of humidity. This illustrates that KPC have no longer follow their ancestor's norm of expanding their houses into a big complex to accommodate generations of family members, which it is not suitable in tropical climate where humidity will be difficult to be discharged. Besides, KPC has got rid their Chinese ancestor's furniture culture by adapting Malay natives' way of life by utilizing elevated timber floor as a living platform to conduct their daily activities. Judging from the KPC house's stilt house architecture, the KPC seem to have adapted into Southeast Asia native architecture tradition and further dissociated with their ancestral traditional house typology in Min Nan, China, where most of the houses are made from masonry and placed on stone platforms (Else Glahn, 1982).

However, the domestic sphere of KPC house is still ruled by the concept of Chinese ritual. Descending from Chinese origin, the practice of ancestral veneration is one of their cultural pillars which have to be performed in the ancestral hall. At two sides of the ancestral hall, the norm of placing male's bedroom at the left side and female's bedroom at the right of ancestral hall has further determined the concept of spatial planning inherited from their Chinese origin. Due to sensitivity to the Muslim-majority communities, the main door of the house where ancestral hall is located is always in closed condition. The smaller-size windows further restricts the penetration of light and air into the buildings, making the level of luminance low and air temperature hardly achieve comfortable level. To solve the problem, KPC have adjusted the use of these spaces. To avoid uncomfortable air temperature and low luminance level, these interior spaces are rarely used during the daytime but only at night when both aspects achieve comfortable levels. To substitute the interior spaces, KPC houses, like native houses, have wide veranda for men to rest and do their daily tasks during the daytime and women and children do their activities in kitchen unit where dining and extended family rooms are located.

These architectural adjustments are needed in order for them to fulfill their daily activities and spiritual needs and at the same time to harmoniously sustain in a new socio-cultural and natural environments. The KPC architecture reveals how certain socio-cultural and ritual-religious variables could be adjusted architecturally towards creating a more socially and environmentally sustainable habitat.

Keywords:

Traditional, architecture, sustainable, environmental strategies, comfort.

ABSTRACT

The traditional mud buildings present throughout the hot dry countries of the Middle East provide excellent references to the sustainable elements of architecture. This paper presents the results of the research of a few buildings in Saudi Arabia, Qatar, Bahrain and United Arab Emirates in terms of architectural problems due to climate, and the environmental elements as their solutions. The buildings studied ranges from mud houses, mud palaces to souks or bazars. These are, Shaikh Issa House in Muharraq, Kingdom of Bahrain, Al-Mulla House in Al-Ahsa, Saudi Arabia (K.S.A), Souk Waqif in Doha, Qatar, and Shaikh Saeed Al Maktoum House in Dubai, United Arab Emirates (U.A.E). Measurements were taken of air temperature, relative humidity, and airflow. Observations were made on the various aspects such as plan, form, orientation, sections, elevations, materials and methods of construction and details of the buildings. Comfort survey was conducted among the occupants. The paper shows that the traditional architectural solutions to the climatic problems of the Middle Eastern countries such as thick walls, small openings, shaded courtyards, use of local materials and a few special strategies work very well in the context in terms of providing comfortable environment indoors. The measurements of temperature, relative humidity and airflow compared to the comfort ranges of the region, reinforce the sustainable design of these buildings.

INTRODUCTION

The case studies for this research are located in Kingdom of Saudi Arabia, Kingdom of Bahrain, United Arab Emirates and Qatar, all of which fall under the broader umbrella of tropical hot-dry climate Ragette, 2012). The buildings range from market or *Souk*, small single courtyard house, to large multiple courtyard houses. The masons used local materials and methods in these buildings. An in-depth pilot research on the environmental behavior and related climate modifying elements and strategies of these buildings were conducted recently. These traditional building in the Middle Eastern hot-dry tropical climate is of mud. Whether made of poured in mud, or sun-dried mud blocks, they are good in making indoors cooler than outside (Bekleyen & Dalkiliç, 2011). The thicknesses of the earth walls help keep the indoors considerably cool (Vincent, 2008). With walls of high thermal mass and other environmental strategies, these buildings are able to keep the interiors much cooler than outdoors. Courtyards in these buildings meet environmental and privacy requirement well (Laffah, 2006)(Awadhi & Hasan, 2011).

FINDINGS: CLIMATE MODIFYING ELEMENTS/STRATEGIES

The Findings of the research is given in the following chart for ease of comparison of the architecture of the four countries. This also shows the environmental strategies, which are common in some of the buildings, as well as strategies that are unique to a single building.

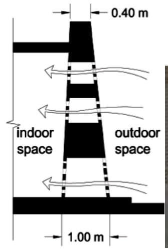
Table 3. Environmental Strategies

Environmental Elements / Strategies	Countries
Compactness Compact urban form, building shading building, shaded walkways. Protection from direct solar radiation & hot wind (fig 1, 2, 3, 4).	    (1) Doha (2) S Arabia (3) Bahrain (4) Dubai
Orientation Building oriented N-S for min. solar radiation and max. exposure to wind & cross ventilation (fig 5). Evaporative cooling from creek (fig 6, 7). Openings in north façade. Tilted east façade for northeast breeze (fig 8, 9).	   (5) Doha (6,7) Dubai   (8,9) Bahrain
Walkways/Alleys Double & triple height buildings, narrow roads, various angles of winding roads, building orientation create shade in the alleys (fig 10).	 (10) Doha
Plantation The photosynthesis strategy of plants reduces the heat gain on the roads, which reduces the temperature of immediate microclimate (fig 11, 12).	
Shaded Walkways/Alleys The alleys in many cases are covered with fabric to provide shade, thereby cooler alleys (Al-Eidi, L., 2013) (fig 14).	    (11,12) Dubai (13) Dubai (14) Doha
Façade Solid walls & minimum openings on the western and southern façades to delay & reduce solar gain (fig 15). **Windows** Small recessed windows & clerestory, few in number, bring controlled & indirect natural light, thus less heat gain. Wooden frame and shutters (fig 16,17)	   (15) Dubai (16) Dubai (17) S Arabia

Parapet Detailing Roof parapet consists of hidden openings which allow air movement and privacy (fig 18,19,20)	   (18, 19, 20) Bahrain
Courtyards Courtyards, generally small & partially shaded most of the time, help air cool down before entering indoors (fig 21, 22). Wells in courtyard help evaporative cooling (fig 23).	   (21) S Arabia (22) Dubai (23) Bahrain
Space Layering Space sequence is from outdoors to wide shaded corridor or *liwan*, then to room. Layering of space makes rooms cooler than outdoors. Breeze gets cooler by passing through this shaded space, before entering the room (fig 24, 25).	  (24, 25) S Arabia
Corridor/Arcade or *Liwans* Courtyards have surrounding arcades or *liwans*. These shaded semi-outdoor spaces block direct sunlight from penetrating indoors and provide shade to rooms; provide passage for occupants without being exposed to direct sun (fig 26, 27). Covered *liwan*, used for sitting, with thick roof and arcaded walls is cooler than outdoors in summer. As found in the study, *liwan* - 35˚C, outdoor - 37 to 39˚C. Arcaded corridors guide the breeze well. **Shading** Shading of walls, openings, courtyards, *liwans* is the most effective strategy to keep interiors cooler. (Batterjee, 2010). This also helps in circulation of warmer air outwards (fig 30, 31).	  (26) Bahrain (27) Dubai   (28) Dubai (29) Bahrain   (30, 31) Bahrain
Wind Towers or *Badjir* Common in this region. Brings in cooler air from higher up which circulates through interior spaces; sometimes water is sprinkled in the surrounding walls to cool the air more (fig 32, 33). House in Moharraq has a large *badjir*, in *Majlis* or women's living room. Temperature below the tower was 1˚C cooler than rest of the room.	  (32) Muharraq (33) Dubai
High Windows High windows work as air fan, since lighter warm air rises up and escapes through high openings, allowing cooler air to enter the room from below (fig 34, 35, 36). ***Roshan*, Perforated Screen Openings** Perforated screen or ventilator or *roshan* very effective in reducing room temp; warm air rises up and escapes through it. The screen diffuses the direct sunlight and reduces heat gain (fig 37).	 (34) Dubai  (35) S Arabia  (36) Bahrain  (37) Doha

3 layers of perforated openings let air escape more frequently, depending on its temp. (fig 38, 39, 40).

(38) S Arabia



(39, 40) Bahrain

Monsoon Window/Horizontal Slit Window
The monsoon windows are small horizontal openings in the walls, which provide natural ventilation, indirect sunlight and privacy. It is mainly used on the exterior walls of 1st floor (fig 41).

(41) Bahrain

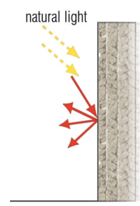
Roof Material
Roof consisting of mud, palm trunks, bamboo, mangrove wood and palm leaves provide good thermal insulation (fig 42, 43).

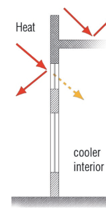
Roof Thermal Mass
Thermal mass of thick roof aid in delaying and reducing solar gain inside. Roof thickness is between 0.30m to 0.70m

(42) Dubai (43) Doha

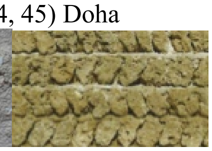
Wall Material
Walls of mud blocks, coral stone, palm trunks and straws act as very good insulators.
Poured in mud, or sun-dried mud blocks of rough texture. A variety of interior materials help diffuse sunlight (fig 44, 45)

Wall Thermal Mass
All four case study buildings have thick mud walls, typical of Middle Eastern architecture; wall thickness is from 0.40m to 1.00m. This gives high thermal mass to the building; thereby reducing and delaying heat gain inside (fig 48). Fursh coral, 0.07 m thick, was used with mud for infill panels between piers and for partitions. Dubai house had a difference of 2.7°C between outer and inner surfaces of exterior wall: •1-outer 35°C, •2-inner 32.3°C (fig 49).

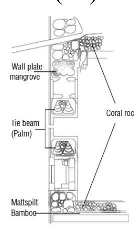


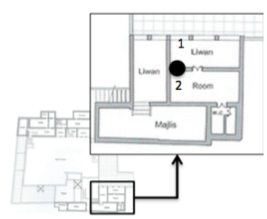


(44, 45) Doha



(46) Bahrain (47) Dubai





(48) Bahrain (49) Dubai

Floor
Mostly earth over compacted sand. Some exterior ones were of rough cut stone. Mud kept floor cool (fig 50, 51). In Dubai, surface temperatures of floors at various spaces were: •1-unshaded area 37.8°C, •2 shaded *liwan* 34.0°C, •3 -room 31°C (fig 52).

FINDINGS: ANALYSIS OF DATA ON TEMPERATURE, RELATIVE HUMIDITY AND AIRFLOW

Comfort Zone

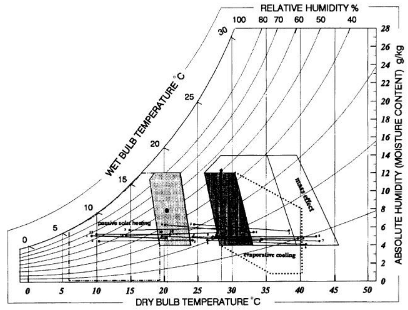

Figure 1 Application of Comfort Zone in Riyadh, Saudi Arabia
Source: (S. A. ALAJLAN, M. S. SMIAI, U. A. ELANI, 1997)

The comfort zones are similar for the hot-dry climates of these four adjacent countries, varying slightly from each other. The comfort zone of Saudi Arabia, which has the lower average temperatures among the four countries, has been taken as a standard for all countries.

The comfort values for different climatic elements can be considered as standard for Saudi Arabia as established by ALAJLAN, SMIAI, ELANI. According to Fig.1 summer temperature range is from 28˚C to 33˚C and Relative humidity ranges from 42% to 55%. With mass effect, and evaporative cooling, both of which is present and practiced in these buildings at a high level, the upper limit of the comfort temperature can be above 40˚C, and humidity can range from 15% to 58%.

The analysis of data in **Tables 4, 5 and 6** is presented below.

Market or *Souk*, Doha, Qatar

It is a semi-outdoor space. As average temperature of Qatar is higher than Saudi Arabia, the comfort zone of Saudi Arabia well served the function of comfort assessment here, as in Figure 1. Data in market spaces met the comfort values in the beginning of winter. Market spaces' temperature range was 22-27.8°C and relative humidity 46.6-59%. Both the values are within the comfort range **as shown in Figure 1** As the Comfort chart suggested, in Figure 1, high thermal mass, night ventilation and evaporative cooling, all of which existed in the buildings, effectively helped the spaces be comfortable in summer and winter.

Al Mulla House, Al-Ahsa, K.S.A.

In winter, when the exterior temperature was low, the interior temperature was warmer and the reverse was observed for summer. Roofs of the house is made of wooden beams, palm trunks and leaves, palm leaf or bamboo mat which, topped by earth, acted as insulating material against the summer heat and the cold of winter. The measurements in various rooms show that internal temperature remains nearly constant around the day on a typical summer or winter day, while the ambient temperature has a large diurnal variation. House has no trees inside the courtyard now. It originally had some in the courtyard, which helped in more comfortable performance of the building. Relative humidity indoors was found to be lower than outdoors, which added to the comfort conditions.

Shiekh Issa House, Muharraq, Bahrain

It is seen that there are variations in data of different spaces depending on the orientation, proximity to courtyard, level of floor, *liwan* location, number and types of openings, etc. Indoor spaces are warmer in winter and quite cooler in summer than the outdoor readings. Temperature and relative humidity are within the comfort range.

Shaikh Saeed Al Maktoum House, Dubai, U.A.E.

Dubai was relatively more humid in both seasons, compared to other countries. In terms of comfort conditions, the building performance in summer was better than winter. In winter, temperature and humidity were almost within the comfort zone. The cooler breeze that was cooling the indoors was due to the presence of the creek nearby. As a result, relative humidity was within the comfort zone. In winter, airflow was almost nil in some spaces which were warmer than the breezier spaces.

Summer had higher airflow in the spaces of all case study buildings. Measurements of temperature and Relative Humidity were within comfort ranges. Comfort survey among the users of the buildings revealed that most of the users were comfortable within the shaded interiors of the buildings, in all four cases. As the survey revealed, only 5% to 10% of the present users preferred air-conditioning in these spaces in summer.

CONCLUSIONS

The traditional wisdom of how to solve architectural problems due to climate lying beneath the various architectural elements was to be unearthed through this research. The paper establishes that the traditional buildings of the hot-dry climate of the Middle East were and are still, able to function as very good examples of sustainable architecture, in terms of passive cooling. The study shows that the hygro-thermal performance in these mud buildings is very good, both in summer and in winter. It points out the various environmental strategies, materials and methods of construction of these buildings in question. Not much has been done in the research of this topic and hence this research is one of the few pioneering researches in Saudi Arabia. It is thus an important step towards rediscovering the traditional architecture of the Middle East from a new angle, the environmental point of view. Modern buildings of these countries are highly dependent on air conditioning that consumes massive amounts of electricity, and nearly 80% of household electricity is used for air conditioning (Taleb & Sharples, 2011).

The traditional strategies could easily be adopted for newer buildings that will help cool passively and thus save energy. The many towns that were sculpted with mud architecture in these places were, and some still are, in a ruined state. The respective governments are now restoring these. These examples of sustainable architecture will thus be sources for academic researches, professional inspiration as well as tourism, for years to come.

ABSTRACT

Climate responsive building design is determined by the local micro-climate and the ability of the building envelope to regulate the indoor thermal environment. The building envelope characteristics are based on the available/accessible building materials and technology. Studies on vernacular architecture across the world showed that wall configurations and the thermo - physical properties of the building materials are used intelligently to maintain comfortable indoor comfort across the seasonal weather variations. Vernacular buildings of North-East India are naturally ventilated. Hence, it is important to find out an optimum wall configuration which will provide enough time lag, reduced discomfort hours as well as optimum thermal performance of these buildings. Various studies on building simulation/modelling show that building dynamic simulation tool can be effectively used to study the building envelope characteristics. In this study, a typical vernacular building in warm and humid climatic zone of North-East India has been considered to study the effect of thermo - physical properties of wall, thickness and material assembly on the indoor environment. Solar energy modular simulation tool TRNSYS 16 is used to carry out the simulations of this building with an objective to improve the indoor thermal environment. Building model is generated in TRNSYS and parametric simulations for different wall characteristics by varying thermo - physical properties and thickness of wall, and insulation thickness on external wall are carried out. Simulation results are obtained in terms of temperature profiles inside the different zones of the buildings. Indoor temperature profile of the building with best suggested wall configuration shows reduction in indoor temperature compared to the base case. In this study, it is also found that other climate oriented features such as shading mechanism like over hangs (very common feature in vernacular buildings) significantly influence the thermal performance of walls.

INTRODUCTION

Thermal performance study is one of the critical aspects of vernacular houses. These structures are evolved through generations, addressing the micro climate variations and also satisfy the needs of habitats (Singh et al., 2009a). Thermal performance of a building refers primarily to how well a building is insulated from the external weather conditions in order to achieve a comfortable indoor temperature. This can be achieved by keeping the internal temperature higher or lower than the external temperature as per the requirement of comfort temperature. Building design is greatly influenced by the severity and climatic variations leading to the need for integrating the building thermal design with the overall design process, helping the designer to decide at the beginning of the design process to bring the built space into comfort conditions (Al-Homound, 1997; Liu et al., 2010). The important parameters required for the design of energy efficient buildings are walls, roof, placement and size of openings, and shading devices (Charde and Gupta, 2013)**.** Building envelope like walls and roofs have important role to play in the heat transfer process between the indoor and outdoor environment of the building. Due to the quest for achieving better thermal comfort standard inside the building leads to higher heating and cooling energy requirements. Borah *et al.* reported that energy consumption for heating will be higher at higher base temperature and the energy consumption due to cooling of the buildings will be higher at lower base temperatures in the buildings of North-East India (Borah et al., 2015).The components of the building envelope can be used as the most effective way of controlling the indoor temperature of the building (Dutta, 2001). Simulation tools such as TRNSYS can be used effectively to study the effect of building envelope characteristics on indoor thermal environments. Singh *et al.* have done thermal performance simulation of three vernacular buildings at different bioclimatic zones of the north-eastern region by using TRNSYS simulation tool (Singh et al., 2009b). Simulation results concluded that the houses are fairly comfortable in pre-winter and pre-summer months compared to winter and summer months and successfully compared with the experimental results. Kalogirou *et al.* investigated the effects of the application of building thermal mass in Cyprus by modeling and simulating a typical house with the TRNSYS simulation program (Kalogirou et al., 2002). Jindal *et al.* analyzed the thermal performance of non-conditioned building of cold regions by using various insulation thicknesses at different positions of walls and roof. It is found that the thermal comfort for the three cold stations i.e. Srinagar, Shimla and Shillong cannot be ensured in the month of January if the building is not insulated (Jindal et al., 2013). The effect of insulation thickness on external walls in different seasons of the year in different climatic zones suggests that optimization of insulation thickness on external walls with respect to cooling loads is found to be more appropriate for energy savings compared to the heating loads (Bolatturk, 2008; Ozel, 2011; Yu et al., 2009). Al-Sanea *et al.* investigated the effects of location of thermal mass in insulated building walls on total and peak transmission loads, time lag, decrement factor, and dynamic resistance under the steady periodic conditions using climatic data of Riyadh. It is found that for a given thermal mass, a wall with outside insulation provides better overall performance than a wall with inside insulation (Al-Sanea et al., 2013). Asan investigated the effects of wall's insulation thickness and position on time lag and decrement factor. It is found that insulation thickness and position have intense effect on time lag and decrement factor (Asan, 1998). Axaopoulos *et al.* analyzed the thermal behavior of external walls using TRNSYS and determined the optimum insulation thickness for the external walls of a residential building in Athens, Greece, considering wall construction, orientation, wind direction and the position of insulation (Axaopoulos, 2014). Huang *et al.* found that the variation in the window to wall ratio for different orientation results into different economical thermal insulation thicknesses of building envelope (Huang et al., 2014). It is also found that the optimum performance can be achieved by considering the windows-to-wall ratio, house orientation, types of insulating materials and windows in addition to the impact of the windows and walls.

Building energy simulation tools are widely used for thermal performance study of building. In this study, a building model generated in TRNSYS 16 is used to analyze the indoor thermal environment of a typical vernacular building at Tezpur, in warm and humid climatic zone of North-East India. Most of the houses of the region are constructed in direct response to the climatic constraints and are naturally ventilated (Singh et al., 2010). A building model is prepared based on the inputs like building construction details, thermo-physical properties of building materials, wall thickness and insulation thickness on external wall using TRNSYS simulation tool. The layout of the building considered for the base case is shown in Figure 1. Windows on the house are distributed on all the facades. It is a single zone house with flat roof and single glazed windows. Since the vernacular house is naturally ventilated, so auxiliary heating, cooling and mechanical ventilation are kept off for all the simulations and the zone air temperature is considered as the primary output parameter.The simulation provides the results in terms of hourly temperature profile inside the zone of the building. Indoor temperature variation for all the simulations is compared with the base case and the results are analyzed to obtain the optimum design parameters. An optimum thermal performance of the building has been achieved by integrating the building optimum design parameters.

METHODOLOGY

Vernacular buildings are constructed across the world based on the local climatic condition. Vernacular buildings are the structures built by local people using locally available material and affordable technology to deal with the local and day-to-day needs (Singh et al., 2009a; Singh et al., 2010). Studies on vernacular architecture reveal that wall configurations and the thermo-physical properties of building materials have a great influence on indoor temperature. In recent times due to quest for achieving better thermal comfort; energy consumption is increasing in buildings. So, it is important to study thermal performance of vernacular buildings with varying building elements which will provide maximum comfortable hours inside the building. In this study, a typical vernacular building of warm and humid climatic zone of North East India is modeled in TRNSYS. Figure 2 represents the methodology followed to carry out this study. Table 1 represents the thermo-physical properties of the materials used for the simulation and Table 2 represents the wall configurations considered for the simulations. First a base case model of the vernacular house is selected to carry out the simulation.

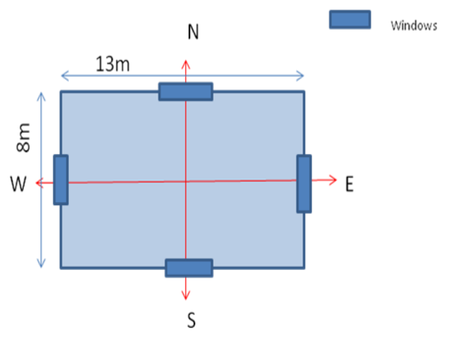

Figure 1 2D layout of the house with single zone

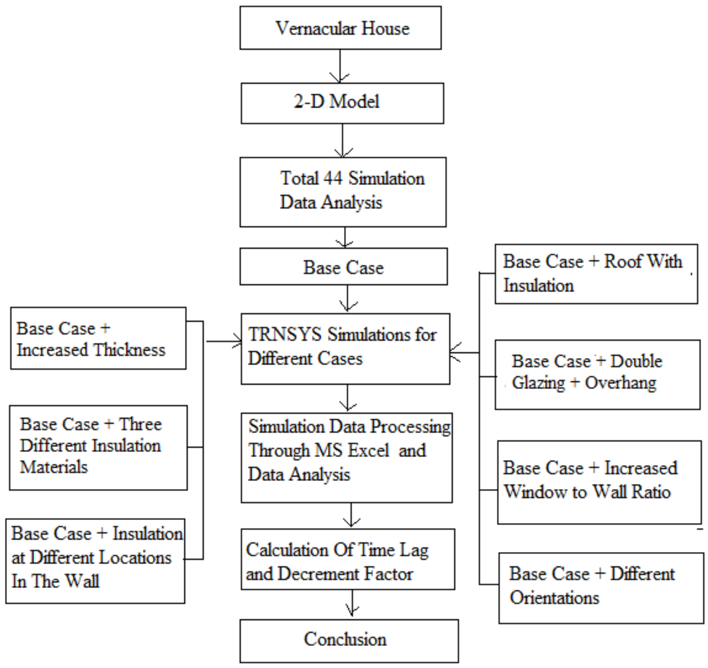

Figure 2 Methodology of the study

Table 1 Thermo physical properties of the materials used for simulation

Materials	Conductivity (W/m-K)	Thermal capacity (kJ/kg-K)	Density (kg/m^3)
Brick	1.301	0.84	2000
Aerated concrete (floor 0.127m thick)	0.289	0.84	1000
Light concrete (roof 0.127m thick)	0.120	0.84	400
Plaster	1.390	1.00	2000
Extruded Polystyrene, Insulation1	0.0278	1.47	30
Cell Glass (High density), Insulation 2	0.061	0.84	250
Polyurethane, Insulation 3	0.022	1.47	35

Parametric simulation studies are carried out by using TRNSYS 16 simulation tool. The standard building subroutine TYPE 56 has been used for the simulation (Singh et al., 2009b). The material properties listed in Table 1 and 2 are used as input parameters to generate the building model. For carrying out further simulations, base case model is used with various design modifications. Figure 3 shows the different scenarios for which the base case model is carried out. The different scenarios considered for the simulation are (i) increasing the wall thickness of the base case (ii) adding three different insulations on the wall of the base case (iii) placing the insulation at three different positions of the wall of the base case (iv) replacing the single glazed windows of the base case with double glazing and providing overhang on the windows (v) increasing the window to wall ratio (vi) providing insulation to the roof of the base case and (vii) considering four different orientations of the house. The infiltration for this house is kept at 3 ACH (air changes per hour) for all the simulations.Since the house considered for the simulation is naturally ventilated so the zone temperature is considered as the main output parameter. The surface temperatures of the wall are also obtained as output parameter.

Table 2 Wall configuration considered for the simulation

Case	External wall configuration (from inside to outside)	Overall heat transfer co-efficient (U) (W/m^{2}K)
Base case	Plaster (0.01m) + brick (0.127m) + plaster (0.01m)	3.545
Base case + A1 (increased thickness)	Plaster (0.01m) + brick (0.254m) + plaster (0.01m	2.633
Base case + A2 (increased thickness)	Plaster (0.01m) + brick (0.381m) + plaster (0.01m)	2.094
Base case + A3 (increased thickness)	Plaster (0.01m) + brick (0.508m)+ plaster (0.01m)	1.739
Base case + B1 (wall with insulation 1)	Plaster (0.01m) + brick (0.127m) + insulation 1 (0.05m) + plaster (0.01m)	2.164
Base case + B2 (wall with insulation 2)	Plaster (0.01m)+brick (0.127m)+ insulation 2 (0.05m) + plaster (0.01m)	2.748
Base case + B2 (wall with insulation 3)	Plaster (0.01m) + brick (0.127m) + insulation 3 (0.05m) + plaster (0.01m)	1.972
Base case+ increased window area	Plaster (0.01m) + brick (0.127m) + plaster (0.01m)	3.545
Base case + double glazed windows	Plaster (0.01m) + brick (0.127m) + plaster (0.01m)	3.545

RESULTS AND DISCUSSION

The vernacular house in warm and humid climatic zone is constructed with different wall configurations and various parametric evaluations have been done to analyze the effect of different wall configurations on the zone temperature. Analysis on the effect of window glazing, window to wall area ratio, providing roof with insulation on the zone temperature is carried out. Simulations are also carried out for different orientations of the building. The two very important characteristics, i.e., time lag and decrement factor, which determine the heat storage capabilities of any material, are also calculated. Simulation data for entire 8760 hours (i.e., one year) is obtained and the results in terms of temperature profiles are analyzed for January and July as the representative month for winter and summer seasons respectively. In this study, zone temperature is the main parameter around which analysis has been done. Figure 3(a) represents the variation of daily minimum zone temperature for all the days in the month of January. It is observed from the profile that variation in overall heat transfer coefficient (U value) depends on thickness and also the zone air temperature is higher in case of the wall with lower U-value, i.e., with decreasing U value, the daily minimum temperature of the zone increases which is desirable in winter. As we know that lower U value provides maximum resistance to the heat flow, hence, reducing the heat loss from inside the room to the outside air. So, it can be concluded from the Figure 3(a) that with the increase in thickness of wall, thermal inertia comes into play and consequently increases the time over which heat gain and loss takes place. This has also effect on the comfort conditions as occupants feel minimum thermal shock with noticeably varying outdoor thermal environment. So, for naturally ventilated buildings due consideration must be given to thermal inertia. Figure 3(b) represents the variation of daily maximum zone temperature for all the days in the month of July. It is observed from the profile that the temperature is lower in case of the wall with lower U-value (maximum thickness), i.e., with decreasing U value, the daily maximum temperature of the zone decreases which is reverse in the case of winter. With lower U value, heat gain from the outside air is reduced and thus the maximum temperature inside the room is low. Thus, from both the figures, it can be concluded that, the wall needs to be selected with U value as low as possible (with optimum thickness to maximize the effect of thermal inertia) to reduce the heat loss from inside the room in winter and heat gain from outside to the inside of the room in summer.

Figure 4(a) and 4(b) represent the daily minimum and daily maximum zone temperatures for each day of the month of January and July respectively. It is observed from the figures that 0º and 45º and 90º and 135º orientation shows similar temperature profile. For orientation 0° and 45º, minimum and maximum indoor temperature decreases leading to decreased indoor temperature swing. This happens because with change in orientations of the building the surface area of the external wall exposed to sun varies and so the heat gain. Since, the selected building is rectangular in shape and of single zone the effect observed here is low. It is found from literature that in the case of multi-zone building with different shapes (L, U, C and H etc.) the variation in indoor temperature is significant. Hence, it is suggested to decide the building orientation wisely before construction to maximize the use of solar passive techniques in the building thus improving energy efficiency and thermal comfort. Figure 5(a) and 5(b) represent the minimum and maximum inner surface temperatures for each day of January and July month respectively. Here, insulation is added to the base case and placed in three different positions (i.e., inside, middle and outside) of the wall. Figure 5(a) shows that in January (i.e., in winter) when insulation is placed at the outside surface of the wall, the minimum surface temperature of the wall has increased compared to the wall when insulation is placed at the middle and inside position because of thermal inertia plays its role. It is observed from figure 5(b) that in July (i.e., in summer) also when insulation is placed at the outside of the wall, the maximum temperature is lower compared to the insulation at middle and inside wall surface. Thus, it is observed that both in summer and winter months, placing insulation at the outside of the wall, shows better thermal performance, out of all the three cases (combined effect of thermal inertia and insulation). Furthermore, it is also observed that there is not much difference when insulation is placed at the middle position of the wall.

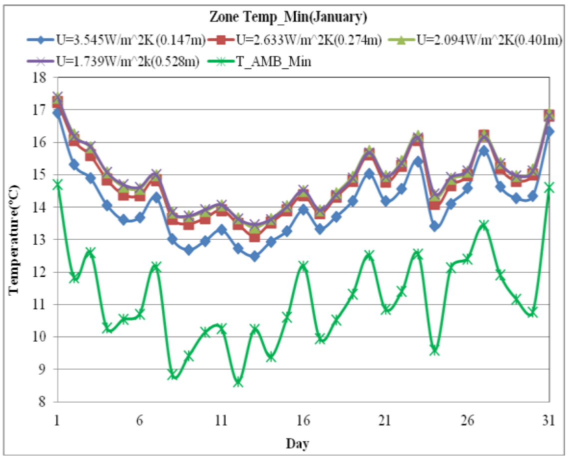

Figure 3(a) Daily minimum zone temperatures for different wall thicknesses

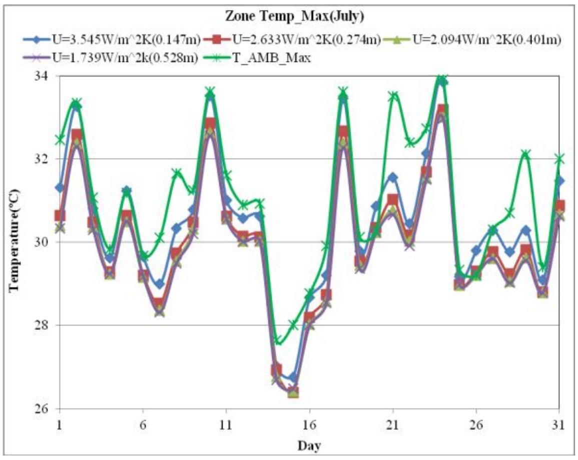

Figure 3(b) Daily maximum zone temperatures for different wall thicknesses

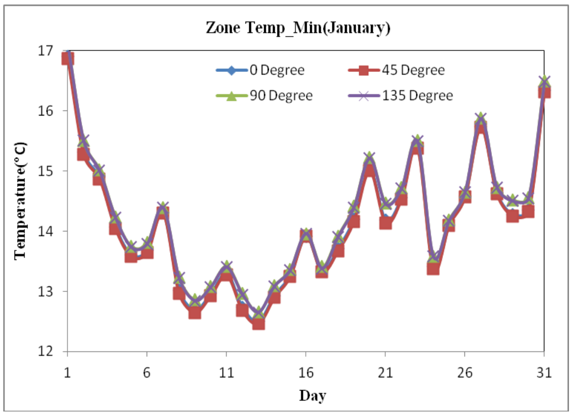

Figure 4(a) Daily minimum zone temperatures in January for the four orientations

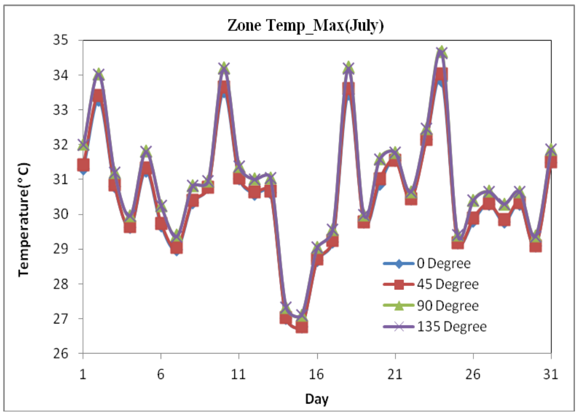

Figure 4(b) Daily maximum zone temperatures in July for the four orientations

Figure 6(a) and 6(b) represent the daily minimum and maximum zone temperatures in January and July respectively for different window to wall ratios. The windows are single glazed and window to wall ratio increases from 20 to 80%. It is observed from figure 6(a) that in January with the increasing window to wall ratio, the zone temperature is decreasing. This happens because with the increase in glazing area heat loss increase from inside to the outside environment. It is observed from figure 6(b), that the zone temperature increases with increasing window to wall ratio because heat gain is more from the outside environment. These two observations clearly indicate that both in summer and winter higher window to wall ratio leads to uncomfortable conditions inside the room. Hence, optimum window to wall ratio needs to be chosen so that in summer there is minimum heat gain and minimum heat loss in winter. Figure 7(a) and 7(b) represent the daily minimum and daily maximum zone temperature for January and July months respectively, when single glazing on windows have changed to double glazing. It is observed from both the figures that the increase in temperature is more prominent in winter because low altitude of the sun allows direct sunlight to enter into the room and increases the thermal gain thus temperature of the indoor environment. Moreover, both the overall heat transfer coefficient and solar heat gain coefficient comes into consideration for glazing. Though, for double glazing, the SHGC (solar heat gain coefficient) is lowered by only 10 % in comparison to single glazing but the effect due to low SHGC is compensated by low U value (U value of single glazing is 4.8 and for double glazing is 2.7). So, in winter the double glazed windows perform better by trapping the absorbed heat inside the room. However, in summer, the solar heat gain coefficient allows the direct sunlight to enter the room through the window and make the room hotter. Hence, in summer it is advised to have appropriate overhang on the window to block the direct sunlight to enter inside the room.

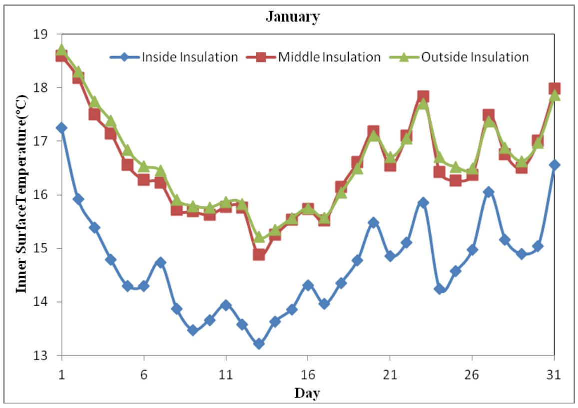

Figure 5(a) Inner surface temperatures for January for three different positions of insulation

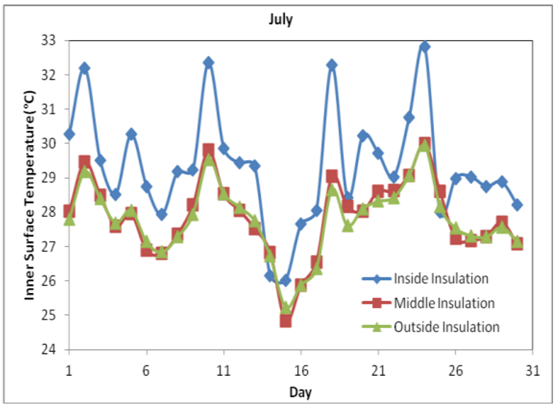

Figure 5(b) Inner surface temperatures for July for three different positions of insulation

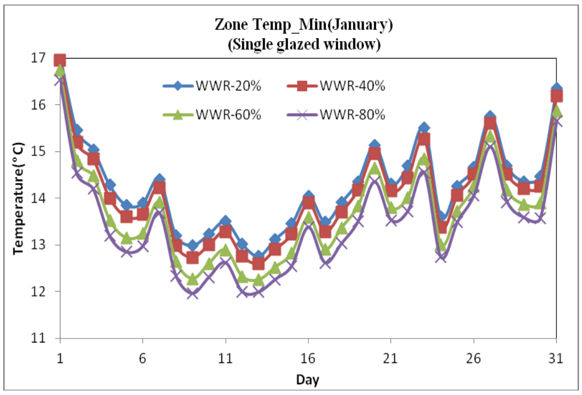

Figure 6(a) Daily minimum zone temperatures in January for different window to wall ratios

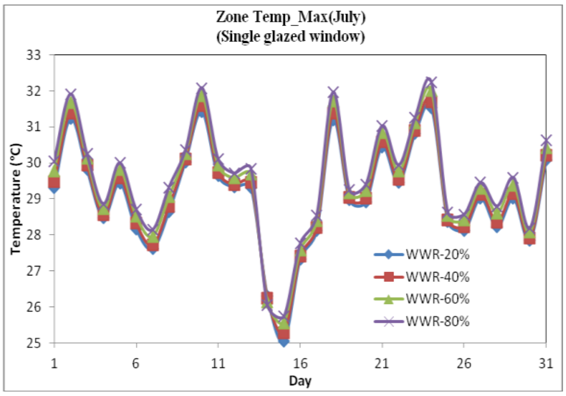

Figure 6(b) Daily maximum zone temperatures in July for different window to wall ratios

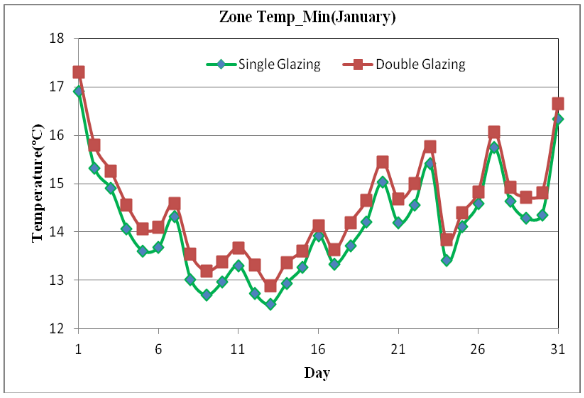

Figure 7(a) Daily minimum zone temperatures in January for double glazed windows

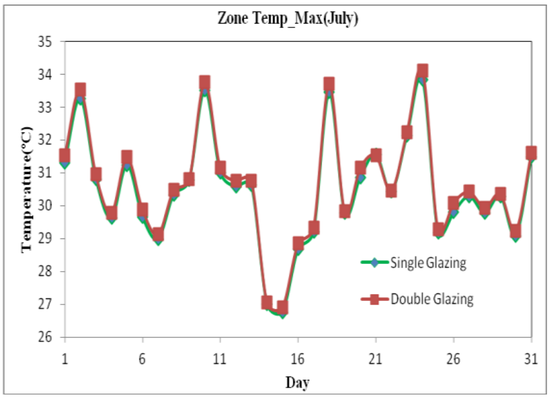

Figure 7(b) Daily maximum zone temperatures in July for double glazed windows

Figure 8 represents the effect on the zone temperature when the roof is provided with insulation. It is observed from the figure that the effect of insulation on the roof is negligible on the indoor temperature profile of the zone. This may be due to high infiltration in naturally ventilated buildings leading to negligible effect on the indoor temperature swing. Figure 9 represents the variation of time lag and decrement factor for different thicknesses of the wall. The variation of time lag and decrement factor is shown for two different materials. It is observed from figure 9 that the time lag increases with the thickness of the wall, whereas decrement factor decreases with the wall thickness. Moreover, both the materials are exhibiting different time lag and decrement factor. This indicates that time lag and decrement factor not only vary with the thickness of the wall but also with the material properties. For better thermal performance, time lag should be high and decrement factor should be minimum.

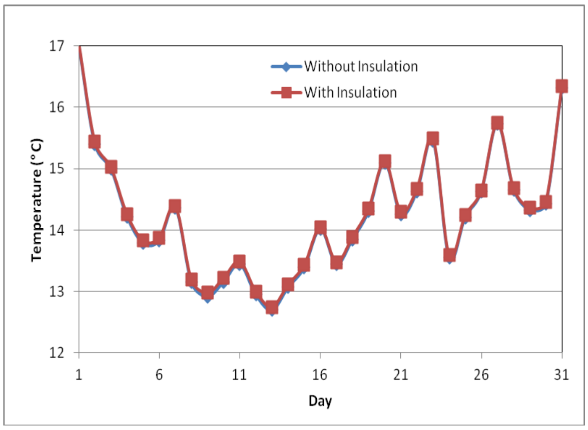

Figure 8 Daily minimum zone temperatures for roof (January) with insulation and without insulation

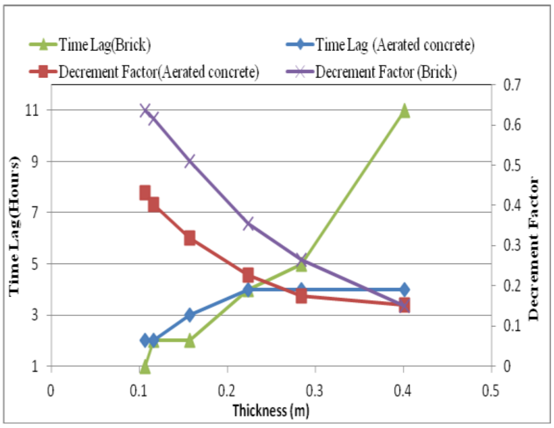

Figure 9 Time lag and decrement factor for different wall thicknesses

The effect of different insulation materials on inner wall surface temperature for a period of 24 hours (i.e., 1 day) in the month of January and July respectively has also been carried out. Three different insulation materials - extruded polystyrene, cell glass of high density and polyurethane are added with the base case and the inner surface temperatures of the wall are obtained. It is observed that in January (i.e., winter) month, the peak of minimum temperature is less in case of polyurethane as the insulation material, in comparison to cell glass and extruded polystyrene. It is also observed that in July (i.e., summer) month, the peak of maximum temperature for the wall with polyurethane as insulation material is lower than the wall with other two insulation materials. Moreover, the 24 hour swing in temperature throughout the day is less in case of polyurethane as insulation material. Hence, it can be concluded that with polyurethane as the wall insulation material shows better thermal performance both in summer and winter months. It is also observed that there is an increase in the temperature for the month of January (winter) when the windows are provided with overhangs. It is also observed that the maximum temperature in the month of July (summer) month is decreasing, clearly indicates that windows with overhang have a significant role to play by blocking direct sun light to enter the room in summer leading to decrease in indoor air temperature but in winter it allows sunlight to enter room thus increases the indoor air temperature.

CONCLUSIONS

Thermal performance analysis of building envelope is very important to evaluate indoor thermal environment of naturally ventilated buildings. The building envelope constitutes the major portion of the building through which maximum heat gain and loss occurs in both the extreme seasons respectively. In this study, a typical vernacular building of warm and humid climatic zone of North East India is considered. This study made an attempt to carry out the thermal performance analysis by varying building material parameters and their effect on the indoor environment. It can be concluded from the study that, with the increase in the wall thickness, the overall heat transfer coefficient reduces and also the overall heat transfer coefficient changes, when the thermo-physical properties of the material changes. It has been found that orientation has an important effect on the indoor temperature; because of different orientations, different area of external area is exposed to direct solar radiation leading to heat gain. It is also found that location of insulation on the wall have significant effect on the thermal performance, showing that insulation applied on the outside surface have less temperature swing. The effect of different insulation material on the wall surface temperature has also been studied and polyurethane has been found showing the best performance. This study also reveals that windows with double glazing have maximum effect in winter when the sun's altitude is less. Hence, if the window is replaced by proper shading mechanism then overall performance can be improved. It is found that increase in the window to wall ratio has significant effect on the indoor temperature swing. Increase in the window area leads to maximum hours of discomfort inside the building in both January and July months. It can also be concluded that providing insulation to the roof has negligible effect on the indoor temperature profile. Time lag and decrement factor are also calculated for different wall thicknesses. It is found that thermal mass of the wall and thermo-physical properties of the wall have a profound impact on time lag and decrement factor. The findings of this study also relate to the policy intervention and best practice needs to be followed in these types of building design. North-Eastern region is in development process and the construction sector is rising in unprecedented way. These types of buildings are well suited to the climatic factors as well as social requirements of the people of the region. Hence, the findings of this study could be useful to the policy makers, architects, and local people for designing better thermally comfortable buildings.

Daylighting Analysis of Vernacular Architecture in Guizhou Province, China

Huang Xuan, PhD
[Shanghai Jiaotong University, China]

Chun Wu, Director
[Urban and Rural Planning Bureau, Miao and Dong Autonomous Prefecture of Guizhou Province]

Wei Su,
[Shanghai Jiaotong University, China]

ABSTRACT

China has 55 minorities, most of whom have their own unique architecture. Due to urbanization these traditions are in danger and traditional dwellings are replaced with modern houses in the hope of better living conditions. By understanding and finding solutions to the problems emerging in these traditional dwellings and by using their features in a more sustainable and more adaptive way to local climate, living conditions could be improved without losing this unique culture. Due to its substantial minority population and varied terrain, Guizhou province in China has a rich source of different types of traditional dwellings. Dwellings representing the typical architecture of three different ethnic groups Han, Miao, and Dong were selected to conduct daylighting analysis. Measurements made during a field work helped to explore how the different building ways, folk customs, topography and other factors impact on architectural daylighting. With the help of the results, suggestions are made on how to reform existing dwellings under the corresponding architectural language and lifestyle, and what modifications should be made to meet the modern daylighting needs of occupants. Different scenarios are simulated using ECOTECT 2011 software (Ecotectt, 2011) to show the positive results of the changes suggested.

INTRODUCTION

China is a multi-ethnic country with a long history and a vast territory, during the thousands of years of its history a vast amount of varied residential building types have evolved. Different regions have different natural conditions and cultural background, which is reflected by vernacular dwellings all over the country. Over the recent decades, due to the acceleration of urbanization, modern architecture became more widespread. Modern architecture promises to accomplish a better living environment, but it contributes to the destruction of traditional vernacular dwellings. Traditional vernacular dwellings represent a valuable heritage and help to preserve the habits and folk-custom of ancient people. More importantly the ecological thinking and technical solutions of vernacular buildings are a significant knowledge source for the sustainable development of new settlements and an indispensable reference on terrain adaptation, climate adaptation and construction of passive energy-saving measures. To renew the vitality of a traditional vernacular dwelling, its adaptability to modern life and comfort must be improved. Daylighting is an important measure of building comfort. Because of limited building and technical resources available at the time they were constructed, traditional houses typically take advantage of natural light. However with changes in living habits and the improvement of living standards, original daylighting conditions are not able to meet the demands of the present. Improvements of vernacular dwellings' should also focus on enhancing daylighting condition, an area which needs to be researched in more detail. Few studies already have been conducted on architectural daylighting of Chinese traditional vernacular dwellings (Wang, Zhuo and Dac'y 2008, Duan, Lau and Ford, 2012, Lin, Li, and Chen, 2013), but it is a generally a neglected area of research to which this paper tries to contribute. There are many types of dwellings in different regions that have not been researched yet, from which this study is focusing on three typical types of dwelling characteristic of three ethnicities, a special group of the Han, the Dong and the Miao, all of which are characteristic to Guizhou Province, which due to its less developed infrastructure and economy was especially neglected. The principle aim of this research is to investigate the daylighting performance of three traditional vernacular dwellings and the factors influencing it, by means of on the spot data collection, analysis, software simulation, in order to suggest viable modifications of the original dwellings, to meet the occupants' lighting needs better. After introducing the characteristics of the locations of the field research, research methodology is explained. Results and analysis will then be presented, together with simulation, finally conclusions are made and suggestions for future improvements are given.

ETHNIC ARCHITECTURE AND LOCAL CLIMATE

The vernacular dwellings selected for the research are located in Guizhou province, in the village of Jiangchang, SanBao and Xijiang (Figure 1). The dwelling in Jianchang is a typical example of Han Chinese vernacular architecture and the 'tunpu' culture retained locally. The dwelling in Xijiang reflects the local architecture of Miao minority and is part of the world's largest Miao settlement while the dwelling in SanBao is typical of the Dong minority. All of the three ethnic groups have a history of hundreds of years and rich cultural traditions, which are reflected in architecture, clothes, food, folk beliefs and entertainment. Guizhou has a typical subtropical monsoon climate, where summer is hot, humid, and sunny and winters are relatively warm.

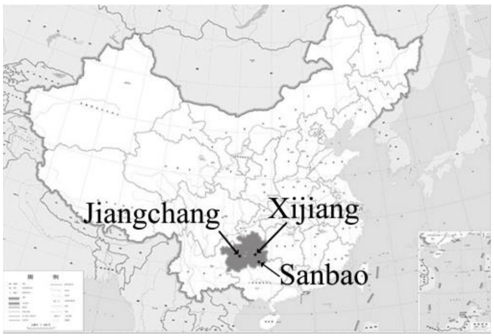

Figure 1: Location of Jiangchang, SanBao Dong and Xijiang Miao in Guizhou province, China

Each of the three dwellings chosen carry the main characteristics of the local traditional architecture. The main structure of the dwellings in Jiangchang consist of a wood structure and the building envelope is made of stone blocks. This is coupled with the most distinctive feature of these buildings, the thin slab stone roof, stacked layer upon layer. (Figure 2 (a)) The Dong minority's dwellings in SanBao Dong are almost solely constructed from wood, from the load bearing structure, through the inner envelope and wooden stairs. Only the kitchen is made of brick, which is usually attached to the main building. (Figure 2 (b)) Both the Han and Dong dwellings usually consist of two storeys, with living areas located on the ground floor and storage places on the first floor. In the Xijiang Miao village local houses are typical mountain buildings, wooden houses on stilts located mainly on a hillside, built row upon row. A unique feature of these dwellings is the semi opened balcony located outside of the living room with railings locally called as 'beauty's leaning'. Buildings usually consist of two to three storeys. The ground level is used for storage or for livestock, accommodation and main living spaces are on the first floor while upstairs is used for storage. (Figure 2 (c))

Figure 2*:* Traditional Dwelling in Jiangchang (a), SanBao Dong (b) and Xijiang Miao (c)

FIELD SURVEY METHODOLOGY

The field research was conducted during the summer, data collection took place from 4th and 9th July 2013, over two days in each location. Daylighting data were collected through spot measurements using Digital LUX METER (TES 1330A) illuminometers. Data collection focused on the floor where main living spaces were located, in the Jiangchang and Sanbao Dong on the whole ground floor, while for the dwelling in Xijiang on the first floor, as for places used for storage or livestock daylighting is not of crucial interest and thus was omitted in this research. In the collection of illuminance values, the researcher took account of individual rooms and functions to determine the number of measuring points. A grid was drawn on the floor plan of each room, with intersection points not further apart than 1 meter, illuminance values were collected at each intersection at 800 mm above floor level, according to the reference working surface level suggested by the Standard for daylighting design of buildings (China, 2013). Inside and outside illuminance data were collected simultaneously by a pair of field researchers. To reduce error and to ensure the accuracy of the data, three complete sets of illuminance measurements were taken in each room under overcast conditions. No additional artificial lighting was used during measurement times. Outdoor illuminance values have drastic fluctuations, even under overcast conditions, resulting in change of indoor illuminance, but for the same test points, the ratio between the indoor and outdoor illumination value should remain stable. Ratio of outdoor and indoor illumination is called the daylight factor (DF), and it will be used as a basis for research daylighting performance in this research.

DATA ANALYSIS

Indoor daylighting condition is influenced by various factors, such as the proportion of the space (depth and width), presence of shading device or outside structures providing shading, the area ratio of windows to floor, the presence of grilles or wooden decoration on the windows and the reflectivity of the walls. The analysis of data focused on these factors.

The first step was to obtain the plan of the dwellings through measurements taken with Leica Disto™ D2 laser ruler and tape measures, layouts and section plans were drawn. Details of the size, position and form of the daylight openings in the house and the presence of shading devices were also recorded.

The vernacular dwelling in Jiangchang village has a simple rectangular layout (Figure 3 (a)). The dwelling is surrounded by a stone wall forming a courtyard. Building layout is simple, only consisting of three rooms arranged next to each other in a linear fashion, with the living room located in the middle facing south. The shape of the bedrooms is long and narrow, the depth reaching 7.5 meters, and the rooms have windows on both of their south and north wall. A bungalow was later built on the southeast corner of the main building. The windows are all the same size of 1300mm (w) *1000mm (h) decorated with grid patterns and with window sills' height at about 1.1 meters. The layout of the dwelling in SanBao Dong is also symmetrical with the total of three bays, the main living area is located in the middle with the main entrance facing south. (Figure 3 (b)) The living room is surrounded by two-two bedrooms on both sides. Each bedroom has only one window the size of 850mm (width) * 900mm (height) and are equipped with safety grilles. Windowsill is relatively high, reaching 1.4 meters. The dwelling selected in Xijiang is a three floor pillar supported building, the back side of the building is connected to the mountain, while the front of it is facing south. The whole design embraces the mountain terrain specifications. The plan is long with an axis from east to west and symmetrical layout. (Figure 3 (c)) In the middle is the main living room area opened on the south side with the 'beauty's leaning', which is connected to the rooms on its sides through a corridor. The kitchen is located on the west side. Window sizes vary on the first floor, with a width between 650 to 750mm and heights between 600 to 900mm. Window sills are at the height at 1 meter.

The three layouts are different and represent the local culture and adaptation to terrain, however there are some features which are present in all the three dwellings. The local subtropical climate of

Guizhou is quite wet, annual rainfall is around 1360 mm. In these wet conditions wood structures need to be protected, thus the presence of a roof overhang was observed at all the dwellings. In Jiangchang the building has a double pitch roof with 1.4-metres overhang on both south and north sides. In Sanbao Dong the south side of the building also has a 1.1 meter roof overhang while the overhang on the north side reaches the kitchens outer wall. In Xijinag it reaches 1.3 meter on both south and north sides. Inside separation walls are made of wood, with a quite dark colour due to the aging of the material. The size and shape of the windows vary but, in each case the glass has a decorative wooden pattern. In Jiangchang this has decorative function, while in the other two dwellings it is a simple pattern and is more part of the traditional way of window construction than a decorative function. Next the area ratio of windows to floor (A_W/A_R) was calculated, by dividing the total area of the windows (A_W) present in a room by the area of the room (A_R). As the national standard minimum requirement are given in fractions, results in decimals were rounded to fractions. (Table 1)

Illuminance data collected was processed first by getting the ratio between the indoor and outdoor illumination value of every test point, and then by taking the average of the three measurements as the measuring points on the daylight factor (DF) values. Based on the data obtained in this way daylighting contours for all the rooms tested were generated using the software package Surfer 8 (2004) and daylighting situation in all the three dwellings was analysed based on the DF isolux contours obtained with Surfer. Results are shown on Figure 3.

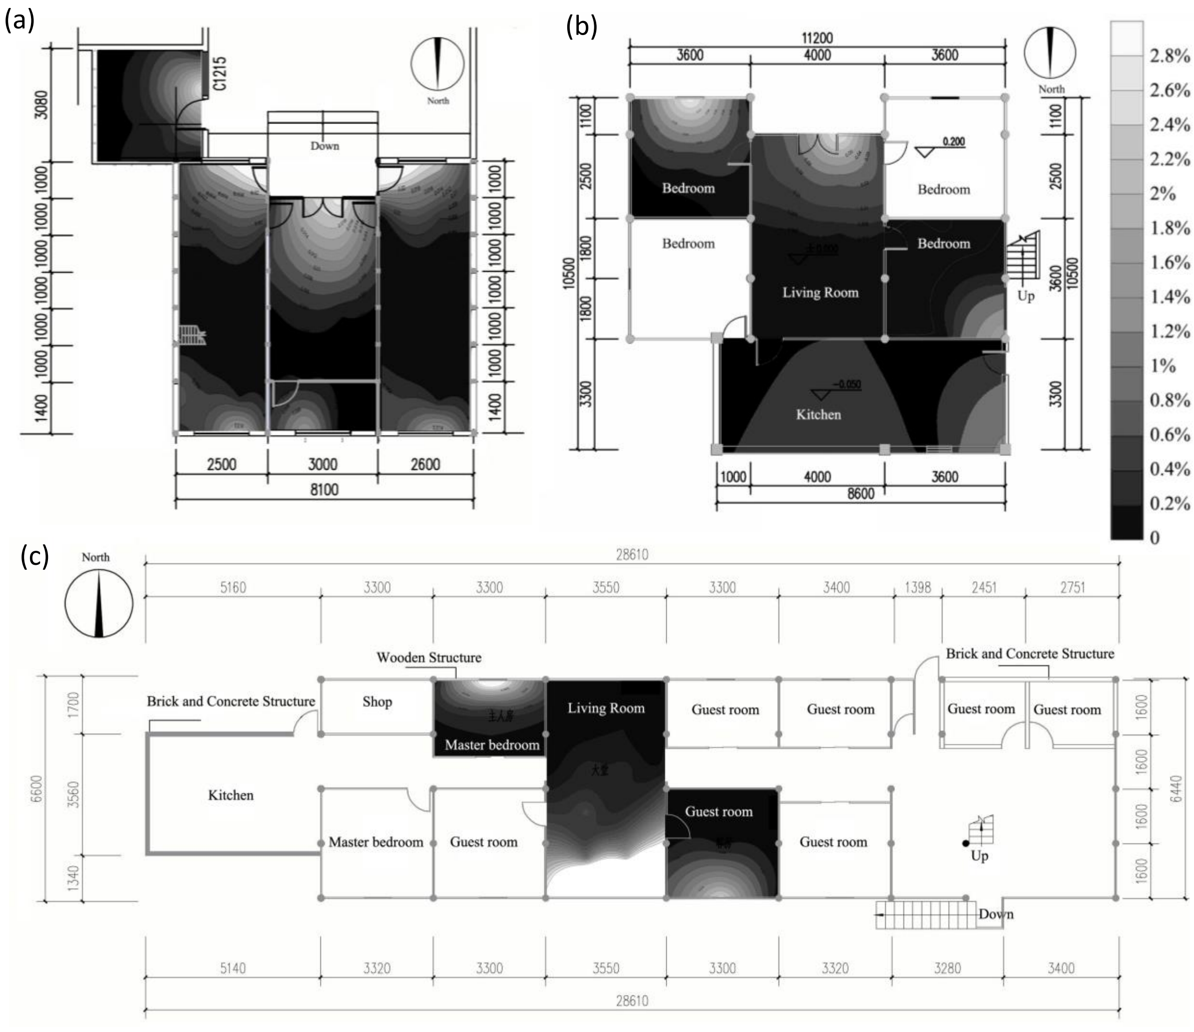

Figure 3: Floor plans and DF isloux contours of rooms tested in Jiangchang dwelling ground floor (a), SanBao Dong dwelling ground floor (b) and Xijiang Miao dwelling first floor (c)

Table 1. Area Ratio of Windows to Floor

Place	Room area (m^2)	A_W/A_R	A_W/A_R in Fractions
Jiangchang			
Living room	15.0	0.17	1/6
East Bedroom	18.5	0.15	1/7
West bedroom	18.5	0.15	1/7
Kitchen	4.2	0.38	1/3
Bungalow	9.0	0.33	1/3
Sanbao Dong			
Living room	24.8	0.08	1/12
East Bedroom	13.0	0.06	1/16
West bedroom	13.0	0.09	1/11
Kitchen	28.4	0.07	1/14
Xijiang Miao			
Living room	23.5	0.34	1/3
East Bedroom	7.6	0.08	1/12
West bedroom	10.6	0.06	1/16

FINDINGS

The analysis showed that daylighting of these dwellings has the following problem:

The minimum daylight factor (DF_{min}) cannot meet the residential building standard

The architectural lighting design standards for residential buildings (China, 2013) sets the minimum value of daylight factor at DFmin=1%. From the data analysis, it can be seen that, the minimum value of daylight factor of the three dwellings do not meet the specification above in none of the rooms, with DFmin values ranging from 0.01% to 0.26%. Living rooms in all the three dwellings have a better daylighting performance than bedrooms, where daylighting conditions are not favourable.

Concluding from the analysis of the data, the following factors have negative effects on daylighting in the three traditional dwellings:

1) **The size and proportions of the rooms.** The face width of the rooms can be considered normal according to modern building standards, however great depth, reaching even 7.5 meters in Jiangchang, results in not good daylighting condition and areas with almost no light. Great depth is especially characteristic and thus problematic for the living rooms, which are the main living area and such should have the best daylighting performance.
2) **The colour of the interior wall.** Internal partition walls are made of wood, which darkened after prolonged use. The dark colour of the partition walls makes the reflection of natural light more difficult, while also contributing to a feeling of darkness.
3) **The size and construction of the daylight openings.** According to the National standard minimum requirement of the area ratio of window to floor (GB50096-2011, 2011) needs to reach 1/7 in general. Normal values for bedrooms are considered to be between 1/6-1/8, and 1/4-1/6 for living rooms. Looking only at this value the situation in Jiangchang dwelling is quite favourable, with all rooms meeting national minimum requirements, however the great depth of the rooms disturbs the daylighting effect. The values are a lot below the standards, ranging from 1/11-1/16, only in one case is the value in the acceptable range, for the living room in Xijiang Miao dwelling. Besides the size, the presence of a wood pattern on windows, reduces the daylight effect even further, by reducing the area of the window.

COMPUTER SIMULATION

Simulation description

To show the effect of the identified problems and to find the best solutions for improving daylighting conditions in the dwellings, simulations were carried out using ECOTECT 2011 software

(Ecotectt, 2011). During simulation, factors identified before to cause problems were impoved compared to original measurements and the positive effect of these changes were evaluated. Three factors were selected to be variable in the experiment, the depth of the room, the colour of the interior wall and the presence of the grid on the window. (Table 3) The layout and original filed measurements of the Jiangchang dwelling were used as the control group for the simulation, as many of the factors causing daylighting problems were prominent. However simulation was only carried out on this one dwelling, findings should also reflect the other two dwellings, due to the similarity of the emerging problems, the similarity of outside conditions and the same orientation. All the simulations were done under the conditions summarized in Table 2.

Table 2. Simulation Conditions

Name	Value
Location	26.14 degrees north, latitude 105.55 degrees east
Daylight Climate zone	IV Daylight Climate zone
Critical illuminance value	4500lux
Illumination sky model	CIE cloudy sky

Table 3. Simulatin options descriptions

Simulation	Variable changed	Change compared to original situation
Control group	None	Variables are the same as in original conditions: bedroom depth 7.5m, living room depth 5.1m, walls are dark stone with dark wood, reflectivity rate is 0.16, grid is present on the window shown by transmission rate of 0.5, doors open
A	Room depth	Bedrooms' depth is reduced to 6 m, livingroom's depth is reduced to 3.6m
B	Indoor wall color	Indoor walls are set as painted a light wood color, the light reflectivity increases to 0.4
C	Window grid	No grid on the windows, transmittance rate increases to 0.7
D	All the above	All the above variables are present at the same time

Simulation results and analysis

Analysis of the different models resulted in five situations showing the impact of each variable on the indoor daylighting condition. Compared to Figure 3 (a), the indoor distribution curve of daylight factor of the control group has a similar distribution trend of the original dwelling (Figure 4 (a)). Although there are still some deviations in the data, the pattern of DF in the simulation experiments can be considered consistent with the existing situation. To show the effect of the different variables on the daylighting condition, average DF and the percentage of all values between DF 0-1% (under standard), DF 1-2% (gloomy but acceptable conditions) and DF 2% (reasonably good) were calculated and compared. When a higher percentage of the values are in the higher DF range the effect of the change of the variable can be considered stronger. (Table 4)

Table 4. Change in Daylighting condition for different simulation described by the percentage of values in different DF ranges

Simulation	Average DF	DF between 0-1%	DF between 1-2%	DF above 2%
Control group	1.77%	47.79%	24.64%	27.56%
A	2.26%	23.05%	39.78%	37.16%
B	2.00%	33.03%	36.04%	30.93%
C	2.27%	31.59%	32.33%	36.08%
D	3.67%	6.3%	32.76%	60.94%

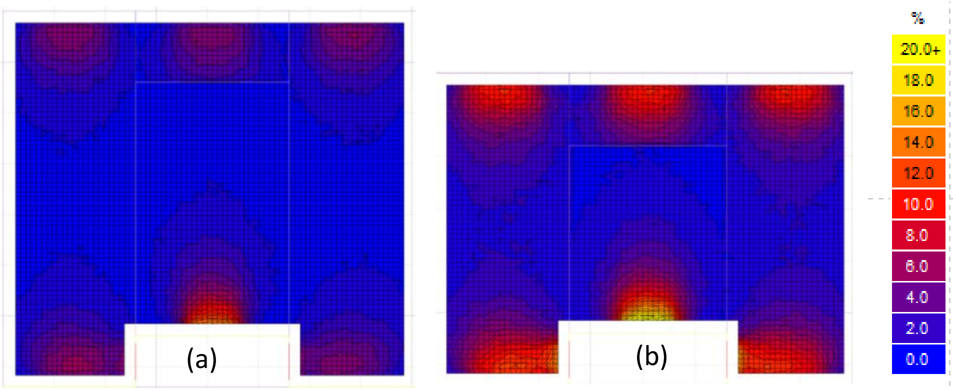

Figure 4: Dayligt factor simulation results, control group (a) and simulation D, all variables changed (b)

The impact of room depth on daylighting: The change of the room depth affected the distance between the north window and the south window, and thus the area ratios of window to floor. From all the variables changing the room depth has the most positive effect on daylighting. The percentage of DF values between 0-1%, values, under the accepted standard, reduced to 23% while the percentage in the range of above 2% increased to 37.16%. Reducing the depth allows the same amount of light to be able to meet the needs of indoor better. Lighting distance on both sides also reflects the advantages of two-sided lighting.

The impact of interior wall surface reflectivity on daylighting: After the colour of the interior walls is changed to a light colour, their reflectivity increases from 0.16 to 0.4 resulting in the increase of the area with a value of DF in the range of 1% to 2%, however it's a smaller increase than in the case of the other two factors. The increase of the interior walls' reflectivity allows better diffuse reflection of the light entering through the windows and the doors.

The impact of grids on the window on daylighting: The grid on the window reduces the area of the window, but since its area is difficult to calculate, it was simulated by altering the transmittance rate for testing purposes. Simulation results showed that when there is no grid present, DF values near the windows increased and only 31.59% of DF values are under the standard compared to the original 47.79%. Removing the grid can increase the injection of indoor natural light and thus can positively affect daylighting condition.

Figure 4 (b) shows the cumulated effect of all changes. It can be seen that daylighting situation improved significantly. When applying all the changes together only 6.3% of DF values are under the standard and more than 60% of the DF values are reasonably good range. Considering the above results suggestions are given for future improvements.

Suggestions for improvement

By analysing the results, it can be concluded that both the large depth and dark interior wall of the traditional dwellings in the three villages have a negative effect on daylighting conditions of the residential living areas. Also, the traditional carved wood decoration and safety grills on the windows increase the self-shading of these houses and decrease the amount of light penetrating the rooms even in the case of an appropriate window area ratio in Jiangchang village. Not to mention in the other two cases, where the ratio of window to floor is much lower than suggested by modern building standards. These dwellings cannot guarantee even the basic lighting requirements of daily life.

Based on the data analysis and the results of the simulation future refurbishment or new build projects should be carried out including measures to increase the amount of sunlight and to improve the natural daylighting condition. To increase the comfort of occupants the following measures can be taken:

The amount of sunlight is most influenced by the area ratio of window to floor. The easiest measure would be to increase the window size. In the case of rebuilding traditional houses, this can be done to an extent when the appearance of the traditional dwellings doesn't loose its originality. However when old dwellings are refurbished this could be problematic.

Another solution can be to replace the original glass of the window with high transmission glass and to replace the fixed carved wooden grilles with ones that can be opened at times, thus daylighting in the rooms can be improved without changes that influence local building style.

Under modern living conditions too large depth of the rooms is not useful anymore for the occupants of these dwellings. It was observed that due to shortage of daylighting the opposite end of the room is usually used as storage only and is not part of the active living space. The most hands on solution would be to reduce the depth of the room, as this is the factor having the biggest positive influence on daylighting condition, but it is a very difficult and complicated job to carry out as part of the refurbishment. Therefore, this modification is generally possible in case of new built dwellings following the traditional design style, but there it should be the primary consideration.

The change in the surface of indoor wall is a more feasible suggestion during refurbishment. In terms of traditional wood building material and stone, plastering on all walls seems too simple and rude, and it would destroy the native beauty of these residential dwellings. Despite painting the walls white would have a stronger positive effect on daylighting, taking in consideration the consistency of the traditional style, the solution suggested here is to clean the wooden walls and repaint them with wood protective paint. Such a change may not only improve the indoor lighting, but also protect the building components.

CONCLUSION

This research consisted of two parts. In the first part lighting data of the traditional dwellings in Jiang Chang Village, SanBao Dong and Xijiang Miao was collected during a field research. Based on the data collected features and influential factors of lighting were studied in detail. The other part was to study the lighting variables of the vernacular dwellings. A simulation experiment was carried out using ECOTECT software, which verified futures assumptions of influencing factors of daylighting. Renovation suggestions, such as cleaning and treatment of wood walls, movable grilles and replacement of the window glass, were given, which measures will improve daylighting situation. In case of new built dwellings using the traditional style, primary focus should be on reducing room depth. All these measures will have a positive effect on occupant comfort and thus contribute to the protection and preservation of these traditional dwellings, and could also be on dwellings in other parts of China. However, further reserach is needed in this area, to understand daylighting conditions in different dwellings and to explore more possible solutions to improve it.

ABSTRACT

India is known for its rich cultural heritage. The culture plays an important role in defining the architecture of a place or people with time. Madhya Pradesh is one of the states of India. The objective of the paper is to study the changes in culture and architecture from vernacular to modern of Madhya Pradesh. Vernacular architecture has been evolved through a process of trial and error for ages. In Methodology the vernacular and urban dwellings are documented and analyzed on various parameters of culture and architecture. The dwelling of potters and bamboo workers are selected from vernacular and urban settlement. The two typical dwelling from BHEL, Bhopal is selected from an urban settlement. The result focuses on influences of urbanization and globalization which brought threat to cultural identity. The urban settlements are designed according to the economic status of the residents without considering their culture. The analysis is to adapt the appropriate technology using locally available material and construction techniques for a sustainable development. It requires an innovative and creative approach to integrate vernacular into the modern architecture. The paper concludes by learning and appreciating the principles of vernacular architecture and integrating them with the contemporary knowledge and technology.

Keywords: culture, architecture, vernacular, modern, sustainable development

INTRODUCTION

Madhya Pradesh is one of the states in India which is centrally located. It is also known as heart of India due to its geographical location. Bhopal is the capital of Madhya Pradesh was formed in 1956. The border of this state touches five states: Gujarat, Rajasthan, Uttar Pradesh, Chhattisgarh and Maharashtra. The influences of these states are prominent in zones and architecture of Madhya Pradesh. Its culture can be divided in four zones such as Bundalkhand, Baghelkhand, Malwa and Nimar. Each zone has its own cultural identity such as language, dialects, customs, rituals and beliefs. The state is famous for its tribal arts and crafts. As per 2011 census of the state the population was 72 million and the tribal population is approximately 20 % of the total population.

CULTURE AND ARCHITECTURE OF MADHYA PRADESH

The tribal and folk traditions of Madhya Pradesh are reflected in the vernacular architecture. The state is known for its visual and performing arts, these art forms are closely associated with their beliefs, customs, religion and values. The singing and dancing are part of their day to day life. It is a community activity performed each day after the work to relax and enjoy. These activities have evolved the necessity of a community space like a courtyard or chaupal in their settlement pattern. These patterns resulted in a strong social binding within the community. Each tribe has its own way of settlement pattern on the basis of their culture and lifestyle like Saharia has circular, Bhil has scattered and Korku has linear. The central space in Saharia is 'chaupal' where grandparents chat and look after grandchildren while the parents are working on fields.

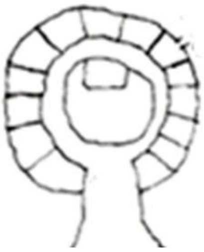

Figure 4 Circular pattern, Saharia

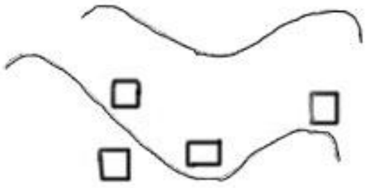

Figure 5 Scattered pattern, Bhil

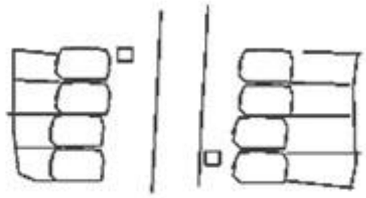

Figure 6 Linear pattern, Korku

Madhya Pradesh is famous for its traditional crafts like bamboo, wood, pottery, painting, metal casting, terracotta and textiles. The sarees from Mahaeshwar and Chanderi are famous for weaving whereas Bagh and Ujjain are famous for printing. The designs are evolved and inspired from the surrounding environment. The weaving pattern in Maheshwari sarees 'Laharia' is most dominating which is inspired from the holy river Narmada. These patterns of textiles are also reflected in the vernacular architecture. The sculpture and murals in the houses are not simply for decoration but are part of their rituals and beliefs. During the festivals and rituals the murals depicted on the walls are Pithora, Sanjha and designs on the floors are Mandana, Alpana and Rangoli. The tribals adorn their roof tiles with animals, human images and some figure which have something to do with witch-craft and evil spirits. Horses occupy a significant status in tribal life as symbol of power and force. It is depicted in different forms in murals, sculpture and even in the structural members of the built form. The bas relief figure of birds, flowers, trees and animals are depicted on the interior walls of houses. The clay figures are prevalent to mark both auspicious as well as inauspicious occasions. The paneled doors of single plank and wooden pillars are carved with the motifs of flora, funa and geometry designs. The Bas relief figure of animals, birds, trees, flowers and god-goddess are depicted on the interior walls. The trees are integral part of a house like a Tulsi chura in middle of a Hindu house, they also have medicinal values.

REFLECTION OF CULTURE IN ARCHITECTURE

The communities of potters, textiles, printer, waevers and bamboo workers are well placed in their native places like textile printers in Bagh; weavers in Mahaeshwar, they have their own settlement pattern as per their trade. When they come to a city in search of employment they have to adopt a new trade or either continues with their own. There cultural identities are well defined in the traditional settlements in their built forms, decorations and lifestyle. The settlement of Bhil or Gond tribe can be easily identified through these identities.

Figure 7 Tribal house

Figure 8 Bamboo workers

Figure 9 Gond painting

TRANSITION FROM RURAL TO URBAN

In Bhopal there is a planned urban settlement BHEL, a township developed for the workers. The planning of the settlement is done on the basis of economic status of the workers from one bedroom unit to four bedrooms unit. The township is designed with facilities like schools, colleges, sports complex, market places and other amenities. The spaces are provided for their religious and community activities although a township developed for the secular and democratic society as per Nehru's vision. There is no such defined culture or identify of the settlement. It has a concept of global village which has a similar character of any other planned city of India. The cultural identities are vanishing from the modern cities. In the urban planning there is no place for traditional settlements and vernacular patterns. Parallel to this industrial development there are also traditional crafts and trades which are integral part of the society, for example a refrigerator could not replace an earthen pot in an Indian house. When a pot is brought in the house, a ritual is performed to fill the water. This shows that the potter is an integral part of the society and the tradition continues in this manner.

METHODOLOGY

The vernacular and urban dwellings are documented and analyzed on different parameters of culture and architecture. The dwellings of Potters and Bamboo workers are selected from vernacular and urban settlements. The dwellings of workers from BHEL Township, Bhopal are selected from an urban settlement. The parameters of changes in culture are characteristics, aesthetics, planning and community living. The parameters of changes in architecture are site planning, response to climate, material, construction method & techniques and cost effectiveness.

VERNACULAR SETTLEMENT OF POTTERS (KUMAHAR)

Potters community lives in separate clusters in village settlement due to their work culture. A traditionl dwelling of potters at Damnod, District Dhar, Madhya Pradesh is selected for a case study. In the dwelling the spaces are required for storage of raw material and finished products, preparation of clay, creation of pots, roof tiles or bricks and firing. In the front there is an open space for working and selling and on the backyard for private space like washing, bathing and other household works. The enclosed spaces are used for sleeping, cooking and living. The toilets are not attached with the dwelling. A separate room for donkey is provided. These communities are associated with ceremonies of birth, marriage and death. The three to four generations live together which forms a strong social binding. The walls are constructed by rammed earth or brick masonry with mud mortar. The brick piers or wooden post are the vertical structural members. The attic is made of bamboo matting with mud mortar or wooden planks and is used as storage space. The stone slabs are rarely used because of site conditions. The roof consists of rafters, purlin with the covering of country tiles. The decorative figures of bird or animal are placed at the ridge. The tiles are moulded and casted or made on potter's wheel. The plastering is done by mud plaster, red clay, white clay and yellow ochre. The flooring has rammed earth covered with cow dung. The wooden door and windows are double leaf. The niches are used for storage.

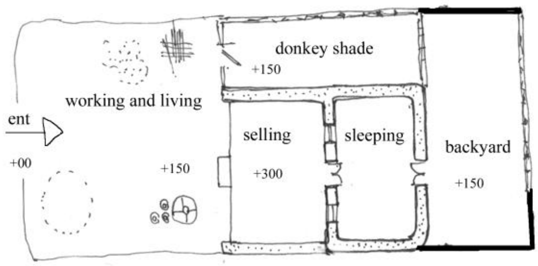

Figure 10 Plan

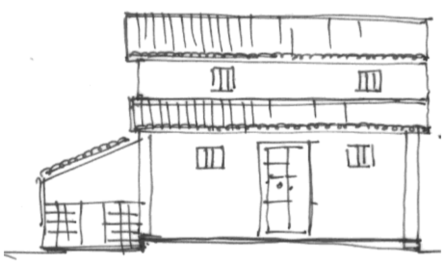

Figure 11 Elevation

When they migrate to cities, they do not have space to settle down as per the work culture. Therefore, they are forced to live on the "eyeshores", 'Jhuggis' or on the pavements. In the planned residential zones, the firing is not allowed where such living and working can be performed together.

The potter's community residing on the pavements of Link Road No.3 in Bhopal is documented. There is a planning proposal for resettlement for these dwellers under JNNURM, which is a multistoried housing in the same locality. In the new dwellings they cannot live and work per their work culture. If they are not given an opportunity to work, they are forced to switch over to another trade. As a result this craft will slowly vanish from the society.

Figure 12 Roadside settlement

Figure 13 Living space

Figure 14 Working space

Figure 15 Selling space

Figure 16 Interacting space

Figure 17 By new settlement

VERNACULAR SETTLEMENT OF BAMBOO WORKERS (BASOR)

Bamboo workers community lives close to the forest. The Basods are the people belonging to community of bamboo craftsmen who are traditionally dependent on bamboo for their livelihood. They are mostly engaged in construction work like scaffolding or temporary structures. Variety utility items are made like furniture, basket, ornaments, musical instruments, effigies, totems etc. A traditionl dwelling of bamboo worker at Churhat, District Satna, Madhya Pradesh is selected for a case study. They have living and sleeping spaces along the courtyard and the working space is outside the courtyard in front of the dwelling. The courtyard is used for household works, storage space for raw material and a pig house adjacent to the dwelling. This community is also closely associated with the society, when a girl is married; the essential utility items are given to her in a basket called 'pitara' or 'dori'. It is very auspicious. The walls are made of thick bamboo matt covered with mud plaster, thick bamboos are used for vertical support. The attic floor is made of bamboo mating, covered with mud plaster. The roof consists of wooden trusses, rafters and purlins of bamboo and covering of country tile or thatch. The mud is used for plastering; flooring is done by rammed earth, covered with cow dung. The timber doors and window frames with bamboo shutters, bamboo jail used for lighting and ventilation.

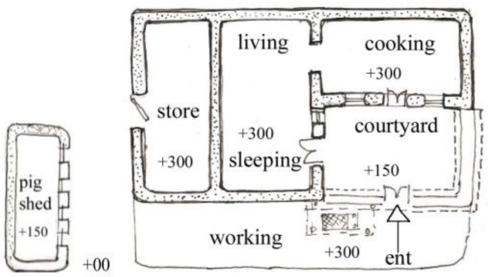

Figure 18 Plan

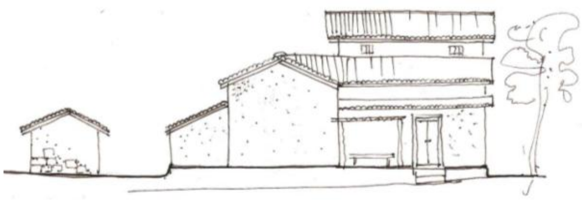

Figure 19 Elevation

This community is residing on the pavements of Link Road No.2 in Bhopal. In the similar way, for resettlement for these dwellers under JNNURM, a multistoried housing is provided in same locality, which is not as per their work culture and will result in vanishing of the craft from the society.

Figure 20 Roadside settlement

Figure 21 Living space

Figure 22 Working space

Figure 23 Selling space

Figure 24 Interacting space

Figure 25 By new settlement

These communities have a tendency to calls his family members or relatives when one gets an employment in the city. They start living in close vicinity; form a community, quite similar to the village pattern. This result in the formation of basti's (informal settlement) like potters basti, basoor basti, lohar basti etc. and are named after their trade. They face hardship in daily life; their biggest strength is social binding. Similarly the construction labors also form basti, named after their state as Chhattisgarhi basti, Orriya basti etc. There lives are challenging; even a birth or a death can take place at the site. Sometimes they come across serious incidences like Gas tragedy, Bhopal in 1984, the residents of Orriya basti were among the victims. It was one of the biggest industrial disasters; lakhs of people lost their life.

URBAN SETTLEMENT IN BHEL TOWNSHIP, BHOPAL

This township has been designed for an organized sector for industrial workers with modern amenities and facilities. It is a RCC framed structure, use of modern materials and construction techniques, technical experts, skilled labor were the prime concern. There is monotony in form and character which has similarity with any other planned urban settlement in India. The dwellings are designed as per the economic status of the worker. There is not a defined character and does not reflect a particular culture. Hence there is a change in living pattern and lifestyle.We have selected two type of dwelling units of the township, Type A and Type C. Type A is one bedroom unit with living room, kitchen, verandah, courtyard with bath and wc with an area of 454 sq ft. Type C two bedroom unit with two verandahs, kitchen, one common toilet and one attach toilet with an area of 883 sq ft.

ANALYSIS

Table 1. Parameters of Changes in Culture and Architecture

Parameters of changes	**Details**	**Vernacular Architecture**
Culture	Characteristics	Different cultures of tribal and folk are well defined.
	Aesthetics	Murals, painting, sculpture are integral part of architecture.
	Planning	Settlement planning as per their lifestyle like circular, squatter and linear.
	Community living	Choupal, otla, chowk, courtyard for social interaction. Strong social binding.
Architecture	Site planning	Planning as done as per topography and landscape.
	Response to climate	Plan form and built form are evolved as per the climatic conditions of the region.
	Materials	Locally available material like stone, mud, bamboo, timber and lime are used.
	Stone	It is used in masonry, roof, flooring, in-built furniture, Chajjas and Jharakhos are provided for shading.
	Mud	Rammed earth, adobe, mud mortar used in random rubble masonry, helps in acoustics and heat resistant.
	Bamboo	Because of strength and flexibility widely used as structural skeleton, roofing structure, composite construction and utility items like jaails, baskets etc.
	Timber	Used as a structural component, in the construction of beams, rafter, trusses, doors, windows and furniture.
	Lime	Used in brick masonry as a binding material, for plastering and fresco painting.
	Brick and Terracotta	Brick is used for masonry walls, piers, jaalis, etc. Terracotta is used in roofing tiles, roof gutters, pottery.
	New materials	Adaptability to new material.
	Cost-effective	Because of locally available material, saves the cost of transportation
Parameters of changes	**Details**	**Modern Architecture**
Culture	Characteristics	Universal characteristics, no reflection of local culture
	Aesthetics	Contemporary art is depicted.
	Planning	People live in isolation, less interaction with others, no place for local arts and crafts.
	Community living	Cultural hubs, sports complex are interaction spaces, intimate relationship and social binding is less.
Architecture	Site planning	Planning is as per the economic status of the user like HIG, MIG, LIG and EWS.
	Response to climate	Eco-friendly materials are in market but are expensive.
	Materials	The market ones are given priority than local ones.
	Stone	With modern techniques it’s used in a better way.
	Mud	Rammed earth, adobe are used in modern design.
	Bamboo	It is used as a new material in modern construction.
	Timber	Used for doors, windows and not as structural member
	Lime	It is rarely used, limited to conservation
	Brick and Terracotta	Brick is used for masonry walls, piers, jaalis, etc. Terracotta is used in roofing tiles, roof gutters, pottery.
	New materials	Adaptability to new materials is more
	Cost-effective	Material and transportation cost are high.

Source: Author

RESULTS AND FINDINGS

The vernacular dwellings have a special character that the spaces are multifunctional and each craft requires a different pattern of spaces. The dwellings are designed by keeping in mind the future expansion. The form of a building is evolved from its functions. Architectural characteristics are defined by their work culture. Pottery is a traditional craft which transfers from one generation to another. So it is continuously expanding as per their requirements hardly any change is seen in the living pattern and lifestyle. Some of the potters migrate to city for employment. Thus, migration is a major problem of urban settlement. The planned housing is defined by the economic status of the user. The modern material are used which are changing with new construction methods and techniques. In vernacular there is a subtle change in material and character. The acceptability of new material and technique is less. Therefore, they have a specific character and lifestyle. In urban settlements the changes are easily noticeable; acceptability to new material and techniques is high. A new character is coming up which has no relevance with the vernacular, it has a global character. The data collection and observations there is no space provided in the urban planning for traditional craft like potters, bamboo workers, blacksmith and weavers etc. which are an integral part of the society. Hence in the urban planning the provisions for these settlements should be provided. The research can give vision to policy makers, planner, architects to look into the traditional crafts and trades, understanding the vernacular traditions and incorporating them in the contemporary planning. The impact of globalization has threatened traditional and cultural values by the forces of economic, cultural and architectural homogenization. This has brought disregard for traditional environment and often considered as a symbol of poverty and backwardness. In the race of modernity, values, beliefs, culture are removed from the society. The steps towards sustainable cities are taken at various level such as Earth Summit, Agenda 21 at the international, JNNURM at national and other inititaves include National Habitat Mission, National Action Plan for Climate Change, Water Mission, Energy Efficiency Mission and so on. (Tipnis, 2012)

INTEGRATION OF VERNACULAR AND MODERN IN THE CONTEMPORARY DESIGN

Vernacular traditions lead a way towards the sustainable built environment. The valuable lessons from vernacular can be integrated with the modern to produce sustainable designs. Vernacular traditions can also be used as a design tool for slum re-developments. The designing of these settlements need understanding users' way of life, social and cultural values. LIC housing by Charles Correa, Anandgram by Kamath Design Studio in India are few examples of integration of vernacular and modern. Architects like Louis Kahn, Lourie Baker, B.V. Doshi, Shirish Beri, Revathi and Vasanth Kamath, Satprem Maini have incorporated the principles of vernacular traditions in their contemporary buildings (Tipnis, 2012).

Anandgram in Shadipur, Delhi is selected as an example of resettlement. It is designed by Kamath Design Studio, Delhi, India in 1983. Architect Revathi and Vasanth Kamath their work is a creative synthesis of attitudes and technologies into an aesthetic habitat and a way of life. They believe in using natural resources and utilize them to the most and are on a mission to substitute concrete, cement and energy-consuming systems with sun, water, wind and soil. Ecology must be understood to encompass both nature and culture (kamathdesign.org). The settlement is designed for traditional community of performing artists and craftsmen in their own traditional pattern by integrating values, customs, rituals, beliefs and lifestyle. The challenge was to provide the built-fabric in relation to the urban form. It is one of the best examples of reflection of culture in architecture in the contemporary design.

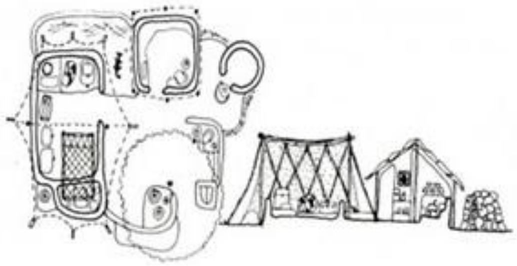

Figure 28 The change in unit after 30 years

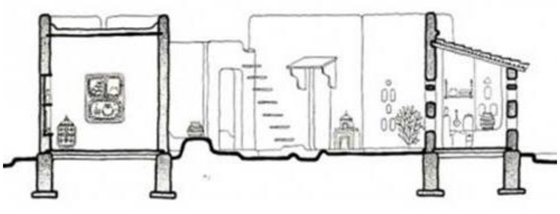

Figure 29 The setion through a cluster

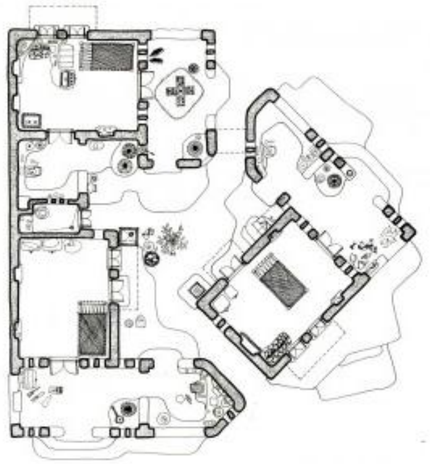

Figure 30 The detailed plan of a cluster **Figure 31** The resettlement plan

CONCLUSION

The changes in culture and architecture are reciprocal. The impact of one is reflected on the other. India’s rich cultural heritage is vanishing due to the influence of urbanization and globalization. In order to protect and conserve our rich cultural and architectural heritage the elements of vernacular should be incorporated in the contemporary planning and architecture. The provision should be made to incorporate vernacular architecture and traditional knowledge in the policies. The policy makers, planners and architects should consider this in their work for betterment of society. The paper concludes by learning and appreciating the principles of vernacular architecture and integrating them with the contemporary knowledge and technology.

“Quality of life is enhanced through good architectural design which responds to the needs and wishes of users and use of natural materials and good urban design which allows creation of green spaces and reduction of noise and pollution.” Birkauser, (Tipnis, 2012).

GLOSSARY

Chaupal: denotes a common meeting place in a village which is owned by the community.
Bhil: one of the main tribes lining in the Jhabua and Dhar region.
Dwelling: is the name given to a house form or for living somewhere.
Jaali: lattices made of bamboo, grass and clay, used on mud houses in Sarguja, Raigarh.
Pithora: votive wall painting made by the Bhils, worshipped with sacrifices.
Sahariya: primitive tribe living in Gwalior, Shivpuri and Morena in the north-westrn part of Madhya Pradesh. The people of this tribe consider Sabari of Ramayana to their first ancestor.

Vernacular Ecology: Environmental Recreation of Ancient Dwellings in Southeastern Turkey

Mina Hasman, LEED AP
Skidmore, Owings & Merrill, Inc.

ABSTRACT

"At the beginning of the 21st century, in a time of rapid ecological degradation, globalization and destruction of much vernacular architectural heritage, concerns for the maintenance of the local, cultural identities, and an awareness of the need to provide sustainable built environments are set to raise an interest in the vernacular traditions" (Asquith & Vellinga, 2006) for a culturally-embedded environmental design future. This paper investigates the Southeastern Turkey's vernacular architecture with the aim to partake in the development of a New Hasankeyf proposal by investigating design guidelines for the new dwellings of the future city. The basis of the explored guidelines relies on the concept of 'recreating the vernacular' with the primary goal to enhance the environmental performance of the proposed dwellings; through passive means and without compromising the cultural/geographical premonitions that it originally derived from by implementing 1) compact form, 2) adapted space layout and 3) improved building elements.

INTRODUCTION

In an era, in which archeological sites are preserved with utmost diligence, Hasankeyf - a declared conservation area in Southeastern Turkey - is left at its destiny, which would be determined by the Turkish Government that attempts to flood the region with its Ilisu Dam along Tigris River as a part of an "integrated irrigation and agricultural project" (Demirbilek, 1997) called GAP.

It is not only the inconceivable truth of inundating such an ancient city which results in a homeless population and ever lost heritage, but also the insensibility of the government's new construction proposal set forth that both encourage a need to offer construction and design guidance for a sustainable, long-lasting, culturally-familiar and aesthetically-amalgamated design approach.

Over the last century, the region has faced a "rapid and uncared growth" as observed by (Demirbilek, 1997) due to fast population increase, changes in the social context and economic restrictions. This has encouraged an incongruous, fast-pace construction without any considerations for (cultural) modern era notions. The main goal of the current research is, therefore, to understand and explore the limitations of the vernacular sustainable strategies in Hasankeyf and learn how the local approaches could be implemented in and further adapted to a new development within the region. Considering this, the paper at this stage, adamantly envisions the 'recreation of the vernacular' as an integral aspect of long-term sustainability by investigating potential passive measures, which could provide annual occupant comfort.

The recreation of the vernacular concentrates on exploring a design of mostly self-sustaining dwellings embedded within an environmentally-responsive enclosure without compromising elements that define the region's unique architecture but enabling it to adapt to the contemporary family needs.

REGIONAL INFLUENCES

Climate & Topography

Hasankeyf is a hillside settlement with an altitude reaching up to 495m perched within a valley in the hot and dry Southeastern region of Turkey. The great temperature difference of about 32°C between the hot summer and relatively cold winter months made it "imperative to adopt to the natural forces from the early days" of the region's history (Alioglu, 2000).

The climate analysis of the closest city of Batman obtained from the climate software, Meteonorm indicates that the area faces two annual extremes with a minimal amount of rainfall and a good amount of global radiation: fairly hot summers and cold winters with a large diurnal temperature difference. Based on this climate analysis, two different comfort bands can be determined by following de Dear's formula calculations as outlined by (Szokolay, 2004): the resulting comfort band for summer ranges between 24°C and 29°C, and for winter, the band falls between the temperature range of 17°C and 22°C.

Culture & Architecture

The historical perspective reveals that in the vernacular architecture of Anatolia, human beings built dwellings based on a specific region's geographic and climatic provisions along with the religious premonition of orienting the main façade towards Qibla - to Mecca, which is the direction of the Holy Land of Islam (Demirbilek, 1997).

Hasankeyf is an exceptional precedent to such a hypothesis: the city's settlement on hillside topography with introverted house layouts, not only accentuates the region's cultural privacy, but also represents the environmental benefits such a settlement and layout provide (Demirbilek, 1997). Moreover, the formation of semi-open (Eyvan & Revak) and open (courtyard & terrace) spaces along with enclosed areas forming the typical 2-level construction, differentiation of rooms for solely male and female occupancy, and small openings to outside mimic the characteristics of the area's closed-in lifestyle (Alioglu, 2000).

The region houses three building typologies: the U-type (- most commonly encountered within the vernacular city fabric), the L-type and the Linear Type. The building forms portray the family status and size, ranging from the most prestigious house with the largest family in the U-type to medium size in the L-type and to the smallest building form of the Linear Type. Despite the difference in their size and form, all the building typologies have traditional flat roofs, same treatment of architectural features and closely related program allocation and space layouts.

CASE STUDY FIELDWORK & ANALYTIC STUDIES

A fieldwork is conducted and measurements are taken in a precedent dwelling - the Gozuoglu House - in Mardin (- a nearby city to Hasankeyf) with the aim to investigate the vernacular building's performance.

The prestigious Gozuoglu House represents region's emblematic, architectural features within its 2-level construction of 90cm-thick, non-insulated, locally-sourced stone walls with single-glazed, small windows and a U-type layout of varied open, semi-open and enclosed spaces.

The house consists of 'living units' as described by (Alioglu, 2000) which include bedroom areas (within Haremlik and Selamlik living rooms) and the most esteemed men (Selamlik) and women (Haremlik) living rooms at the upper level. These spaces are commonly occupied during the summer season due to their high volume with ceilings reaching up to 5m (Demirbilek, 1997). The external shutters supplement indoor comfort within these spaces by providing protection against (direct) sunlight during the peak hours of the day.

The winter season targeted lower level, on the other hand, embraces daily 'service areas' (Alioglu, 2000) including an office (live/work room) and a study room along with a kitchen across a storage space, and an earth-dug room, which is most commonly used during the summer season as it stabilizes the indoor temperature and maintains the space cooler.

Fieldwork

The fieldwork of the Gozuoglu House is completed using Tiny Tag data loggers (for room dry-bulb temperature) on the sunny days of 4th - 6th of July 2011, during which the average outdoor temperature ranged between 30.1°C and 31.2°C. The intent of the fieldwork is to understand the temperature performance of two similar spaces at different levels based on solar radiation impact. A living room - Haremlik and a live/work room - the office space are chosen due to their comparable layout and size (28m^2 of floor area in Haremlik and 25m^2 in the office) along with analogous window-to-floor ratios (13% in Haremlik and 11% in the office), occupancy pattern and ventilation rates. (Note: Both spaces were not occupied during the fieldwork period).

The obtained data logger results indicate that thermal mass maintains both spaces' internal air temperatures at a fairly stable level (with a 2°C fluctuation) throughout the day despite the large 20°C diurnal fluctuation of the external temperature **as seen on Figure 1**.

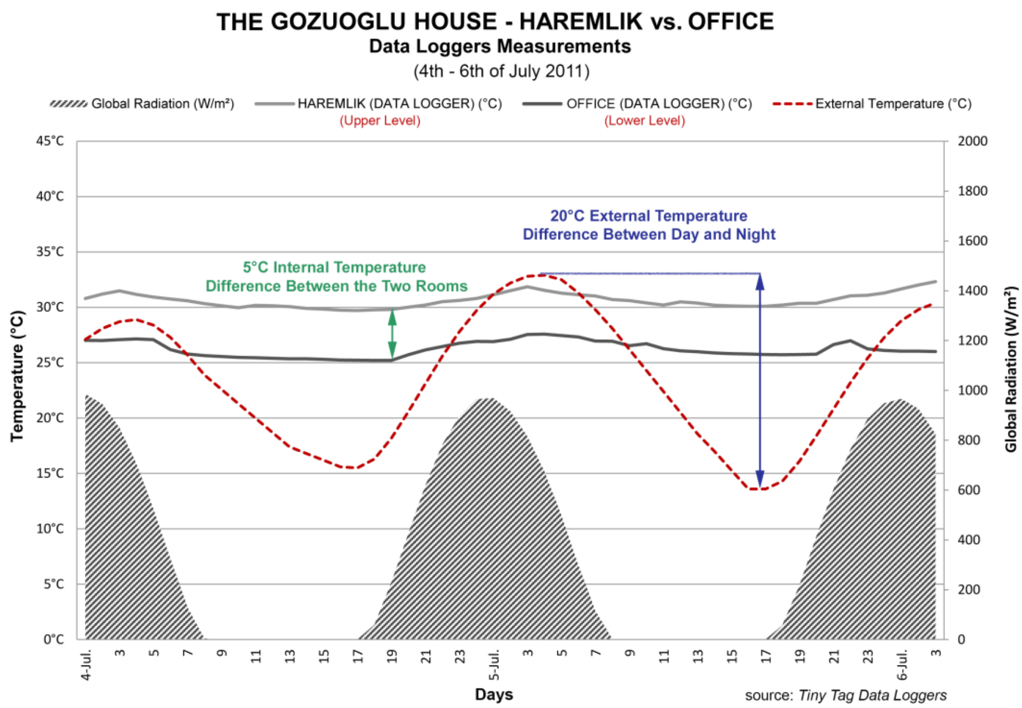

Figure 1   Fieldwork measurements' graph of two rooms in the vernacular Gozuoglu House

The 5°C internal air temperature difference between the upper level Haremlik and the lower level office highlights that solar radiation potentially plays an influential role in the increase of the internal air temperatures - a theory that needs to be confirmed by the subsequent analytic studies: the unobstructed Haremlik's east and south facing windows increase solar access, whereas the lower level office's only east facing, overshadowed (by terrace above) windows limit it.

Hypotheses

Analyzing the climatic characteristics of the city including S-SW wind flow pattern and high solar angles along with observing the case study fieldwork results, a series of strategies are formulated based on initial environmental hypotheses, which focus on passively improving the indoor comfort within such a vernacular enclosure:

- Increase of solar access into spaces
- Compact spaces of airtight, thermal mass construction
- Shading elements
- Night time ventilation (with additionally openable, upper pane windows and/or skylights)
- Maintenance of the vernacular's semi-open and open spaces that further contribute to the indoor

comfort enhancement: during winter, these spaces provide buffer from the cold outdoor temperature while during summer, they offer a shaded microclimate environment (Fathy, 1986; Koch-Nielsen, 2002), extending the daily family life.

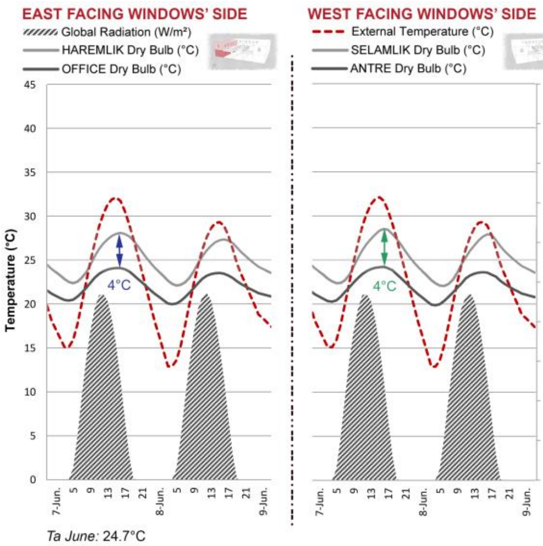
Analytic Studies

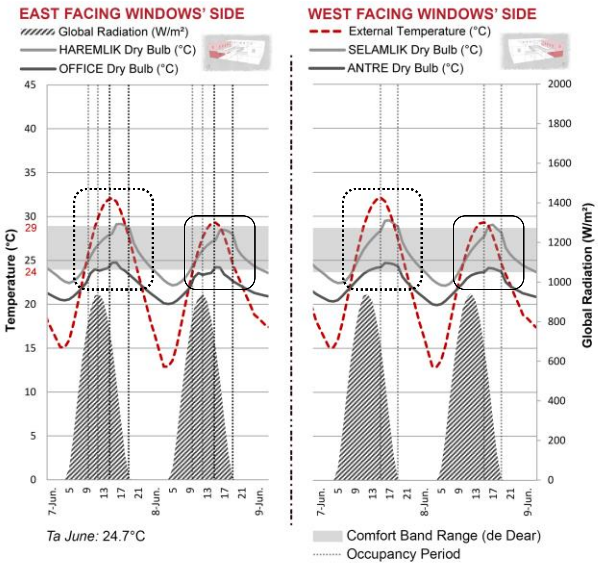
At the conclusion of the obtained fieldwork, analytic studies are conducted using Thermal Analysis Software (TAS) for calibration, understanding of the dwelling's annual performance and confirmation of the proposed strategies in relation to the formulated environmental hypotheses.

The created base case model complies with the vernacular case study precedent in terms of building form, layout and inputs. The completed TAS model is examined for building's performance of levels, orientation, solar radiation access and internal heat gains throughout a typical summer (7th - 13th of June) and a winter week (1st - 7th of December). The analysis and comparison of each simulation are evaluated against the comfort bands (24°C - 29°C for summer and 17°C - 22°C for winter) calculated according to de Dear's formula.

Four rooms are selected for the simulations: Haremlik (the upper level living room with south and east facing windows), Selamlik (another upper level living room with south and west facing windows), office (the lower level live/work space with east facing windows) and Antre (a lower level living room with west facing windows). Both of the lower level rooms as well as the upper level ones are given the same window-to-floor ratios of the vernacular (13% on the upper level and 11% on the lower level) to minimize the parameters that would influence the outcome.

Similar to the fieldwork measurements, the summer simulation results for both orientations indicate that solar radiation has a valid influence on increasing spaces' internal air temperatures: the more exposed upper level portrays approximately 4°C warmer temperatures (before the internal heat gains are applied) compared to the lower level rooms **as indicated on Figure 2**.





Infiltration: 1ach

Figure 3 The east and the west facing summer temperature graphs of the Gozuoglu House Base Case simulations – Influence of internal heat gains (all source: TAS)

Despite the impact of solar radiation, the influence of orientation (East vs. West) is minimally observed due to the U-type building form that overshadows itself: two same level rooms portray a fairly close temperature range. Nonetheless, it can be clearly identified that the impact of internal heat gains is the most direct: the temperatures of both levels initially increase following the external temperature pattern, however, with a time-lag due to the dwelling's heavy-mass construction. Once the internal heat gains (i.e. mainly occupancy and some lighting) are applied into these spaces, the internal temperatures reach their peak approximately at a 1°C - 2°C higher level **as highlighted with on Figure 3**. When the internal heat gains are removed as spaces become unoccupied, the internal temperatures decrease following the pattern of the external temperature. Nevertheless, the internal temperature levels do not necessarily mimic the external temperature drop if the internal heat gains are continuously applied within these spaces **as highlighted with on Figure 3**.

Reassuring the previously formulated hypotheses, the free-running (without heating or cooling) Gozuoglu House Base Case exhibits a much poorer performance during the cold winter season with internal temperature levels falling below the calculated comfort band of 17°C - 22°C, following a fluctuation line of 7°C - 14°C **as highlighted on Figure 4 (a) and (b)**.

(b) The eastern wing temperature graph

Figure 4 (a) The western wing and (b) the eastern wing winter temperature graphs of the free-running Gozuoglu House Base Case simulations (source: TAS)

Moreover, the winter season simulations highlight the better performance of the lower level spaces (- the office to the West and Antre to the East) due to their less exposure to the interchanging outdoor temperature. Following this line of thought, it is not only the higher volume of the upper level with taller ceilings and a larger window-to-floor ratio, but also the exposed surfaces further contribute to the heat losses that occur at this level, in return diminishing its performance.

Critical Review

The conducted fieldwork and current analytic studies confirm the initially formulated environmental performance hypotheses for the investigated vernacular dwelling, in which the heavy-mass stone construction and small window-to-floor ratio maintain the internal temperature levels stable during both winter and summer months, however, passively achieving indoor occupant comfort during the hot summer period, but not providing it for the cold winter season. Considering this, the focus of the future analytic studies in this paper is to enhance the vernacular building's performance during winter while reducing the Annual Heating Load Demand and maintaining the summer indoor comfort.

Following the pattern of the previous section, a new hypothesis is formulated stating that the building scale manipulations such as improving the construction (i.e. implementing double-glazing and insulation) and increasing window-to-floor ratio along with defining a layout that is proportionate to the targeted occupants (in terms of floor area for the resulting internal heat gains) would increase the building's performance during the winter season while also maintaining the desired summer comfort.

PROPOSAL & ANALYTIC STUDIES

Vernacular dwellings of the region (especially the U-type building form) were meant for large families because traditionally married males never left their family home (Alioglu, 2000). Nonetheless, current married generation prefers to privatize their individual, core family life from the extended relatives. Considering this, guidelines are presented for the 'recreation of the 'modern' vernacular' with the New Hasankeyf Base Case being created following the reiterated parameters:

- Compact dwelling size proportionate to a single family of 4 people, which corresponds to the Linear Type encountered within the vernacular fabric (Note: Per the previously completed analytic studies, the U-type building depicts the worst performance among all the typologies due to its form, which limits solar access and enables heat loss via large amount of exposed surface area. It is also due to this reason that the Linear Type is chosen to represent a new dwelling prototype for the future city of Hasankeyf).
- Reduced stone wall thickness from 90cm to 30cm for ease of transport, labor and cost reduction
- Adequate space layout to accommodate the modern era adaptation of programs (i.e. identification of programs for the vernacular model). (Note: Separate bedroom and bathroom spaces were not a part of the vernacular dwelling layout; instead they were a part of a 'shared space' system. However, with the increasing need of individual privacy within a dwelling, the locals of the region are encouraged to redefine some rooms to provide for the needs of those 'unidentified' programs. This 'forced' process often takes away from the function and the proposed layout of another vernacular space in the building, posing contradiction to the traditional occupancy pattern and space layout).

The created New Hasankeyf Base Case has the input values **as shown on Figure 5**, deriving from the region's precedent characteristics.

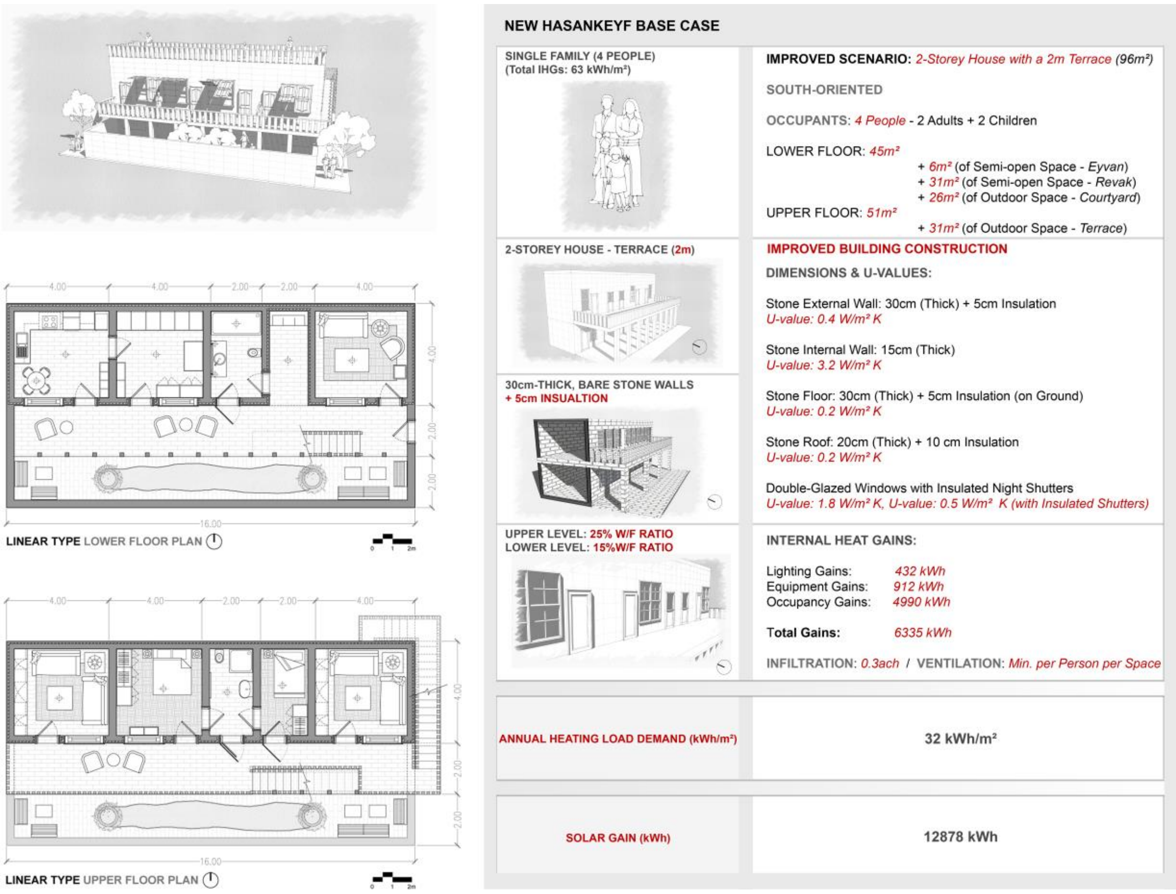

Figure 5 The New Hasankeyf Base Case diagrammatic drawings and analytic model inputs (source: TAS)

The New Hasankeyf Base Case's simulations conducted using TAS restate the previously encountered outcome: the model exhibits a good performance during the summer period with temperature patterns (for both levels) falling within the target comfort band, whereas it suffers throughout the cold winter season. As hypothesized earlier, the following building scale manipulations are additionally considered for the enhancement of the proposed dwelling's annual performance:

- Addition of insulation along the exterior of structure (from the vernacular none to 5cm thickness)
- Change of glazing type (from the vernacular single to double-glazing)
- Increase of window-to-floor ratio (from the vernacular 11% (at lower level) and 13% (at upper level) to 15% (at lower level) and 25% (at upper level) both with insulated, external shutters)
- Reduction of terrace depth (from the vernacular 4m to 2m depth)

A architectural approach combining the considered parameters along with an optimum South (Qibla) orientation has been established based on a balance of Annual Heating Demand reduction and increase of Solar Gain, and it is reflected within the design prototype for the New Hasankeyf dwellings. To quantify the proposed prototype's performance, a set of a typical summer and a winter week simulations has been completed comparing an upper level living room (Selamlik) to a lower level one (living room/office). The obtained summer simulation results of the free-running (without heating or cooling) New Hasankeyf Base Case **as seen on Figure 6 (a)**, indicate a stable profile for the lower level living room/office, whereas it portrays a bigger fluctuation pattern for the upper level Selamlik due to increased ventilation strategy applied in order to maintain the internal temperature levels within the set comfort band with newly increased window-to-floor ratio.

The New Hasankeyf Base Case's internal temperature profiles portray significant improvements of approximately 20-25% for the winter model performance when compared to the vernacular Gozuoglu House Base Case: both the upper level Selamlik and the lower level living room/office display a more regulated temperature pattern with a daily fluctuation reaching up to 4°C **as indicated on Figure 6 (b)**. The obtained results highlight both levels' potential for achieving comfort range with increased occupancy and/or minimal heating input: it has been observed that when there is constant solar radiation above 500 W/m^2 and the external temperature exceeds 10°C, the lower band of the comfort zone can be achieved during the occupation hours under free-running conditions. Moreover, there is an evident improvement in the lower level space's internal temperature levels from the Gozuoglu House Base Case condition. The improvement also applies to the upper level Selamlik's internal performance with a 3°C higher temperature range compared to the vernacular Gozuoglu House Base Case model. Considering this, the band in which the heating system would operate in order to reach the comfort range would be much smaller and therefore, significant savings can be achieved.

Despite the prototype dwelling passively not achieving a complete annual range within the calculated comfort bands, the proposed guidelines relay an achieved summer comfort and an enhanced winter performance without compromising the origins of the vernacular's architectural existence: the primary focus of the research is to offer guidelines to design for inhabitants who are devoted to meticulously preserve their cultural traditions mirrored onto the region's architecture and lifestyle.

The conducted research of the previously formulated hypotheses via supplementary analytic studies in this section, reassures the set theory in regards to the 'recreated' vernacular dwellings' performance. More importantly, this research leads to an outcome that can provide guidelines for the New Hasankeyf dwellings' passive design approach, through which not only current, but also future builders, designer and occupants can dwell upon, learn and grow, carrying on the precedents. The primary scope of this study has been to investigate the limits of the localized vernacular passive measures in order to enhance the environmental performance of dwellings within the Hasankeyf area. Nonetheless, further studies that are based on alternative performance metrics would explore useful measures that not only 'recreate', but also assist in achieving a more efficient and improved sustainable design by 'redeveloping' the vernacular lessons learned in this initial research.

ARCHITECTURAL DESIGN

The New Hasankeyf proposal derives from the architectural syntax of the vernacular, which is based on a 4mx4m grid layout (Ozbek, 2004). It represents housing units that achieve desirable indoor living conditions throughout varied seasons. The premise of the units' design lies on maintaining the vernacular language based not only on its space layout, usage and building form, prolonging the roots of the cultural lifestyle and traditions, but also on its architectural aesthetic that smoothly amalgamates with the existing surrounding.

In addition to preserving the vernacular's space layout and function, the bathroom and the bedroom spaces are compensated in the new proposal, all with either standard or high-level windows. Reiterating the transitional spaces, the New Hasankeyf proposal consists of terraces forming Revaks (semi-open spaces) below, which lead to a sheltered, private courtyard, in which comfort is enhanced with water elements and vegetation.

The varied façade treatment evident in materiality, scale and ornament application along with diverse opening sizes (15% on the lower level and 25% on the upper level) and ceiling heights (2.5m at the lower level and 5m at the upper level) visually contribute to the seasonally desired transition of the two levels: the linear patterned, local wood finish with smaller windows encapsulated with minimal, insulated, wood shutters on the lower level reflects the simplicity of the 'service areas' it encloses behind; whereas the elegant, local stone arrangement and the larger windows with ornate, insulated, wood shutters highlight the prestigious 'living areas' of the upper level.

The beneficial reconsideration from the vernacular example in the New Hasankeyf prototype is the secure extension of family life onto the flat rooftop enabled by the elaborate railing design, which, in addition to the terrace's, defines the perforated, horizontal framing of the building's overall façade.

CONCLUSION

The New Hasankeyf proposal depicts the pictogram of a vernacular ecology harmonized with the deeply rooted cultural texture of Hasankeyf in Southeastern Turkey. It presents an improved but closely paired to vernacular design that provides guidance for designers and builders who would partake in building dwellings for the soon-to-be-submerged city.

The proposed guidelines simply do not dwell upon a novel design; they instead focus on the 'recreation of the vernacular' with an enhanced environmental performance. It is nonetheless, acknowledged that the vernacular model faces constraints as passive design approaches are enforced. Considering this, design alterations to the vernacular model such as providing a glazed enclosure at terrace level to pre-heat the air to be supplied indoors and/or active systems would additionally need to be integrated to achieve full comfort.

All the unifying elements of the proposal are created to respond to the current family needs and environmental conditions for a building scale enhanced performance as discussed by (Yannas, 1994) along with finding a balance within the traditional composition of the area. It is through these considerations that the guidelines highlighted within this paper can be followed for a sustainable modern era adaptation of the new and soon-to-be emerging Hasankeyf dwellings.

ABSTRACT

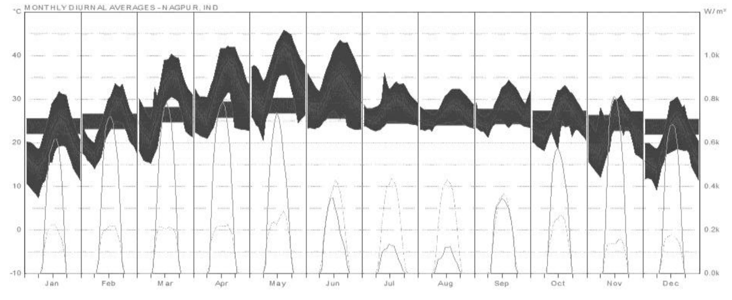
While designing a high-spec office complex for a multi-national organisation, the challenge lies in finding an integrated solution in terms of comfort and energy use while complying with the varying expectations due to the flexible nature of the users. The project was approached with the intention of creating an exemplar in environmental design with respect to naturally available resources, while minimizing site-disturbance. This would be achieved through an overall Net-Zero cycle of water, energy as well as an effort towards carbon neutrality. Façade efficiency encompasses both daylight and energy-use. The additional but vital criteria put forward by the client, for a 100% glare-free working space added to the challenge of optimizing fenestration design. The design process for the built-envelope therefore involved solar control, daylight distribution, glare control, and finally controlling heat loads from the built envelope by employing simple manual calculations based on principles of heat transfer.

1. INTRODUCTION

As a fast developing nation, India has seen rapid globalization in the recent past, and that is set to continue well into the near future. Consequently, the demand for smart office spaces with high specifications and all the latest modern construction techniques is booming. In a mainly warm-tropical climate such as India's, it implies an unnecessarily high dependence on external resources to operate optimally. The optimization of daylight and energy consumption is fundamental in building design and thus, pivotal in addressing the comfort aspirations of the users, where an equilibrium between visual and thermal comfort needs to be maintained. The contradictory objectives of maximizing daylight penetration and reducing glare are further compounded by the thermal implications of strong solar ingress. Drawing on lessons from the vernacular, solar protection strategies like façade shading and mutual shading prove to be an effective solution for warmer periods of the year. The opportunity of utilizing this solar ingress for thermal comfort is often encouraged during the cold season. However, the relatively low altitude of the sun during this period further complicates the task of achieving glare-free conditions. Being part of the global milieu whilst responding to the local context, is what this paper aims to highlight; a climate-responsive approach towards achieving thermally comfortable office design with primarily glare-free working conditions throughout the year in the challenging climate of Nagpur, India. The objective for the project was, *"to facilitate integration of solar-passive design principles with modern building design, and create an exemplar of an energy-efficient building."* The design process was simplified by reducing the time spent and dependency on analysis software at the concept stage, and instead relying on basic principles, using software to confirm the results (effect of) from the said calculations.

2. ANALYSING THE CLIMATE

The composite climate of Nagpur sees 18 weeks of hot-dry conditions with daytime temperatures often exceeding 30°C and reaching up to 45°C (Fig.1). During the next 14 weeks of the monsoon period (June-September), the city receives 1.07m of rainfall (annual average). The city experiences high humidity (60%-90%) and frequent precipitation together with daytime temperatures dropping below 35°C and remaining close to comfortable values (below 30°C) on an average. Climatic conditions, therefore, remain on the warmer side for most part of the year with a short period (6-8 weeks) of mild winters, with warm days and cool nights. The high intensity of incident solar radiation adds to the challenge of meeting the requirement for **100% glare free, 100% day-lit working conditions** with a maximum solar heat gain from the built-envelope being ≤ 1.0 W/ft^2 (of built-up area).



Typology	*: Corporate Office Complex*
Location	*: Nagpur,India (21.1°N,79.1°E)*
Status	*: In progress*
Site area	*: 142.18 acres*
Gross floor area	*: 73,327m^2/block (1,52,100m^2 total)*
Permissible FAR	*: 1.5 + 1*
Building height	*: 45m (12 floors)*
Building occupancy	*: 20,000 people*
Occupancy period	*: 9am-6pm*

3. MASTER-PLAN

The master-planning process began with a basic assessment of the carrying capacity for the site on a net-zero cycle of water. This was followed by addressing the energy demands for the targeted occupancy further leading to the planning and allocation of services/resources on site (Figure-2).

3.1 Carrying Capacity for Water Demand

The 142 acre site gradually slopes down towards an adjoining artificial water tank (Dahegaon tank) ending in a 32 acre low-lying zone at the junction (Fig.2b). Considering the conventional annual water consumption of 45.0lpcd (domestic, flushing, HVAC and irrigation) the site was found to be sufficient for supporting 20,000 persons. Additionally, a water reservoir of approximately 20 acres (at a depth of 3m) was calculated for the said rainfall collection (Table-1). This reservoir was placed in the low-lying section of the site - as a visual extension to the existing water-tank- to effectively collect the surface run-offs from the natural topography.

3.2. Carrying Capacity for Energy Demand:

Once the carrying capacity was established, the gross built-up area for the project was defined with a targeted density of 130sq.ft per person. Targeting an 80% improvement over the baseline energy consumption of 140kWh/m2/yr. as per GRIHA recommendations, the primary energy consumption was estimated at 25kWh/m2/yr. with 35kWh/m2/yr. being load from equipment. The reduction in primary energy load (lighting and HVAC loads) as governed by robust building design has been discussed in sections-4 and 5 while the corresponding equipment loads were reduced by employing efficient systems (Table-3). The annual energy consumption for the project was thus, targeted/calculated at 60kWh/m2/yr. Integrating renewable resources to offset the energy demand presented a requirement of a 36 acre solar farm (Table-2).

Table-1. Carrying Capacity on Water Demand Cycle

Rainwater Harvesting potential		
Site Area	5,75,361	sq.m.
Annual rainfall	1.07	m/yr.
Run off factor	0.5	
Total rainwater collected	3,07,250	cu.m. /yr
Rainwater Harvesting potential *@20% evaporative losses*	2,45,800	cu.m. /yr
Water Consumption per person *@45.0L/person /day*	11.7	cu.m./yr
Carrying Capacity	**21,009**	**~ 20,000**

Table-2. Carrying Capacity on Energy Demand

Renewable Energy Resources		
Carrying Capacity for people	20,000	ppl
Built-up area @ 130ft^2 per person	2,41,548	sq.m.
Target EPI (Building Loads)	25	kWh/m2/yr.
Occupancy Loads	35	kWh/m2/yr.
Estimated Annual Energy Consumption	60	kWh/m2/yr.
Total Annual energy consumption	1,44,92,888	kWh/yr.
Required installed capacity of solar PVs*	9,662	kWp
Area required for installing solar PVs**	1,44,929	sq.m.
Area required for installing solar PVs	**36**	**Acres**

Table-3. Energy Consumption Parameters

Parameters	**Conventional Load Density (W/sq.ft.)**	**Improved Case (W/sq.ft.)**
Lighting Load	1.5	0.3
HVAC Load	4.5	1.0
UPS & Server Load	2.5	0.7
Raw Power Load	0.5	0.2
Utility Load	0.5	0.2
PHE Load	0.5	0.1
Total	**10**	**2.5**

*Estimated average of 1500kWh energy is generated annually per 1kWp of installed capacity in the case of Nagpur, India.

**Installing 1kWp of solar plant requires 15 sq.m.of land area.

3.3. Carbon emissions:

Creating a natural renewal cycle of the estimated resource consumption by the project was an imperative for achieving the minimum possible site-disturbance. This included attention to carbon sequestration as a step towards attaining carbon neutrality. The average annual greenhouse gas (GHG) emission for the project was calculated as shown in Table-4. Sequestration of these emissions was planned through afforestation given the site area available for the project. ***It was concluded that 71acre tree cover was sufficient to offset the annual per capita carbon emissions for the occupants of the office.***

Table-4. Carbon/ Greenhouse Gas Sequestration

Average per capita emission in India	1.2	tCO_2/yr
Avg. CO2 emissions per year for 20,000 persons	**24,000**	**tCO_2/yr**
Avg. carbon absorption per tree	0.012	tCO_2/yr.
Total no. of trees required for complete sequestration *(as per United Nations Environment Programme,2008).*	96,000	(@ 4 trees/tCO2[1])
Required area under tree-cover	**2,88,000**	**(71acre)**
Annual sequestration	100%

3.4. Site-Planning

Preliminary planning based on principles of environmental design helped define zoning and resource allocation as illustrated in Figure-2. The water reservoir was designed as a lake, adjoining the existing water-tank in the low-lying area of the site. This facilitated effective rainwater collection from the surface run-offs mainly due to the sloping terrain. Moreover, the location of the lake was an opportunity for utilizing the South-South-West summer winds, enhancing the microclimate on site by evaporative cooling. Water canyons were designed along radial roads in the South-South-West direction to further enhance the cooling effect along pedestrian walkways. The 36-acre solar farm was placed towards the Southern part of the site for maximizing the available solar energy. The building-zone (26 acres) was seated overlooking the 'lake' to maximize on the benefits of evaporative cooling. The strategic location of the proposed building was further enhanced by views of the lake on one side while 60 acres of the 71 acre green cover was proposed for the remaining site area on the opposite side. The balance 11 acre green cover was planned to be integrated within the building zone. The building zone was further divided into 4 parts (5.5 acres each) based on the carrying capacity (5000 persons each), for optimally phasing the master-plan.

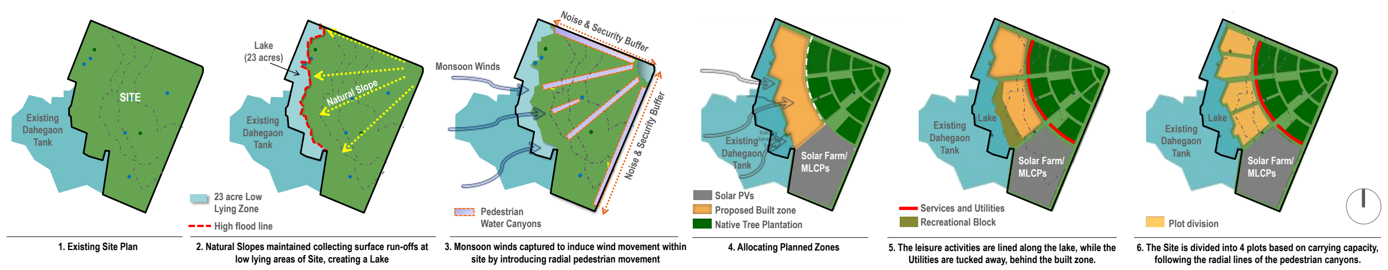

Figure 2. ***Site plan showing master-plan development for the project***

4. BUILT FORM

4.1 Floor-Plate Design

The design methodology for the built-form was formulated with visual comfort in the work-space as the priority. The basic environmental criteria of providing 100% day-lit working spaces governed the design for the typical floor-plate. Based on the principle that the extent of daylight penetration in a building floor plate is 2 times the height from the floor to top of the window, the ideal depth of the floor plate with a 4m height was limited to 16m. The programme brief specified a requirement for 90 workstations and corresponding facilities for a single module. This module was optimised around a core shared by 2 modules, such that common facilities are accessible by all 180 employees. Moreover, building regulations for accessible fire-escapes limited the maximum length of the floor plate to 100m (max. distance between 2 staircases must not exceed 90m).

In order to accommodate the required 180 workstations with peripheral circulation, the width of the floor-plate needed to be increased from 16m to 18m (Fig.3a). This decision gave rise to the challenge of increasing the daylight penetration inside the space. The consequent steps undertaken to achieve 100% day lit work-spaces have been discussed in the following section. The final design for the typical floor-plate was developed with an efficiency of < 100 ft^2/ person (Fig.4b).

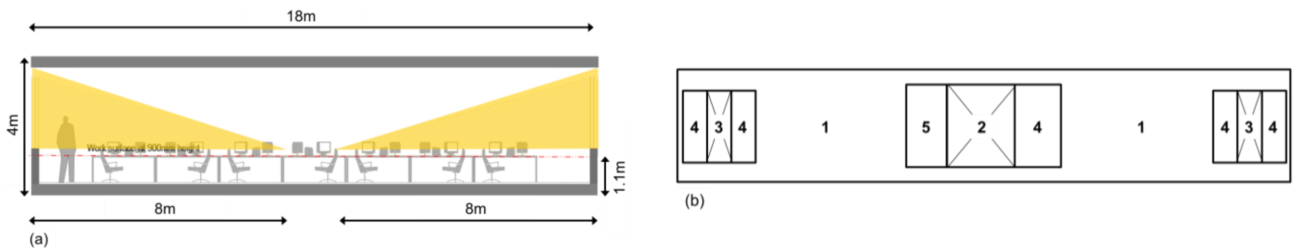

Figure 3*(a) Daylight penetration in the typical module (b) Typical Floor-plate resulting from design brief and preliminary daylight thumb-rules: 1. Workstations (90x2), 2. Main service core, 3.Fire-escape, 4.Meeting Rooms, 5.Facilities*

4.2 Morphology

The orientation of the building was determined based on the sun-path diagram as explained in Fig. 4. Due to the location of the site at 21.15ºN 79.09ºE, a pure N-S orientation is vulnerable to both the morning as well as evening sun of an azimuth angle of up to 21.15°. However, rotating the building by a similar angle (on either side) naturally results in obstructing the solar azimuth for at least half the day. This meant that the solar control devices could now be designed for single sided protection, also simplifying the architectural implications. Finally, it was concluded that ***for the given location orienting the plan at 22.5° reduced the shading requirement on either façades.***

The founding stratum of soil on-site was primarily a Basalt Stone and would not permit high structural settlements and the allowable bearing pressures were expected to be high. A maximum of 10 to 12 storey structures were possible in accordance with the maximum permissible height, which was also restricted by laws regarding aviation caps in the area. Furthermore, the architectural intention was to break the tower down to a more *human-scale*, bringing the users closer to the level of the landscape and creating a relationship with the outdoor environment. The building was thus, divided into 3 blocks of 4 floors each. Here, the 4 floors were stacked on each other forming a tube with a capacity of 720 employees. These modules were then staggered at 22.5° either ways and at 45° overall, mutually shading each other, and as a result, creating 'new-ground' or break-out spaces as shown in (Fig.5). The stacked tubes were further multiplied (total 8 blocks) to accommodate a total of 5000 persons. Various cases for interlocking these modules were explored in order to determine the most robust morphology for the complex (Fig.6). The objective was to design for flexibility in the configurations in terms of future expansion of the complex while maintaining the self-sufficient character of the blocks. The resulting morphology was a network of shaded courtyards and open terraces. (Fig.7)

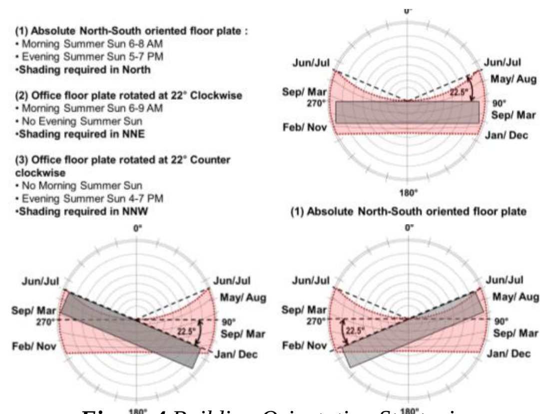

Figure 4 *Building Orientation Strategies*

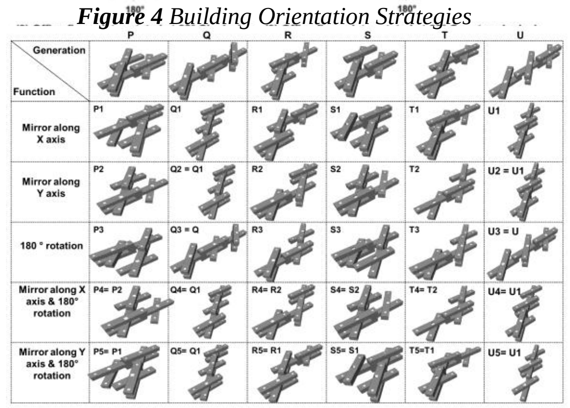

Figure 6 *Exploring potential configurations for the 8 blocks*

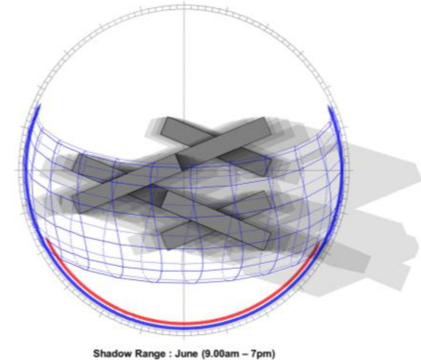

Figure 7 *Overall massing*

5. PERFORMANCE INDICATORS

The process of integrated daylight and thermal performance evaluation also addresses glare as an integral parameter for visual comfort. The design of the built envelope was, therefore, governed by the following parameters:

- ***Solar Control:*** Manual calculations, Ecotect analysis
- ***Glare***: Ecotect analysis
- ***Distribution of Daylight***: Ecotect, Radiance analysis
- ***Heat Loads***: Manual calculations

Devising a method of simple manual calculations (on a Microsoft Excel spreadsheet) allowed for simultaneous cross-checking of the thermal implications of each step taken while designing the fenestrations.

5.2. Solar Control

Solar shading design for a typical opening on each of the four orientations (NNW-SSE and NNE-SSW) was carried out. The basic window size was taken as 2.4m x 2.1m with sill level of 1.1m. The first step involved identifying the critical angles [2] to be shaded during the occupied period of the day i.e., 9am to 6pm. These angles helped define the optimum shading angle and therefore the depth of shade required. Designing for angled louvers was discouraged for this context, to avoid obstructing the pleasant views overlooking the landscaped surroundings. It is important to highlight that in north facing windows, the direct solar ingress is due to the summer sun i.e., when the altitude as well as the azimuth are relatively higher. Thus***, the shading for north-facing windows was designed for the Summer Solstice (21st June) where the azimuth angles were critical***. Figure 8(a) represents the shading design process for a typical window facing North, North-East. It was concluded that 422mm deep vertical fins spaced at 600mm c/c could be adopted for North, North-East orientation as this solution helped maintain views across the entire height of the window while effectively shading the morning sun.

Following the same methodology 600mm wide fins spaced at an overall 600mm c/c proved to be optimum for North, North-West facing windows. For reasons of architectural economy, it was decided that the depth of the vertical fins should be uniform for both northern orientations (NNE, NNW) i.e., 600mm deep fins with 600mm c/c spacing.

Solar controls for south facades were designed considering 21st December (winter solstice) for peak design parameters because the sun drops down to the lowest altitude levels (0.6° at 5.30pm). Here, the solar altitude was identified as the critical angle. It is important to highlight that Nagpur tends to see mostly clear sunny skies and so the tendency of experiencing glare is quite high. The need for shading the low winter sun in addition to the summer sun was a challenge arising due to the target set for the project to achieve 100% glare-free working conditions. ***Direct visibility of the sky from a user's level (1.25m) and glare-causing sun patches from the upper part of the window were therefore a key concern.*** A solution for this was to obstruct the bright sky view from the upper end of the window.

Consequently, the window was divided in 2 equal parts-

- **Daylight Window at 2.1m**: Frosted in order to diffuse possible glare patches
- **Vision Window at sill level of 1.1m**: 50% visible light transmission (clear)

In the case of south facing windows, (Fig.8c,d), both the SSW, SSE windows tend to get direct solar radiation the entire day from 9am to 5.30 pm (sunset). Also, the altitude drops significantly after 4pm and goes as low as 0.6° at 5.30pm on the 21st of December (extreme case) making shading at this angle highly impractical.

While designing for the South, South-East windows (fig.8c), it was observed that vertical fins of depth and spacing of 600mm were effective for obstructing the sun after 11am till 5.30pm. Horizontal overhangs were explored for providing shade for the remaining morning period. A combination of both horizontal and vertical projections was therefore, required to shade the opening up till 11 am. Furthermore, distancing the workstation at 1.5m from the glazing and the partition facing this corridor was designed as an effective obstruction for the 9am sun as a strategy to provide shade without making the shading projections too deep. The role of the shading devices was reversed for the south, south-west window where the vertical fins were now effective from 9am to 11am and overhang helped distance the direct sun from the workstation (Fig.8d). The workstation design comes into play up till 4pm. This protected the worktop without compromising on the visual comfort of the user. However, it was observed that beyond 4:15pm the intensity of solar radiation is not high enough to cause glare and may be acceptable in the current scenario. ***The resultant shading device is a system of fixed horizontal and vertical shading fins varying with the solar exposure of the windows.*** Figure-9 represents the shading effect of the solar control devices.

4.3. Daylight Distribution and Glare Control

Due to high frequency of bright skies, the average illuminance was expected to be above acceptable limits. However, optimizing the distribution of this daylight within the floor-plate (18m depth) needed to be investigated. Also, dividing the window in 2 parts, with half the total opening being frosted, was bound to further affect the daylight penetration inside the building. Internal light shelves were therefore explored as an effective strategy for this condition and were integrated with a 600mm depth at 2500mm height. South facing windows suffer from direct solar radiation for most part of the day. Despite frosting the daylight panel, the high levels of external illuminance could lead to the panel itself becoming extremely bright. This aspect was countered through light shelves at 2500mm which obstructed the direct view of the daylight panel from the occupant's seated level. Additionally, a comparison of the insolation on the various orientations influenced the decision to reduce the overall window area on the southern facades. This was done by introducing a solid band (insulated) of 400mm below the light shelf, reducing the area of the daylight panel. The resultant was a z-section with the light shelves at 2500mm, external overhang at 2100mm and a 400mm wide solid band in between (Fig.10a). For northern orientations, the daylight available is diffused and therefore, glare-free. This fact was exploited by the addition of internal light shelves on the northern facades which were expected to increase daylight distribution inside the workspace. Further extending the light shelves by another 600mm towards the outside led to a significant improvement in the ... the ... e elevational elements (as the south windows) and at ... olved compliance with LEED 2011NC criteria ... ***of 10 foot candles (fc) (110lux) to a max*** ... ***on September 21st at 0900 and 1500 hour*** ... cal unobstructed floorplate oriented NNE|SS ... Figure 11*. Designing solar control for fenestrations*

5.4. Thermal Efficiency

The cumulative solar heat gains (W/m^2) of the designed façades, resulting typical module and complete building were calculated to assess the overall thermal efficiency of the envelope**. *The maximum solar load from the building envelope was targeted at ≤1.0W/ft^2 with an intention to achieve the lowest possible value without compromising on the design principles for the project.*** The formulae and methodology adopted were based on heat transfer principles for opaque and transparent building elements (Table-5) as advised by the Energy Conservation Building Code-2007. Figure-12 illustrates the methodology followed to calculate the thermal efficiency of the building. The key parameters were identified as:

- Window: Wall Ratio (designed at 22.5%)
- U-values of fabric (Walls, Slabs, Glazing)
- Effective Solar Heat Gain Coefficient of Glazed Elements

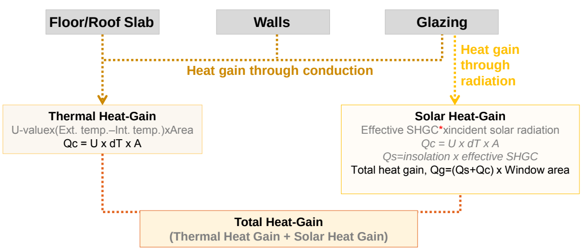

Figure 12. *Methodology to calculate cumulative heat gains*

Table-5 Thermal Properties of Building Elements

Orientation	U-value (W/m^{2}k)	Effective SHGC
Roof Slab	0.317	-
Walls	0.345	-
Daylight Panel-SSW	1.040	0.15
Vision Panel-SSW	1.040	0.03
Daylight Panel-NNE	1.040	0.14
Vision Panel-NNE	1.040	0.13

The heat gain process through opaque elements like walls and slabs of a building mainly comprises heat gain through conduction. Transparent building elements, on the other hand, have higher vulnerability to heat gain through solar radiation in addition to conductive heat gain. Heat gain from solar radiation is based on the solar heat gain factor (SHGC) of the glass which, in turn, depends on the specifications of the glass and on the angle of incidence. Owing to the solar shading design, the effective SHGC in this case was much lower than the maximum SHGC which played a significant role in reducing the overall heat gain from incident solar radiation. ***Finally, the solar heat gain for the entire building was calculated and resulted in an overall thermal efficiency of 0.79W/sq.ft.***

Figure 13. *Resulting Design of the Office Complex (Nagpur, India)*

5. CONCLUSION

This paper presents the process followed to achieve a holistic solution for efficient climate sensitive design of an office complex for composite climatic conditions. Sound integration and planning of the renewable resources available on site helped achieve a Net-Zero cycle of energy and water consumption. The conscious decision to restrict the buildable zone allowed for ample tree cover for natural sequestration of carbon emissions during the life cycle of the building. Orienting the building along the North-South axis at 22.5° either ways significantly reduced solar exposure. Efficient solar control design helped achieve a 100% glare-free and fully day-lit working environment with a minimal WWR of 22.5%. A robust building envelope was created by further pushing the thermal performance of the fabric to achieve thermal efficiency well below the 1.0W/ft^2 mark. The success of the entire process is clearly demonstrated by the fact that all the pre-requisites for the project were met within respectable limits, coming together in an architecturally relevant design.

ABSTR ACT HEADING

This study quantified the impact of morphological variation on the heating and cooling energy consumption in buildings. Using the eQuest simulation program, a series of parametric simulations was conducted to derive the amount of heating and cooling energy consumptions for the numbers of floors, floor areas, and space volumes. Numerical tests were performed in a typical two-story single-family residential building located in the two different climate zones in the USA – the hot/humid and cold regions. Analysis revealed that the amount of heating energy in the cold climate was the most significant component in buildings: thus, an energy-efficient heating system and energy-conscious operation needs to be considered for saving energy. In addition, the amounts of heating and cooling energy were all proportional to the building's number of floors, floor area, and volume of space. Therefore, the building is required to be planned based on the morphological impact on the building energy efficiency.

INTRODUCTION

The survey results conducted by the Ministry of Knowledge Economy of South Korea in 2009 indicated that almost quarter of the annually consumed energy in Korea was used in buildings (22.3%). Among this amount, 51.0% was used by residential buildings. In addition, 63% of the energy in residential buildings was consumed by single-family houses and 37.0% was used by multi-unit dwellings. Thus, single-family houses and multi-unit dwellings respectively accounted for 7.2% (=0.223*0.51*0.63*100) and 4.2% (=0.223*0.51*0.37*100) of the total national annual energy consumption. The heating and cooling systems consumed 58.1% of the total energy used in residential buildings. Therefore, it can be inferred that 6.6% (=(7.2+4.2)*0.581) of the total national energy was consumed for heating and cooling in residential buildings (Moon, 2011a; Ministry of Knowledge Economy, 2009; Lee, 2006).

Numerous researches have been conducted regarding energy-efficient building thermal-control theories, systems and control technologies. The reinforced insulation level of building envelope was proved to be one of the most significant determinants for increasing building energy efficiency (Kim & Moon, 2009; Moon, Han, & Oh, 2011; Moon, 2011a), and the optimal controlled ventilation and infiltration was able to improve heating and cooling efficiency as well as to comfortably condition the indoor air quality (Moon, 2011b). In addition, the optimal control strategies for operating thermal-control systems have been widely investigated using state of the art control theories such as artificial intelligence (Moon & et al. 2014; Moon & Han, 2012; Moon, 2012; Moon & Kim, 2010). In particular, Kim has conducted a research on the relationship between the width-to-depth ratio (W/D), the surface-

to-volume ratio (S/V) and on the heating and cooling loads, in which heating and cooling loads were proportional to the W/D and S/V (Kim, 2013).

Energy savings and CO2 productions by the building is expected to be remarkably impacted by the building configuration. This study, thus, aimed to investigate the quantitative impact of morphological building variation on the amount of energy consumption for thermal conditioning. In order to accomplish the research objectives, the energy consumption pattern according to the changes in the number of floors, floor area, and space volume was analyzed for a single family house located in two different climate regions (cold climate: Detroit, Michigan, USA; hot and humid climate: Miami, Florida, USA). The numerical simulation method was applied for the tests and the findings of this study will be used as sound fundamentals for planning the energy-efficient and environment-friendly residential buildings.

RESEARCH METHODS

For calculating energy consumption by the morphological changes of building, a test building was modeled **as shown in Figure 1**, which has the typical features of a U.S. single-family house (U.S. Census Bureau, 2005). It is a two-story, south-facing, flat-roof building installed windows without shading devices and doors. An identical building was employed for the tests in two different climatic regions: hot/humid climate (Miami, Florida, USA) and cold climate (Detroit, Michigan, USA). The climatic conditions of Seoul, South Korea and of the two U.S. cities are **summarized in Table 1**. As Seoul, South Korea shows similar climatic conditions with Detroit, Michigan, USA, the outcomes for the cold climate will be more applicable to understand the Korean conditions.

The heat transfer coefficients of walls, roof, floor, windows and doors were 0.31, 0.16, 0.24, 1.64, and 2.00 W/m^2K, respectively, which were lower value than standards for both Miami, Florida and Detroit, Michigan. Window-wall-ratio of envelopes was 0.15 in average with 0.20 for south, 0.10 for north, 0.15 for east and west. In addition, 0.30 ACH (air change per hour) was applied for ventilation and infiltration rate (Haysom & Reardon, 1998). As internal heat gains, four people and their hourly weighted heat and moisture gains (ASHRAE, 2004a; McArthur 2004), lighting fixtures with 5.38 W/m^2 for living area, 12.8 W/m^2 for storage, 13.8 W/m^2 for laundry, and miscellaneous with 3.2 W/m^2 for living area and 1.6 W/m^2 for laundry were applied.

For space heating and cooling, a furnace (26.70 KW for Miami, Florida; 31.67 KW for Detroit, Michigan) and DX colis (16.55 KW for Miami, Florida; 14.06 KW for Detroit, Michigan) were installed considering the normal and setback periods for energy saving based on the occupancy schedule. The set point temperatures in the normal and setback periods were 22.22°C (72.0°F) and 15.56°C (60°F), respectively, for the heating system, and 25.56°C (78°F) and 27.78°C (82°F) for the cooling system. The normal and setback periods were different among weekdays, Saturdays, and Sundays and holidays **as shown in Table 2**.

The eQuest3.63 numerical simulation tool, which is an acronym of the quick energy simulation tool and was based on the DOE-2.2 of by the U.S. Department of Energy (DOE) and Lawrence Berkeley National Laboratory, was applied for calculating the annual heating and cooling load and the energy consumptions according to the morphological building changes (eQuest, 2009). The validity of this program for further simulation has been confirmed in the previous studies (Kim & Moon, 2009; Moon & Han, 2011; Moon, Han, & Oh, 2011; Moon, 2011a; Moon, 2011b). The test period was the year 2012, and the TMY2 weather data were employed for the hot/humid and cold climates.

The test variable for analysing the energy consumption patterns were number of floors, the floor area, and the volume of space as **summarized in Table 3-5**. The basecase of the first variable was a two-story building **as given in Table 3**. Based on the base case, one- and three-story buildings were comparatively simulated. The total floor areas of three cases were identical while the areas of the walls, floor, and roof were changed. For example, compared to the basecse, the three-story building had a larger wall area but significantly smaller floor and roof areas while the one-story building had a reduced wall area but increased floor and roof areas.

The basecase of the second variable was a building with 224.5 m^2 (2,400 ft^2) floor area **as given in Table 4**. With the basecase, five variations for the building area by the changes in width and depth were tested. No changes in the number of floors and in the building height were considered.

The basecase of the third variable was a building with a volume of space 303.0 m^3 (21,600.0 ft^3) and five variable cases based on the change in building height were tested **as given in Table5**. The other components such as buiding width, depth, and number of floors were not changed from the basecase.

RESULT & ANALYSIS

Annual Heating and Coolin g Loads

The annual heating and cooling loads were presented **in Figure 2**. In the hot/humid climate region, the cooling load (43,284 KWh) has taken most of the load (43,447 KWh). The heating load was just 164 KWh. On the other hand, the heating load (10,041 KWh) was significantly larger than the cooling load (1,910 KWh) in the cold climate region.

The total amount of heating and cooling loads was 4.3 times larger in the hot/humid climate compared to that in the cold climate. This is mainly due to the significantly larger cooling load in the hot/humid region. However, the total amount of annual heating and cooling energy will not differ as was the loads since the efficiency of the cooling system is normally higher than that of the heating system. That is, the increased heating load is directly proportional to the increased heating energy in the cold-climate region while the increased cooling load is relatively less effective for the increased cooling energy in the hot/humid-climate region.

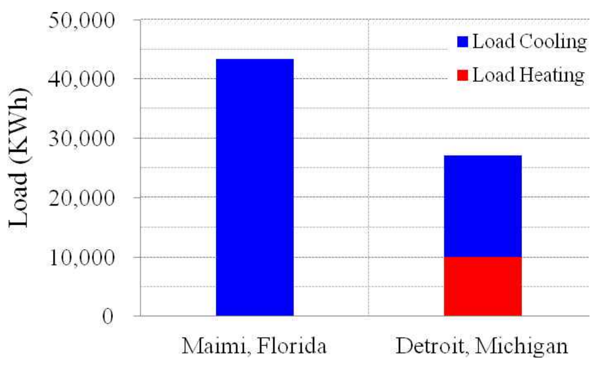

Figure 2 Annual heating and cooling loads for two climate regions.

Amount of Heating and Cooling Energy Consumption According to the Morphological Variations

Number of Floors. The energy consumption pattern for different number of floors is compared **in Figure 3**. The amount of heating and cooling energy increased as the number of floors increased. This is due to the fact that as the number of floors increased, the roof and floor surface area, which had relatively smaller heat transfer coefficients, decreased while the wall area, which had a larger heat transfer coefficient, increased. The increasing ratio was 92.26 KWh/floor for heating and 1,010

KWh/floor for cooling in the hot/humid climate region. Compared to the basecase, which is two-story building, the one-story building saved 7.8% and 9.5% of heating and heating energy, respectively. On the other hand, the three-story building comsumed 8.3% and 18.0% more energy for heating and cooling.

Identical to the hot/humid climate region, the amount of heating and cooling energy increase when the number of floors increased in cold climate region. Their amounts reached as much as 1,364.8 KWh/floor and 340.0 KWh/floor for heating and cooling energy, respectively. Compared to the base case, the one-story building saved 20.4% and 1.37% energy for heating and cooling while the three-story building used 15.2% and 5.8% more energy for heating and cooling. This analysis indicates that the low-rise building can be more energy efficient for a buiding with same area.

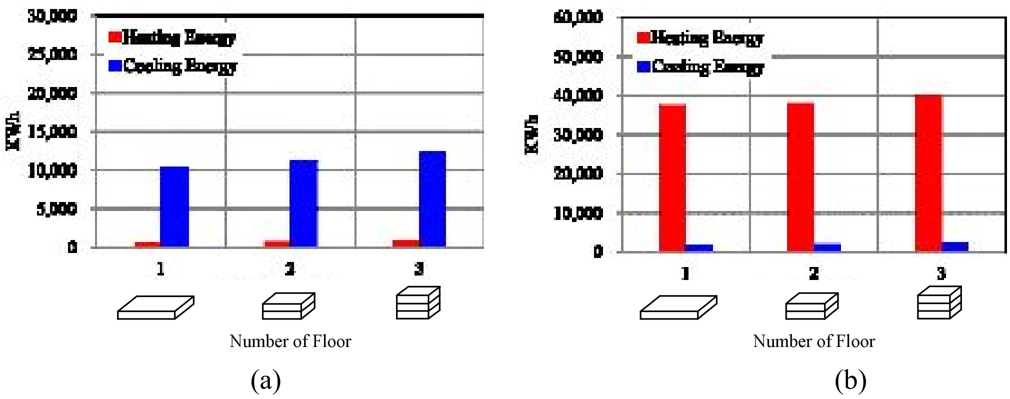

Figure 3 Amount of heating and cooling energy by different building floor: (a) Miami, Florida, USA, (b) Detroit, Michigan, USA.

Floor Area. The energy consumption for the change of floor area is shown **in Figure 4**. The cooling energy significantly increased in the hot/humid-climate region as much as 41.83 KWh/m^2 while that of heating energy was 1.73 KWh/m^2. The case of the smallest building area saved 27.0% heating energy and 52.1% cooling energy. On the other hand, the case of the largest building area has comsumed more energy by 40.2% for heating and by 50.5% for cooling. However, the amount of energy consumption per floor area was reduced as the floor area was increased. For example, the heating and cooling energy consumption was respectively 5.6 KWh/m^2 and 58.2 KWh/m^2 for the smallest building while those of the largest building were 2.7 KWh/m^2 and 45.94 KWh/m^2.

Similarly in the cold climate region, more heating and cooling consumed as the floor area increased. The increase ratio was 124.71 KWh/m^2 for heating and 6.61 KWh/m^2 for cooling. Compared to the base case, the smallest building saved 50.4% and 43.5% of heating and cooling energy, respectively while the largest building consumed 45.5% and 47.6% more energy for heating and cooling. However, similar to the hot/humid region, the amount of heating and cooling energy per floor area was decreased for the larger building. 230.21 KWh/m^2 and 10.17 KWh/m^2 were used in the smallest building while 151.25 KWh/m^2 and 7.50 KWh/m^2 were consumed in the largest building. Based on the analysis for the change of floor area, it can be concluded that the properly planned building area can be beneficial to improve building energy performance.

Volume of Space. Figure 5 compares the amount of heating and cooling energy for the change of space volume. Voluminal change was more related to the cooling energy increase in the hot/humid climate region as much as 14.6 KWh/m^3. The amount of heating energy increase was 0.94 KWh/m^3. Compared to the base case, the least-volume buiding saved 4.9% of heating energy and 4.5% of cooling energy while the largest-volume building used more energy as much as 14.0% for heating and 14.8% for cooling.

In the cold-climate region, the heating energy increase ratio was far more significant (37.7 KWh/m^3) than that of the cooling energy (3.77 KWh/m^3). In addition, the increase ratios were more significant than that in the hot/humid climate region. Compared to the basecase, changes in the heating and cooling energy for the least- and largest-volume buildings were 7.3% and 3.6% reductions and 21.5% and 10.9% increases, respectively.

However, similar to the analysis result for the floor area, the amount of heating and cooling energy consumption per space volume was reduced as the largest-volume building was applied. The amount of heating and cooling energy per spaced volume for the least-volume building was 2.53 KWh/m^3 and 39.94 KWh/m^3 for the hot/humid region and 135.91 KWh/m^3 and 6.57 KWh/m^3 for the cold region. Those of largest-volume building were reduced to 1.97 KWh/m^3 and 31.04 KWh/m^3 for the hot/humid region and 101.40 KWh/m^3 and 5.59 KWh/m^3 for the cold region.

IMPLICATIONS & CONCLUSIONS

The objective of this study was to investigate the energy consumption pattern by the morphological variation of buildings. For this, typical U.S. single-family houses with different number of floors, floor area, and volume of space were numerically modeled and comparatively tested for two climatic regions; hot/humid climate and cold climate. Below is a summary of the study findings.

(1) The cooling load was larger than the heating load in the hot/humid climate region while the heating load was larger than the cooling load in the cold climate region. The total amount of heating and cooling loads was 4.3 times larger in the hot/humid climate compared to that in the cold climate.

(2) The amount of energy used for heating and cooling increased along with the number of floors since as the number of floors increased, the roof and floor surfaces having lower heat transfer coefficients became smaller while the wall area having a higher heat transfer coefficient became larger.

(3) The heating and cooling energy increased as the floor area became larger. In particular, the cooling energy used in the hot/humid climate region and the heating energy used in the cold climate region predominantly increased.

(4) The amount of energy used for thermal conditioning was found to be proportional to the volume of a building. Identical to the change in the floor area, the cooling energy used in the hot/humid climate region and the heating energy used in the cold climate region remarkably increased. The increase ratio was larger in the cold climate region.

(5) The amount of energy per area or volume was reduced as the larger buiding was applied in both climate regions.

From the analysis, it can be concluded that the morphological variation in residential buildings has a direct impact on the amount of energy consumption for building thermal conditioning, and based on the findings, proper planning of floor numbers, size and volume need to be considered to advance the building energy efficiency. This study was conducted in only two cities in the U.S.; thus, performance tests for cities with other diverse climatic conditions and for Korean cities are warranted in the futher studies. In addition, data analysis is required for the actual results from existing buildings.

ABSTRACT HEADING

Europe of the beginning of the 20th Century: the desire to break away from the past and transform domestic spaces following the modern movement was clear. But there was a part of this production which sought to project the dwelling space based on traditional ideas. There are attributes of vernacular architecture, will be considered in the production of this time.

In this context we gave the focus of the study, looking at the veranda within the domestic environment of modern architecture in Brazil.

The veranda, as an intermediary space, was present in distinct eras of Brazilian housing, and together with this transformed itself of form, use and meaning.

The proposal of this investigation is to study the veranda as an architectural element, intermediary space and domestic living area, with the intention of identifying the distinct interpretations, from the formal and the principal elements from an environmental point of view. The analyses also look in which the domestic environment was incorporated into modern architectural production.

The second part of this investigation deals with the object of the study: the veranda as an intermediary space. This is undertaken by the presentation and analysis of case studies selected to represent the distinct compositional resolutions of the intermediary space in the modernism period (1930-1965).This study cases were also redraw, using digital tools which simulate incident solar radiation, thermal and lighting analysis. This helped to identify the solutions related to the comfort thermal and luminous of internal areas and observe the veranda as a step between interior and exterior, always considering different environments in this context.

INTRODUCTION

The Europe of the early twentieth century presented a panorama of major changes in different areas of life and knowledge, especially when it came to scientific and technological advances that eventually influenced, by new theories and concepts, the artistic production.

Clarissa Pereira is a professor in the Department of Architecture, Unifra, Santa Maria, Rio Grande do Sul, Brasil. Underlea Bruscato is a profesor in the Department of Graphic Expression, UFRGS, Porto Alegre, Rio Grande do Sul, Brazil. Arnau Muñoz is a research fellow at Q_ARTS arquitetura, Santa Maria, Rio Grande do Sul, Brazil.

Among other issues, modernity sought to change the way of think and project dwelling space, which in this research will be discussed from the point of view of the intermediary space of the veranda. At the same time, Brazil was looking to find their own ways in the artistic and architectural production.

Although it was clear the desire to break with the past and transform the domestic space guided by the ideals of the modern movement, there was a part of this production that wanted to design and build the living space based in tradition. There are a number of attributes of vernacular architecture, which will be taken into account in the architecture of this time.

BASIC TYPES AND VARIATIONS

Separate by typologies the intermediary space conformed by the veranda was appropriate from the beginning, when reduce to one type the complexities of an arquitectonic object it is not perceived yet.

That is why the expression compositional resolution appears as a synonym for explaining these works, considering not only the intermediary space but other transition spaces from the home environment.

For this research, it was necessary to establish a selection criterion that could better represent each study case. Examples are sought in the major mass media of the time, looking at the theoretical and practical production of architects considering its importance for Brazilian architecture in this context. With this, it was proposed to look at these selected houses, from the point of view of the intermediary spaces.

Nine modern houses made between 1930-1965 are chosen to represent each compositional resolution

After an initial reading and considering the before mentioned methodology, five basic formal design structures for the veranda in the contexto are established:

1- Veranda by Horizontal Plane extension

2 Veranda by Horizontal / Vertical Plane extension

3 Veranda by Subtraction

4 Veranda by Addition

5- Veranda by Pilotis

Identify and synthesize into five basic types allow us to separate case studies by groups of similar formal structures (with its variations).

With this, an understanding of the works is done, not only analyzing its formal qualities, but also the relations between the interior and the exterior, the permeability between these two environments and consequently the privacy levels.

Classify the works by typologies also help to identify when the veranda is designed with reference to tradition and (or) when is innovation.

At first, a look at the vast repertoire of modernity is done to find examples that accurately approach to the compositional resolution in its most essential form (or that could be "conceptually reduce" to one type). From this idea, the Mendes House by architect Oscar Niemeyer and Spartacus Vial by David Libeskind were selected to represent the way to design the veranda in their respective type.

On this same reflection, Osmar Gonçalves House by Oswaldo C. Gonçalves is chosen because of its formal simplicity and clarity to identify separately the volume of the main house ant the intermediary space.

Guilherme Brandi House was a little different, because there were other houses that might better represent the idea of typology by extension of the horizontal and vertical plane. But although the house has a simple volume, some items such as the facade composition, awaked some curiosity to study. Another reason for study this Sergio Bernardes house would be the variety of how this architect works the intermediary space in the domestic architecture.

It was slightly different the decision to choose Beira Mar residence. Being the typology that is closer to the traditional architecture (and this has never ceased to be part of the modern repertoire), traces of modernity in both function and formal composition were sought to find in the examples. This work of Oswaldo Bratke was the most appropiate to represent the compositional resolution of the veranda, from a floping extension of the roof.

Trying to approximate (reduce) to one type, I realized that there were other reasons that led us to study these spaces, and is fot that, that other reasons were considered appropriate for the selection.

To represent the compositional resolution identified as horizontal plane extension, an easy reading was pretended. But looking at some Oscar Niemeyer works (both Canoas house and Dalva Simão house and another house build much later in France following the same concept), a different way to conform the intermediary space from the prolongation of the curved roof is perceived: the curve that characterizes the Brazilian architecture should be contempled here.

Other reasons that led me to define the election were the different purposes of the veranda in the same house, like in Saavedra House, besides being clearly appropriate to represent the space generated through the inverted roof.

Magalhães Gouveia House would be the example more difficult to fit in a typology, but because of being a unusual roof design for the time (and that it is a proper addition) was choosed to do the analysis under this point of view.

Finally, we have the well known Carmen Portinho house by Reidy, for the way the architect incorpores (later) the veranda in the space liberated by the pilotis (without having the original function of pilotis).

STUDY CASES

In recent years, we have witnessed a technological revolution. The architecture is also a reflection of this situation, since there are new tools that have changed the way we work. Creation possibilities have increased, as well as accuracy. These new tools give new possibilities that allow more experimentation through simulation.

Using Ecotect software, we intend to analyze the works considered as representative of the different typologies for the varanda, pretending to find some answers related to both thermal and lighting, from the viewpoint of the presence of the intermediary space.

The analysis will be divided into five main points:

a) Shadow analysis

In this analysis we will proceed to simulate the cast shadow by the intermediary space in itself and the adjacent room. With this analysis, it is intended to reach some conclusions as to verify if the situation of the veranda is determined by the solar orientation or because of terrain conditions.

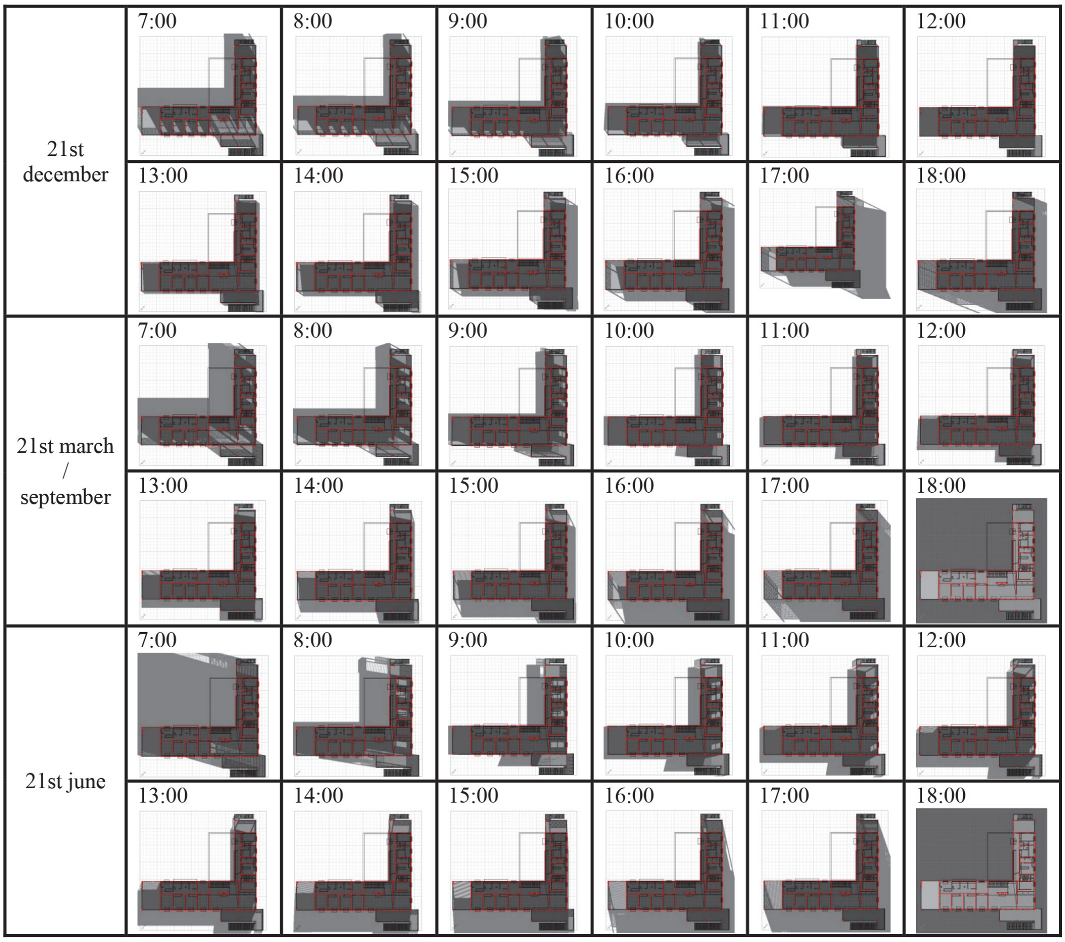

Figure 1. Saavedra house veranda shadow analysis

This house has 3 verandas (1-SO 2-SE, 3-NO). Each receives direct sunlight at different horaries due to its orientation, so each one can be enjoyed at its moment.

Dalva Simão house – The north facade is the only one that is connected to the exterior through big openings and it only recieves direct sunlight during the winter, while in summer the roof extensión that conform the veranda protects the interior from the direct sun.

Guilherme Brandi house - Receive the solar incidence relatively constant throughout the whole year, during the afternoon.

Mendes house - Receive morning sun, and is during the summer the highest exposure.

Osmar Gonçalves house – Incidence druing the afternoon but the presence of the protection makes the veranda suitable to use.

Carmen Portinho House- The internal veranda recieves the sun in the afternoon, and is in winter when the exposure is lower, while the external veranda (pilotis), that has the same orientation, receives direct sunlight in the early hours of the day too.

b) Solar radiaton analysis

It will proceed to calculate the solar radiation in the intermediary space and the contiguous room, in the four year seasons between 7:00 and 18:00, expressed as average daily values. With these results we try to see the influence of the varanda on the adjacent rooms and its solar radiation.

SOLAR RADIATION ANALYSIS					
House		Spring	Summer	Autumn	Winter
Dalva Simão		1134,23	1208,46	1233,63	1284,64
Casa Saavedra	1	1203,65	1286,4	828,5	841,99
	2	1044,13	1107,22	768,36	771,28
	3	1305,15	1429,07	1382,26	1382,49
Guilherme Brandi		691,9	734,07	395,96	415,64
Casa Mendes		1193,78	1270,92	775,97	812,73
Osmar Gonçalves		626,9	984,36	573,29	564,17
Carmen Portinho	Interior	908,97	952,67	561,18	527,12
	Pilotis	1134,23	1208,46	1233,63	1284,64

Figure 2. Solar radiation table results

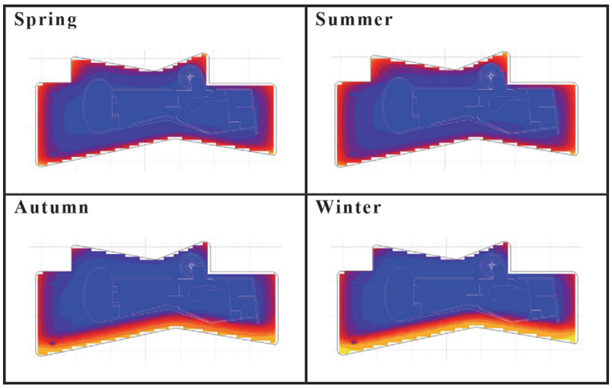

Figure 3. Dalva Simão solar radiation

We can observe that all of the houses receive more solar radiation during the spring and summer, except Dalva Simão house, that is because its orientation and roof design that makes autumn and winter when the higher levels of solar radiation (as we can see in the figure above).

c) Daylighting analysis

For the calculation of daylighting factors the Ecotect uses a geometric version of the Split Flux Method (BRE) and Design Sky values that are derived from a statistical analysis of outdoor illuminance levels. They offer a worst-case scenario that you can design to and be sure your building will meet the desired light levels at least 85% of the time.

This simulation will be made at 0,75m from the ground level, to see if the adjacent room to the veranda achieves the lighting levels established by the brasilian standard NB-57.

DAYLIGHT ANALYSIS		
House		Lux
Dalva Simão		363,45
Casa Saavedra	1	369,33
	2	377,82
	3	298,59
Guilherme Brandi		338,57
Casa Mendes		215,89
Osmar Gonçalves		190,76
Carmen Portinho	Interior	362,26

Figure 4. Daylight levels table results

All of the residences achieve good levels of daylighting, making them suitable even for reading, except Osmar Gonçalves house, and Mendes house, because of the protection.

d) Sun incidence on facade analysis

With this analysis we try to see when the façade under the veranda receive the direct sun.

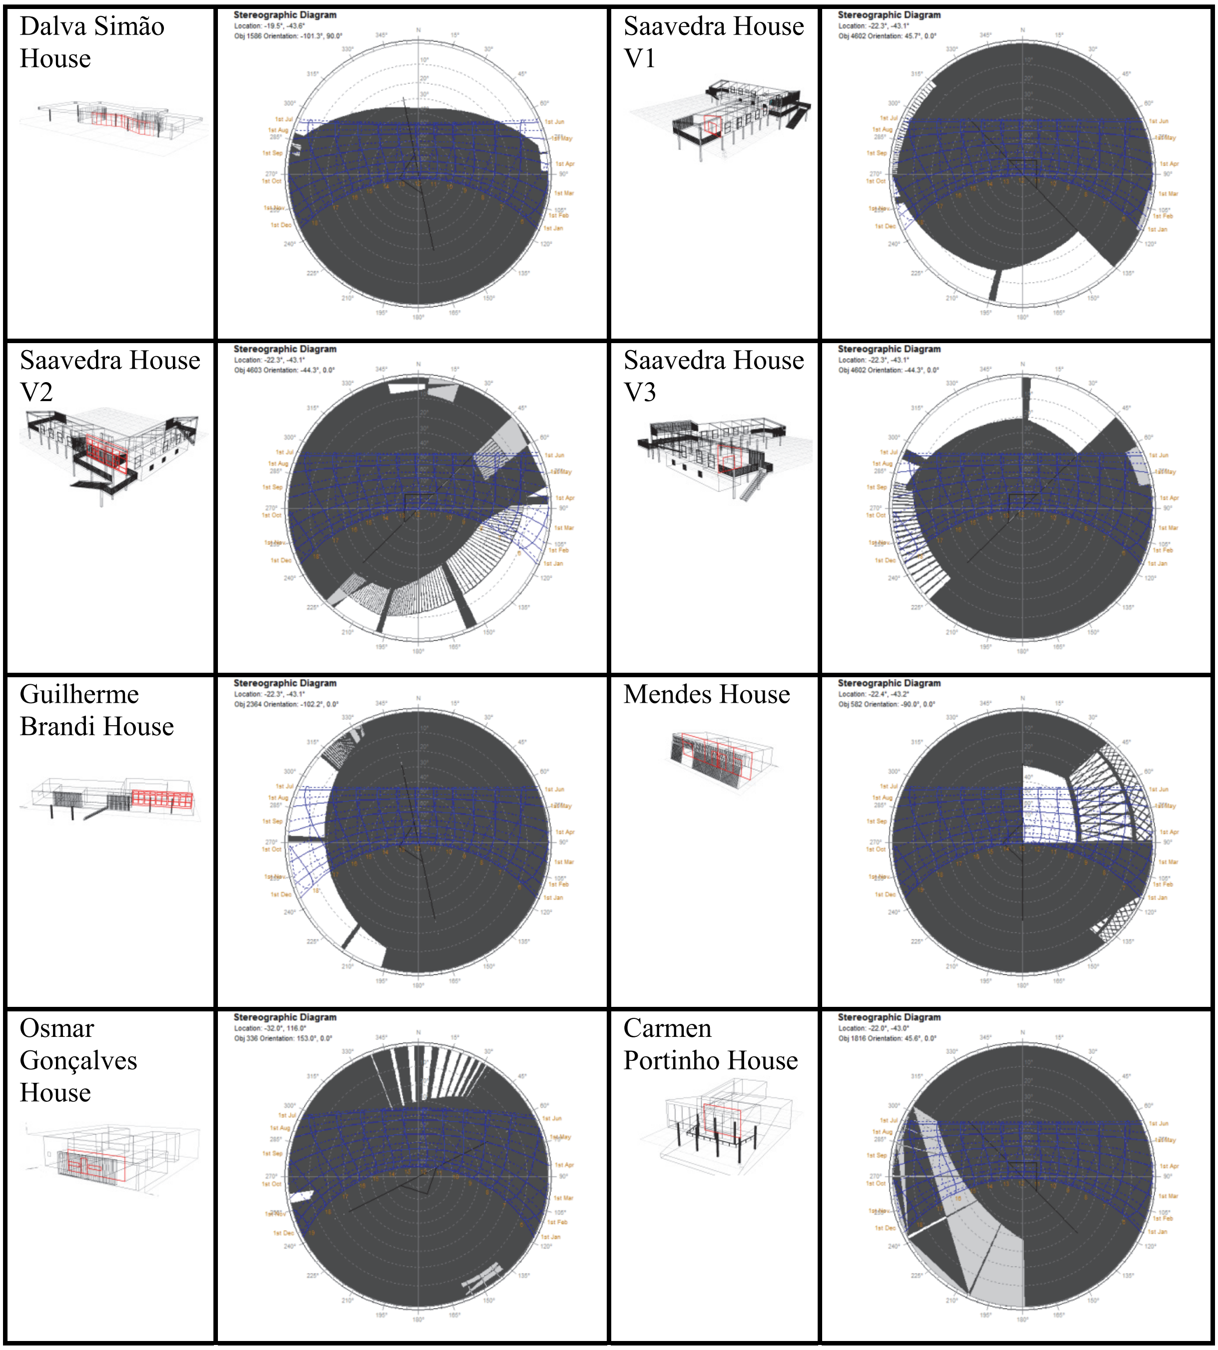

Figure 5. Stereographic diagrams on facade

e) Sun protection on facades analysis

For this analysis, we propose to analyze the residences that have some kind of enclosure in the veranda to protect from the solar incidence. The simulation is done with the enclosure and without, so to compare the two situations, and verify the most efficient for each context.

Mendes House	With	Spring 1932,32Wh 	Summer 1523,79Wh 	Autumn 906,76Wh 	Winter 900,21Wh 
	Without	Spring 4444,21Wh 	Summer 4762,48Wh 	Autumn 3441,8Wh 	Winter 3327,63Wh 
Osmar Gonçalves House	With	Spring 871,81Wh 	Summer 925,4Wh 	Autumn 947,29Wh 	Winter 940,88Wh 	Without	Spring 2372Wh 	Summer 2566,31Wh 	Autumn 2446,45Wh 	Winter 2439,7Wh 
Figure 6. Solar radiations on facade

Considering the Brazilian weather and the orientation of these spaces, we can see that the election of the architects about putting a protection is a good solution, achieving a solar radiation reduction between 60%-70%.

CONCLUSIONS

Being a quite extense study, we can confirm that in the architectonic production of the modern Brasil there was a search for a design diversity of the intermediary space, as so the variety in functions. The design of this space was also to work with a second skin for the building, and in this way adapt the international language to the climatic context.

Municipalities Leading the Way to a Low-Energy Building Future

Ayme Sharma, M.Arch
Marken Projects

Dianne Hunter
Fort St. John City Manager

Marty Paradine, M.Sc, MBA
Fort St. John Energy Manager

ABSTRACT

What happens when a municipality becomes the owner and builder for an innovative low-energy project? Marken Projects joined forces with a small group of motivated individuals from the City of Fort St. John's in northern British Columbia to build a passivhaus that would serve as a demonstration project for future developments in the city. This project is not only one of the first completed passivhaus projects in British Columbia, but at 56 degrees north latitude, it is the most northern in Canada, matched only by one in Finland. It serves as an example of the important role that municipalities can play in introducing new ways of building and new technologies. It has been used as a demonstration to teach builders and homeowners about passivhaus and low-energy building design. The City will be able to communicate lessons learned and best practices observed through constructing and monitoring the project themselves, and by validating technologies not typically used in Fort St. John. They have already succeeded in breaking down local pre-conceptions about energy efficient homes during the construction process. By taking on the role of General Contractors, they faced challenges that lead to increased costs and longer construction timelines but the practical knowledge they gained from building the project themselves outweighed these challenges. Upon completion of the home in the autumn of 2014, it will eventually be sold at market value making this a break-even project for the City. They will retain ownership for three years following completion in order to complete the building commissioning, monitor its energy performance and hold open houses for the community to experience this house and learn more about it. This type of leadership role by a municipality can go a long way towards changing the way building happens.

INTRODUCTION

Marken Projects Design Studio joined forces with a small group of motivated individuals from the City of Fort St. John in northern British Columbia in 2011 to build a passivhaus that would serve as a demonstration project for future developments in the city. This project is not only among the first completed passivhaus projects in British Columbia, but at 56 degrees north latitude, it is the most northern in Canada, matched only by one in Finland. There were many reasons that the City of Fort St. John's took on the challenge of becoming owner/builder of their own passivhaus project. Many municipalities in British Columbia are reluctant to consider such an endeavour. Three long years since its inception, the house is finally near completion. But whether after all of our efforts, The City can declare the project a success, is still undecided. They have set extremely high expectations for themselves before they are ready to do so. In this paper we discuss the motivation and challenges in making this project happen; we describe the project and the future plans for leveraging it to change local building practices. This project serves as an example of the important role that municipalities can play in introducing new ways of building and new technologies.

Ayme Sharma is a building designer and Managing Director for Marken Projects Design Studio, Vancouver, BC.
Dianne Hunter is the City Manager of Fort St. John, BC. Marty Paradine is the former Energy Manager, Fort St. John, BC

PROJECT INCEPTION

Fort St. John is a city of about 18,000 residents in northeastern British Columbia. It is a unique community that is experiencing tremendous growth driven by development in the energy sector, particularly in the unconventional natural gas sector. The City's slogan is *The Energetic City*, referring to energy derived from the region's natural resource exploration and to a tangible mantra for the attitude of the residents. Boasting one of the highest birth rates in the province and an average age of 31 years, many young families move to Fort St. John as they see within it great opportunities to build a solid financial future for their families while also enjoying a great quality of life.

Living in the heart of the province's energy sector (natural gas, hydroelectricity, wind farms, coal, geothermal) the environmental impacts of how energy is extracted from natural resources is a stark reality for Fort St. John. They are part of the region in the province that produces the greatest proportion of energy for export per capita thereby affording others a high quality lifestyle. From this "backyard" vantage point, they can clearly understand the importance of minimizing the environmental impacts of energy extraction by looking to better ways of generating energy. In British Columbia, there are many communities with resource extraction based economies. The residents of these communities are often perceived as having little interest in environmental issues. In fact, with an abundance of resources and the natural beauty surrounding these communities, it is not difficult to understand why environmental concerns such as energy conservation are not a priority for residents. Fort St. John stands out as a very progressive community that takes stewardship of the environment seriously. Over the past 7 years, they have aimed to become an environmental leader in the Peace River region through the use of pervasive sustainable and environmental best practices. Their approach is to prioritize conservation as one of the easiest and best sources of energy. If a rural, northern community with an extraction-based economy can show this type of environmental leadership, there is hardly an excuse for others not to follow in their footsteps. Their projects have been numerous:

- They partnered with BC Hydro to hire one of BC's first Energy Managers, making energy a strategic focus of the community.
- They developed a Community Energy and Emissions Plan (CEEP) to improve energy efficiency, reduce greenhouse gas emissions and foster green energy solutions in the community.
- They have developed a Carbon Neutral Plan for taking action on reducing emissions from municipal operations.
- They have significantly reduced water use in the community through metering and toilet change-out incentive programs.
- They have launched innovative projects such as the micro-hydro project that will use wastewater to generate power to sell back to the utility company – protecting the environment while using a liability as an asset.

The turning point that led to the inception of the passivhaus stemmed from a proposal from BC Hydro (a provincial electric utility) to build a third hydro dam on the Peace River. The dam, referred to as Site C, will be located 7 km from the downtown center. The City is working to protect their community from the negative impacts of this dam. The dam will flood thousands of acres of arable land that could be producing food for the community. Once flooded, this land will be lost forever. The dam would not be necessary if all homes in Fort St. John were constructed to the passivhaus standard. This harsh reality motivated the City to take action to demonstrate extreme energy conservation.

APPROACH

The passivhaus concept was promoted by the City's Energy Manager and supported by the entire organization including City Council and senior management. The passivhaus project was perceived as an opportunity to:

- Demonstrate that building a home that consumes approximately 80-90% less heating and cooling energy than a typical code-built house is possible in Fort St. John.
- Demonstrate to local builders that highly energy efficient homes can be built at comparable prices per finished square

foot as homes built to building code standards in Fort St. John.

- Demonstrate different building techniques and innovative products and technologies.
- Build a net-zero energy ready building in accordance with their Carbon Neutral Plan.

Budget Problems

Funding for the passivhaus was approved through the City's budget process in 2012. The passivhaus was part of the Capital budget and was funded through industrial taxation. The house will eventually be sold at market-value and this money will go back into the Capital budget reserve. In this way, the project was envisioned as a break-even project for Fort St. John. The initial construction budget was $300,000. It was naïve to assume that the project could be constructed for this amount, especially when new houses in Fort St. John cost around $500,000. Lack of experience in this type of project led to poor budgeting resulting in having to go back to Council on two occasions for additional funds; this created tension within the working group and some negative backlash from the community. A major unexpected factor that increased costs was that the City had to assume the role of general contractor.

Disinterest in the Building Community

The City did not begin the passivhaus project with the intention of becoming the builder. After the design and construction documents were completed, they issued a call for tenders, but received only one respondent. The construction market is so busy in Fort St. John that there were not many builders interested in taking on the challenge of building something new. Fort St. John is a rapidly growing community with limited development resources. Local developers are struggling to provide for a rapidly expanding market. They are conservative in their construction practices and choose to maintain the standard construction practices and building styles that have worked well for them in the past. There is no need for developers to take risks with new techniques and products in this market. This fueled the desire of the City to demonstrate to builders that passivhaus construction is feasible in northern B.C. and that offering this kind of construction could be a competitive advantage over time, as the province becomes even more proactive on climate change. This is what led the City to take on the role of general contractor, which has resulted in many challenges that have slowed down the construction of the house and increased costs. As the price of housing escalates, the push for change will likely come from the end consumer who is looking for affordability, not only in the initial price of the house but in the ongoing operating costs. It is the City's objective to educate the consumer who will then seek a change in construction style from the local builders.

OUTCOMES

The Fort St. John passivhaus is a 2000 sqft 2-1/2 storey home with 3 bedrooms, 2.5 bathrooms and 1 flex room. The house is designed to be universally accessible. Construction of the house broke ground in January 2013. The Prefabricated thermal envelope panels traveled 700km north from the factory in Williams Lake, BC to arrive onsite in March. The panels were erected in 10 days. Following this, the windows were installed and the thermal envelope was taped and sealed in the spring of 2013. The thermal envelope is described in **Table 1**.

Figure 1 (a) Prefabricated thermal panels arriving on site. (b) Erection of the panels was complete within 10 days.

After this, the construction progress suffered from long delays, first due to the need to procure more funds from City Council; then due to heavy workloads of staff. The project also suffered from staff turnover and attrition, which is very typical in a northern community. Once the construction momentum fell off track, it was very difficult to convince busy subtrades to complete the remaining work. The drywall was not completed until early spring of the following year.

Thermal Envelope	Thickness	Assembly	Effective R-Val
Walls	18.75 in.	11-7/8" TJI prefabricated wall system paired with a 2X4 Service Wall	56
Roof	21.25 in.	16" TJI prefabricated roof system 2X3 service ceiling	70
Floor	16 in.	ICF perimeter, backfilled, 12" XPS R52, 4" concrete top slab on grade	52
Windows	-	Optiwin Al2Wood Windows (aluminum exterior and wood interior)	8
Doors	-	Euroline triple paned entry doors with thermal inserts and exterior cladding	8

Table 1: Thermal envelope: wood construction with cellulose insulation and ROXUL batt insulation in the service walls; SIGA tapes and membranes were used to achieve airtightness

The mechanical system consists of a direct-ducted ventilation system with heat recovery (HRV) and a combination of electric resistance heating (baseboards) and point source air conditioning (air source heat pumps) for backup heating and cooling. Domestic hot water is provided by a hybrid electric heat pump. This system will consumes about 90% less energy than a typical code built house due to an extremely energy efficient building envelope. The heating/cooling cost for the year is estimated to be $200-$400, which amounts to annual savings of approximately $1000-$1800 when compared to a house built to provincial building code standards in this climate. The house is net-zero energy ready, meaning that it is an ultra-efficient building that can be adapted to net-zero energy at a later date through implementation of renewable energy technologies on site. A 2.82kWp solar photovoltaic (PV) system installed on the roof will produce about 3500 kWhr/year (~25-30% of the homes total energy requirements). The remaining southern portion of the roof is prewired with electrical junction boxes for future PV expansion. Energy monitoring equipment is installed with an on-line analytics subscription for monitoring.

Figure 2 (a) Heat recovery ventilator installed in upper level closet. (b) Outdoor installation of air source heat pumps.

This home is 100% electric, utilizing provincial hydro-electric power. Using air-source heat pumps in the house with backup electric baseboards installed throughout, the house will emit 0.05 tonnes of GHGs per year — over a 99% reduction in tonnes of GHGs relative to a typical single-family detached dwelling. A single-family detached dwelling emits around 10 tonnes of CO_2 per year, on average. An airtightness level of 0.6 Air Changes per Hour @ 50pa or below is anticipated (pending blower door test). By comparison, an average home built in the 2000s in Canada would be at 3-4 ACH@50pa.

The final construction cost has not been tabulated, as the project is not yet completed. The City has approved a total of $580,000 for construction. Thus far, the cost of the house remains on par with the cost to build a new home in Fort St. John. With the value of the land included, the cost is $350 per square foot, similar to newly constructed homes in Fort St. John. Typical new build prices in Fort St. Johns range from $330-$380 per finished square foot.

Performance Ratings. Pre-certification as a passivhaus was achieved through PHIUS. The house also achieves a preliminary Energuide Rating of 90, is certifiable as LEED Platinum (should dual certification be sought) and is Net-zero Energy Ready.

Figure 3 (a) Exterior view from the northeast. (b) Exterior view from the southeast.

INFERENCES AND CONCLUSION

In spite of the delays due to budget issues and lack of experience as general contractors, the execution of the passivhaus has been excellent. It has been constructed exactly as designed. Upon completion of the home in the autumn of 2014, the City will retain ownership for 3 years in order to complete the building commissioning, monitor its energy performance and hold open houses for the community to experience this house and learn more about it. During this time the home will be rented as temporary housing for staff recruited to work for the City. Having an employee live in the home will allow flexibility in arranging for tours, demonstrations, etc. The house will be rented to a family to ensure the City is gathering real-time data that reflects the intent of the demonstration: a single-family residence. It will eventually be sold at market-value making this a break-even project for the City. But even though the City may be able to recover all of their costs, the money is not an indicator of the success of this project. The knowledge gained by the City cannot simply remain with them. A rigorous education and marketing plan is currently in development to ensure that the passivhaus does not become a stand-alone project. The City needs to ensure that they are not simply describing and demonstrating *what* a passivhaus is to the community of Fort St. John, but that they are able to sell the community on their vision for *why* they did it. If they are successful, then this small single-family residence can mark the beginning of a new building movement in Fort St. John. The education and marketing plan includes:

- Utilizing the house as a laboratory whereby builders and the public can see how the house actually performs.
- Providing tours, workshops and training opportunities for the public to understand the simple construction concepts around the passivhaus and how they can be replicated in the community.
- A Construction Manual and that can be provided to other builders.
- Web updates of energy consumption on the City's website.
- A Home Owner's manual

For the City, the markers of success include (1) verification that the final cost of construction is the same or similar as a typical single-family home in Fort St. John, (2) confirming that the performance of the house meets the anticipated energy conservation levels, (3) the uptake by private developers that initiate new projects to the passivhaus standard and finally (4) motivating community members to prioritize energy conservation in the design and construction of their homes. Success for the City of Fort St. John may ultimately mean that energy expansion projects such as the proposed Site C hydroelectric dam will not be necessary.

During construction, the project has been used as a demonstration to teach the local building community about passivhaus construction and low-energy building design. There have already been small signs of success in breaking down local pre-conceptions about energy efficient homes. The subtrades on-site expressed that they saw the value in ideas such as a service wall and prefabrication. One contractor has even decided to build his own passivhaus for his family. Smaller builders preferred the prefabricated building techniques since they could be erected quickly and were more manageable for smaller crews. This removes some of the construction risk associated with the high cost of labour in the region and the extremely short construction season, making it possible for them to compete with bigger construction companies. A City Building Inspector that took the lead as the General Contractor saw the benefit of becoming a Certified Energy Advisor (CEA) to help facilitate future lower energy building projects in the region. When he completes his training, he will be the first CEA in Fort St. John. As 1 of only 3 city building inspectors, this type of training will offer him great insight into evaluating and influencing the energy performance of construction in Fort St. John.

The City employees that are involved in completing the house since the thermal envelope was sealed have reported exceptional indoor comfort and consistent indoor temperatures even without the HRV commissioned. There has been no need for any additional heating for workers onsite throughout the winter of 2014 at outdoor temperatures well below 0 degrees Celsius. During the hottest days of the summer of 2014, the house maintained a comfortable temperature; the geometry of the roof overhangs provided adequate shading from the summer sun to prevent overheating. The indoor environment is also reported to be remarkably quiet.

In this Northern region of the province, access to building materials and products are limited, inflating costs. Some design ideas that were great from an architectural perspective were not so good from a cost and construction perspective. This incongruency should have been considered at the design stage to mitigate cost escalation. For example, labour costs are so high that a significant amount of money could have been saved by simplifying the roof construction using a truss system over a prefabricated flat roof panel rather than framing a cold roof over a vaulted thermal roof panel. Another example was the extremely high costs of procuring a crane on-site. This has implications on the cost benefits of using prefabricated panels. All of these lessons will be passed on to local builders in a construction manual.

As the project nears completion, the City's Energy Manager and visionary behind this project has said goodbye to Fort St. John and moved on to another position in Alberta. This has been a loss for the City but he leaves behind the groundwork for a bright passivhaus future. This type of municipal leadership that we were fortunate to witness can go a long way towards changing the type of building that happens in our communities. Instead of writing green building guidelines and bylaws, the City of Fort St. John chose the more difficult path of implementing an actual project. We will continue to watch with interest to see what the project impacts will be in the future and whether the City of Fort St. John is able to leverage their efforts in creating this small house to have a larger impact on transforming the local building community.

ABSTRACT

This study aims to analyze the benefits of applying a Zero Energy Building (ZEB) as an alternative to conventional buildings in isolated and environmental protected areas in Brazil as a hosting unit. A Zero Energy Solar-House (ZESH) is defined, considering its fabrication, assembly systems, use of natural resources and strategies for energy efficiency, leading to low environmental impact. A Brazilian scenery is described regarding energy feeding conditions in isolated areas, the occupation of protection areas, which are coveted by real estate market and touristic exploitation, and the consequent environmental impact. The ZESH harnesses sun's energy throughout a photovoltaic (PV) system for energy generation, solar collectors for water heating and passive environmental conditioning. Besides, it has local wastewater treatment and solid waste management systems, reducing the environmental impact arising from the occupants activities. To verify the ZESH model, this study takes the Ekó House Project, an efficient solar house prototype that meets the ZESH premises. This study results in accounting greenhouse gases (GHG) emissions reduction by the solar PV electricity generation instead of diesel generators. Results point out a potential to avoid up to 14.4 t of CO_2/year for one ZESH unit. It is observed that the ZESH contributes to enable the occupation of these areas by local communities or touristic exploitation with responsibility, low resources consumption and reducing the environmental impact when compared to conventional buildings, allowing these areas to develop on a sustainable way and benefiting local communities.

INTRODUCTION AND APPROACH

Brazil is a country known for its rich biodiversity, a coastline with almost 8000 km long and the world's largest tropical rainforest, the Amazon. Brazil is ranked fifth in the world in relation to territory and is the largest country in both South America and the southern hemisphere. Given the Brazilian territorial dimension, many communities are still living in isolated locations with restricted or no access to infrastructure such as electricity, sanitation, transport, health and education. To obtain minimum comfort conditions, these communities rely on isolated systems, when possible, mostly through diesel generators, which are very expensive, cause environmental impacts and affect population's health (Di Lascio, 2009). Furthermore, the lack of infrastructure for sewage treatment and solid waste management also cause environmental impacts such as contamination of soil and water courses (UNEP/UNWTO, 2005).

Besides the demand and impact of the native populations living in isolated areas, often these sites are targeted and exploited by tourism sector, which often causes similar impacts in environmentally sensitive areas. Some negative impacts can be associated with tourism, such as disordered development or inappropriate tourism scale to the area, causing degradation of the resource base and ecosystems; increasing pressure on the natural environment, with degradation or destruction of fragile ecosystems; impacts resulting from the implementation of roads, sanitation, airports, urbanization, and centers for final disposal of solid waste, that could cause negative environmental and social impacts (Brasil, 2009).

On the other hand, there are also positive impacts of tourism activities in isolated and environmental protection areas. Examples include the diversification of economic activities, employment generation and income for local communities; improvement in sanitation; proper handling and disposal of solid waste; improvement in water quality in water bodies and aquifers due to the installation of domestic wastewater treatment systems; possibility of expanding educational and environmental awareness programs (Brasil, 2009).

Many of mentioned impacts, positive and negative, have a direct correlation with the buildings for housing and lodging in remote locations and environmental protection areas. Thus, this study aims to analyze the contribution of a Zero Energy Solar-House (ZESH) model to reduce environmental impacts and improve the quality of life of local populations and in touristic areas, analyzing how architecture can respond to a demand for social and economic development with low environmental impact.

OCCUPATION AND ENERGY ACCESS IN ISOLATED AREAS IN BRAZIL

In Brazil the electric energy is provided almost entirely by the National Interconnected System - SIN a large hydrothermal system, with a strong predominance of hydroelectric plants. Only 3.4% of the country's electricity production capacity is out of SIN (ONS, 2013) mainly in small isolated systems located in the Amazon region. These isolated areas are almost entirely located in the Northern Region and are served by thermal generation (EPE 2013).

The regions without access to electricity are regions where enroll minors Human Development Index - HDI (Di Lascio, 2009). The lack of access to electricity limits the access of isolated populations to basic infrastructure. The power supply from the diesel is often unfeasible economically. With an intense demand for energy, the cost to universalize regions such as the Amazon under the current model, which is based in isolated fossil fuel thermal systems, supported by a strong allowance, can be very costly to the country. The cost of power generation from existing generation systems is made possible by the Fuel Consumption Account - CCC, which in 2006 reached R$ 4.5 billion, approximately 25% greater than the amount of R $ 3.6 billion approved for 2005 (Gonzalez, 2008). Is worth point out that in remote villages, away from the distribution grids, there is only power when the community itself manages a generator and a mini grid, with no public electricity service. Moreover, the diesel to power these engines is usually acquired at a very high price from traders (Di Lascio, 2009).

Besides the issue of economic viability, the diesel generators impact the health of communities supplied by this fuel. In many isolated communities lamps fueled by diesel oil or kerosene are used. This alternative, in addition to being inefficient (7.3 diesel lamps are needed to obtain the same luminance of a 9 watts compact fluorescent lamp) causes respiratory and ophthalmic diseases (Di Lascio, 2009).

The alternative of using overhead transmission and sub-transmission lines has a high rate of acceptance by planners. However, when observing the regional reality, is possible to realize that this type of infrastructure is too costly, or even ecologically unsustainable for many isolated areas (Di Lascio, 2009).

In Brazil, the Light for All (Luz para Todos) program was launched by the Federal Government in 2003 with the challenge of ending the electricity exclusion in the country and bring access to electricity to more than 10 million people (Programa Luz para Todos, 2009). In places where the electricity arrives, the population acquire consumer goods that they could not have when was relying on diesel generators.

Among those appliances, most families buy televisors, refrigerators, blenders and water pumps (Seo, L. M.; Esteves, J. R., 2010. This also encourages these communities to diversify its economy. Some residents are opening their own business, sometimes associated with tourist activities, such as small hotels or restaurants. The access to electricity also favors public facilities such as health centers and schools, improving the quality of life of these communities, allowing an improvement in healthcare services, education and digital inclusion (Seo, L. M.; Esteves, J. R., 2010).

Many are the benefits obtained through the access to electricity. Thus, it is important to notice the suppressed demand for electricity in isolated areas and the importance of adopting energy efficiency measures together with the electricity access.

TOURISM IN ISOLATED AREAS

Considering initially mentioned positive influences that tourism can have on isolated areas, this study assumes the possibility to integrate environmental tourism activities with the native communities of such areas, collaboratively, looking toward a benefit to both parties. Naturally, this can only happen through a sustainable tourism way, which is the “tourism that takes full account of its current and future economic, social and environmental impacts, addressing the needs of visitors, the industry, the environment and host communities” (UNEP/UNWTO, 2005).

UNEP points out that tourism has the potential to contribute to local communities, especially the poor, through the development of local economy. The extent of the direct benefits to communities depend in large part on the percentage of tourism needs that are offered onsite, as product, labor, tourism services, and, increasingly, the "green services" on energy efficiency and water and waste management. UNEP also shows that over a third of travelers are in favor of eco-tourism and are willing to pay between 2% and 40% more for this experience. Tourists are interested in relevant social, cultural and environmental issues for the destinations they visit, and are interested in supporting hotels committed to protecting the local environment (UNEP, 2011).

Programs of the Ministry of Tourism in Brazil define indicators of environmental sustainability for tourism in the country, this study assumes as relevant for a ZESH hosting unit the following indicators: water and energy consumption per guest, waste generation per guest and the percentage of solid waste recycled or sent to composting (Brasil, 2007). Furthermore, it is important to highlight the potential that such tourism development may represent with regard to education and environmental awareness, influencing its audience to adopt different habits to reduce consumption of natural resources and environmental impacts (Projeto Ekó House, 2012).

It is noticeable that the global tourism economy represents 5% of the Gross Domestic Product (GDP) and accounts for about 8% of total employment (UNEP, 2011). It is expected that the "greening" of tourism contribute to improvements in energy efficiency, water and waste systems, and enhance the potential for job creation in the sector with greater hiring and prospecting site and significant opportunities in tourism oriented to the local culture and the natural environment (UNEP, 2011). Thus, this study works with a scenario in which tourism projects focused on isolated and environmentally sensitive areas are developed along with local communities, promoting economic and social development, improving quality of life in an environmentally sustainable manner.

POTENTIAL OF SOLAR ENERGY IN BRAZIL

Brazil has favorable conditions for harnessing solar energy. Average annual irradiation varies between 1.200 e 2.400kWh/m^2/year, values that are significantly higher than most European countries. As shown in **Figure 1**, the higher irradiation areas are the areas 5 to 8, in which the average productivity varies between 1.260 e 1.420Wh/Wp/year (EPE, 2012).

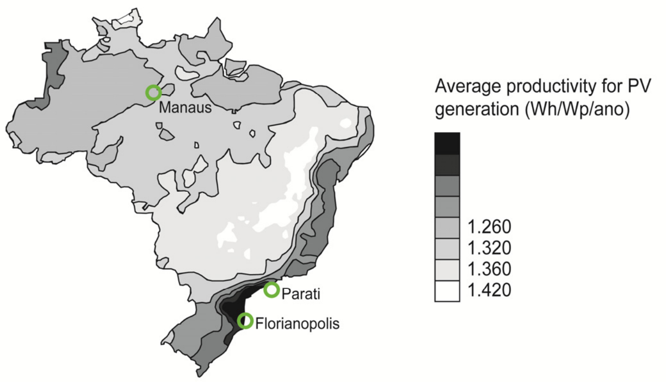

Figure 1 Solar irradiation in Brazil. (EPE, 2012)

In addition to this, in locations without conventional electric service, photovoltaic (PV) systems constitute a viable alternative when compared with the extension of the power grid, diesel generation and other sources (Pinho, 2008). The problem lies in the economic conditions of people living in these isolated areas that cannot afford such systems. However, some kinds of subsidies may contribute on economic viability of PV systems in Brazil, such as reducing taxes on industrialized products, discount on income tax, specific lines of credit (EPE, 2012). Besides, the same way the government subsidizes diesel, subsidy for PV systems could increase, given the social and environmental benefits by the use of PV as an alternative to diesel. Subsidies could also be associated with sustainable tourism development.

ZERO ENERGY SOLAR-HOUSE BASED ON EKÓ HOUSE PROTOTYPE

A Zero Energy Building **-** ZEB is defined as a building that produces, through local sources – and preferably renewable ones – the energy it consumes, considering an annual balance (Torcellini et al, 2006). The ZESH modeled for this study integrates several systems to ensure its operation and functionality, comfort for the occupants, and low environmental impact. To verify this ZESH model it is adopted the Ekó House prototype. This prototype was developed by Team Brasil, a partnership between University of São Paulo and Federal University of Santa Catarina, and represented Brazil in Solar Decathlon Europe 2012 competition, held in Madrid.

Ekó House is taken as reference for this study because it meets the guidelines of a ZESH. In addition, the specific purpose for which the prototype was conceived is hosting in isolated environmentally sensitive areas in Brazil. The prototype can be connected to a local grid and could export the surplus energy to meet the demand of local facilities, like schools and healthy centers, or dwellings in these isolated locations. The ZESH strategies and systems are presented below.

Solar trajectory and orientation

The ZESH adopts a geometry that results in elongated facades facing north and south orientation, in order to obtain a better use of the sun throughout the year. In summer, when the sun is more directly overhead, radiation is less intense on north oriented facades than is east and west oriented facades (Southern Hemisphere). In winter the sun is lower, and radiation is more intense in north oriented facades than in east and west oriented facades, as shown in **Figure 2**. North oriented facades receive more direct solar gains in winter and less in summer than other facades.

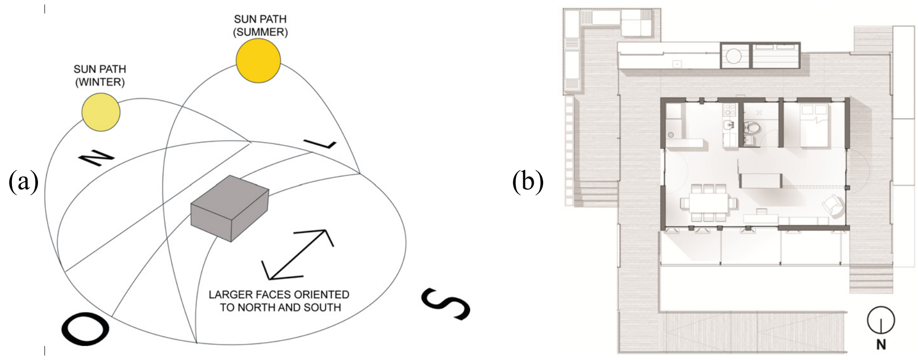

Figure 2 (a) Solar trajectory and (b) building geometry. (Projeto Ekó House, 2012)

Building envelope

Many strategies are possible to achieve environmental conditioning. The envelope elements of a ZESH have appropriate thermal performance, based on climate conditions of the location, through strategies such as insulation, the use of thermal mass and/or natural ventilation, among others. The Ekó House prototype has high thermal insulation levels and windows properly dimensioned and positioned, ensuring natural lighting and ventilation. This results in good comfort conditions with low energy consumption by integrating passive and active strategies. Simulation models indicate a Daylight Autonomy of 60% for the Ekó House prototype (Projeto Ekó House, 2012).

However, the climatic conditions vary widely, as well as the solutions to adapt the buildings to each climate. Considering this, a pre-fabricated structure made of modular panels is proposed to enables the use of different materials and, therefore, different strategies to the envelope, allowing an adaptation of the ZESH to different needs and conditions. Besides, the use of wooden pre-fabricated structural panels allows faster and cleaner assembly when compared to conventional constructions. **Figure 3** shows this modular construction system.

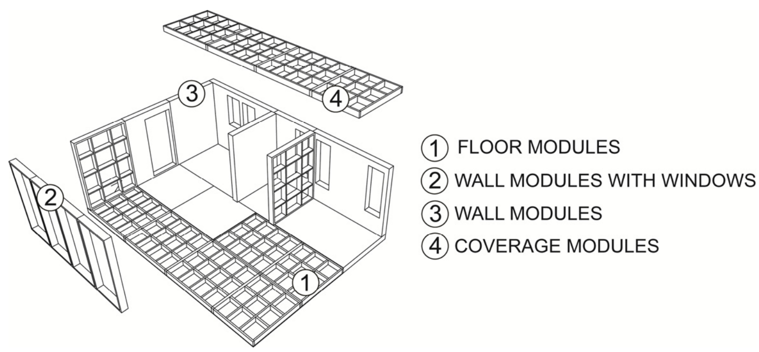

Figure 3 Modular system of a ZESH. (Projeto Ekó House, 2012)

Management and treatment of waste and sewage

Domestic waste, when correctly managed, can reduce significantly the volume of rejects to be discarded. Specific compartments for waste disposal can be integrated in the house design, both inside (for dry waste) and outside (composter). Adequate space for waste storage and organic material composting are essential and help the occupants to dispose wastes correctly.

In a ZESH there is a concern with the proper treatment and disposal of wastewater. Ekó House sewer system is decentralized. A composting toilet, which requires no water, is adopted. This technology accelerates the composting process to avoid odors and contribute to reduce fresh-water consumption (Projeto Ekó House, 2012). Through this system, it is possible to obtain an organic compound free of contaminants, avoiding the need for larger scale systems for treating such waste. The wastewater from shower, sink and washing machine, kitchen sink and dishwasher is treated by a natural system planted with hybrid filters macrophytes (wetlands). After this process the water can return to the environment without harming nature (Projeto Ekó House, 2012). Through such systems consumption of potable water is reduced. Furthermore, there is a system for collecting rainwater, which can be used as non-potable water or even be treated and consumed. **Figure 4** illustrates such systems.

(a) 

(b) 
Figure 4 (a) Systems for waste treatment and (b) composting toilet. (Projeto Ekó House, 2012)

Such systems for solid waste and wastewater management may waive the installation of large infrastructure for such purposes, and contribute to avoid contamination of soil and water bodies in areas where such infrastructure is often unfeasible.

Structure for solar systems

Architectural integration of solar system into ZESH is supposed to enable the profitable and advantageous use of solar energy into good quality architectural design. The architectural design can influence the performance of solar systems, allowing its integration into the envelope faces with higher levels of solar radiation and the proper arrangement of the system.

In Ekó House prototype, the roof surface is the suitable area for installing PV array due to its advantageous irradiation, is the face that gets higher incidence of radiation throughout the year, so it was used for the installation of solar systems. An aluminum frame, fastened to zipped metallic tiles supports PV systems and solar collectors. This structure is oriented to the North (considering the location in Brazil) and can be adjusted at different angles (10°, 15°, 20°, 25° and 30°). This ensures the efficiency of solar systems throughout the year and in different regions of the country, as shown in **Figure 5**.

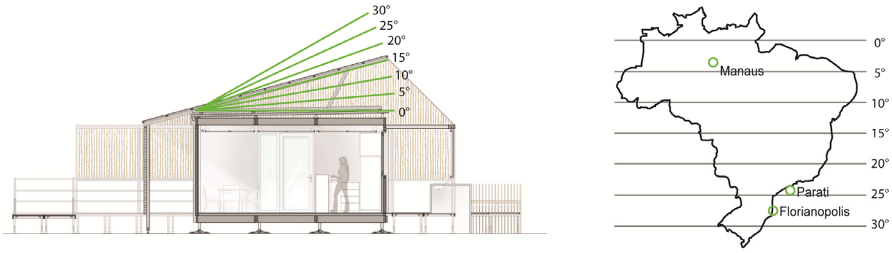

Figure 5 Structure for solar systems in the Ekó House prototype and adaptability to different Brazilian latitudes. (DIAS, 2014)

Water heating system

Heat water demand is associated to bathing, home appliances and in the thermal conditioning. Solar radiation can be harnessed to meet this demand in a ZESH. Solar collectors can be applied associated with electric shower, gas heating, electric boiler, among others. Flat plate solar collectors and evacuated tubes systems are examples of widely used collectors. The Ekó House prototype has four u-pipe solar collector (evacuated tubes) ensuring a high efficiency system.

The fastening system shall also be suitable to the envelope and it is important to provide appropriate space for reservoirs, passing pipes, and integration with other heating systems. Access for maintenance is also essential to ensure system performance.

PV Solar System

The solar PV generation on single houses can happen in two ways: with a system interconnected to the grid; or through a standalone system, and a storage system and/or additional generation is needed to ensure system's energy security. For the ZESH hosting unit is considered the adoption of a photovoltaic system associated to a battery bank and diesel generator set. It is important to notice that, in Brazil, the use of alternative fuels for electricity generation in autonomous systems has increased, as the use of biodiesel (Gonzalez, 2008) and even experimental processes such as gasification from the seed of the acai berry, which has a cost three times less than the cost of diesel per kWh generated (Freitas, 2006). Thus, it is possible to have a system that complements photovoltaic generation with a lower environmental impact.

The Ekó House prototype comprises 48 monocrystalline PV panels, with an 18.5% efficiency and 11 kWp of total installed capacity. Considering the location in Madrid, the PV system generates, on average, 1.790kWh/month, enough to meet the prototype energy demand, which is around 735 kWh/month, and still provide around 1.055kWh/month of clean energy to the grid (Projeto Ekó House, 2012).

In a ZESH the architectural design must contribute to a higher efficiency of the system, ensuring that PV modules are arranged on the sides of the envelope with better solar radiation, or even through the use of devices which adjust the tilt or track the sun, adapting the PV system for the orientation throughout the day and the year. Moreover, the architectural design should also provide suitable and safe conditions to place other equipment forming part of the solar PV system, as inverters spaces, in addition to providing space and appropriate protections for electrical wiring, terminals, fuses and circuit breakers. Cleaning and maintenance of the modules shall also be considered in the architectural design to ensure the best system performance throughout its lifetime. (Projeto Ekó House, 2012). ZESH solar systems are exemplified in **Figure 6**.

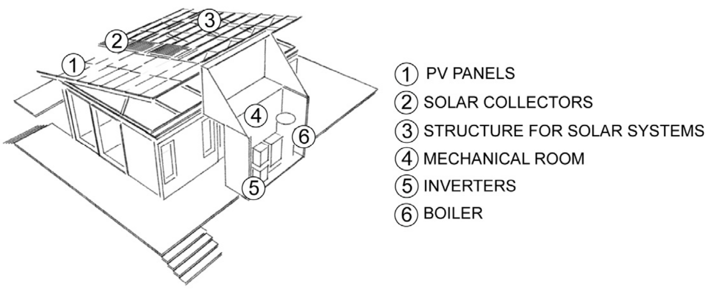

Figure 6 Solar systems for a ZESH. (Projeto Ekó House, 2012)

The strategies adopted in ZESH confer a degree of adaptability, allowing the model to meet different demands. The full model, including all of its systems, responds to comfort standards of developed countries. However, the modular system allows beginning with the most basic systems to lower cost, and then install systems and expand square footage by attaching new modules. This modularity also provides flexibility in the final occupation, and this model can meet the demand for housing by local communities or units for hosting tourists.

ENERGY CONSUMPTION IN A ZESH

The data presented here are from the Ekó House prototype, which are fundamentally derived from computer simulations to estimate values of energy generation and consumption by this prototype over a year of operation. The energy consumption considers the prototype in Madrid. Is worth remembering that this prototype was designed to meet the standards for the use and comfort at developed countries due to the participation in the international competition Solar Decathlon Europe 2012. The project has been conditioned by the rules and requirements and does not represent the standard of living of the largest part of Brazilian population, especially those living in isolated areas. Thus, it is possible to assume that the Ekó House average consumption, of 735 kWh/month, represents a situation of highest level of electricity consumption, even for hosting units in Brazil.

The energy generation was simulated on RETScreen® 4 software and consider both the prototype in Madrid and in some places in Brazil with potential to apply the prototype as a hosting unit in isolated areas. The PV system is the same of the prototype in all places, with 11 kWp. The slope and orientation of the system are changed in order to achieve better efficiency of the system for each location. These places are Manaus, in the Amazon region; Parati, touristic place located near Rio de Janeiro with some isolated communities; and Florianopolis, which is an island with some few isolated spots and less favorable solar radiation levels along Brazilian territory. **Figure 7** brings energy balance data for the Ekó House prototype.

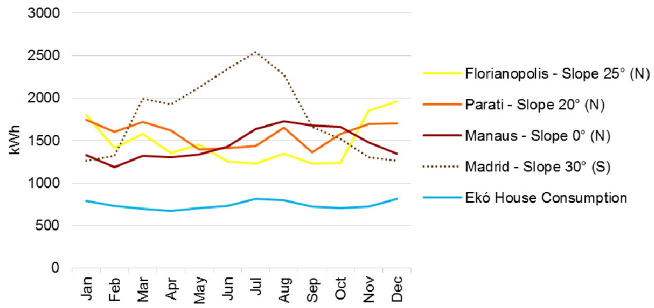

Figure 7 Ekó House energy balance considering different locations for energy generation. (Projeto Ekó House, 2012; RETScreen® 4)

It is possible to observe that even with a consumption that reflects standards of developed countries, the prototype proves more efficiency than homes in countries like the U.S., where the average consumption is 903 kWh/month for each residence (EIA, 2012). Besides, the PV system has a positive balance throughout the year. In addition, the modular structure favors the adoption of different materials for the envelope. This enables an adaptation to the climate of each region, providing appropriate comfort with lower energy consumption

Regarding GHG emissions associated to energy generation, the emission factor for diesel oil generator set is 808 g CO_2/kWh (IPCC, 2007). When properly maintained, the generators have normal efficiency of 350 g/kWh, but most groups used in isolated areas in Brazil receives no adequate maintenance, increasing fuel consumption for about 500 g/kWh (Di Lascio, 2009). For the PV systems it is applied an average emission factor of 46 g CO_2/kWh (IPCC, 2012). Thus, avoided emissions by generating energy through PV system instead of diesel would be 762 g CO_2/kWh.

The table and graph in **Figure 8** demonstrate energy generation and avoided emissions for one year of operation of a ZESH. It is worth noting that even a high energy consumption situation is compensated by the use of a clean source. Besides, the more efficient is the electricity consumption in ZESH units, more clean energy can be shared with local communities.

(a)

	PV Generation (kWh)	Energy Consumption (kWh)	PV Surplus Energy (kWh)
Florianopolis	17696	8820	8876
Parati	18910	8820	10090
Manaus	17411	8820	8591

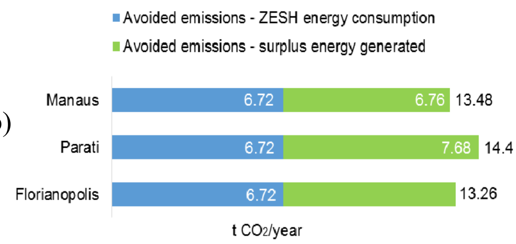

Figure 8 (a) Energy generation and (b) avoided emissions for one year of operation of a ZESH.

CONCLUSION

This study concludes that ZESH demonstrated and verified by the Ekó House prototype represents an alternative to enable the occupation in remote and environmentally sensitive areas with low environmental impact, promoting access of local communities to a basic and autonomous infrastructure that can contribute to its socioeconomic development. This ZESH can be adopted both by local people and by tourist developments. It is a model that responds positively to environmental indicators set by the Brazilian government and to the concept of sustainable tourism defined by UNWTO.

The solutions proposed for this ZESH model, demonstrate the important role of architecture with regard to the use of the sun, both associated with passive strategies for greater energy efficiency, and for obtaining energy through active systems such as PV and water heating systems. In this way, it is possible to maintain comfortable levels for occupants without necessarily increasing energy consumption. The prototype also demonstrates that it is possible to associate to a housing unit some systems that ensure access to basic infrastructure for sewage treatment and solid waste, avoiding contamination of soil and water, and providing healthy and hygienic conditions for local and tourist populations.

Finally, the ZESH model presented in this study can be adopted and contribute to the mitigation of global warming by reducing GHG emissions, to an improvement in the quality of life of local populations in remote areas, to develop tourism in a sustainable way in environmentally sensitive areas, to promote socioeconomic development in remote communities, and also to educate different audiences (local and visitors) about how some appropriate systems and habits can reduce the impact of human activities on the environment.

ABSTRACT

India is witnessing green building revolution. With rating schemes like LEED, IGBC and GRIHA in place and practice, building stakeholders are becoming more aware of sustainability issues. Issues under sustainability are clubbed under - Site, Energy, Water, Waste and materials and Environment. For most rating schemes across the world, Energy carries maximum number of points. High importance has been placed on energy because of current world energy scenario. Buildings are assuming critical role in energy dynamics. In India, building construction is taking place at a much higher rate than usual. Buildings consume tremendous amount of energy and this rate of energy consumption in buildings is also increasing. As per rating schemes, a comparison of energy consumption with base case or even an absolute figure of energy consumption is considered for ranking the energy efficiency of building. However, our traditional vernacular systems and passive features of building and design which impacted thermal comfort in response to climate are not accounted for in judgment criteria. At no place is the thermal comfort creation though spatial planning is emphasized, encouraged and rated. Therefore, in today's time when relevance of energy efficiency is far larger than earlier, it becomes imperative that thermal comfort be achieved through spatial planning and efficiency of spatial planning be made judgment criteria for rating sustainability quotient of a building. Hence a common parameter needs to be evolved to quantify and judge achievement of thermal comfort through spatial planning and passive techniques in any building across the globe in context to the climate in which building is placed. This research is aimed at development of such parameter and its applicability in rating schemes. The paper details out the parameter, methodology to calculate it for any building and its relevance for building sustainability.

INTRODUCTION

India is a developing economy and building construction industry contributes substantially towards GDP, resource consumption, energy demand and pollution. (Tiwari P, 2001) Buildings therefore need to be constructed in a manner that they have least negative impact on the environment and maximize health and other benefits. (Arif M et. al, 2009) This fact has been duly recognized and that is the reason we have two successful Green Building Rating systems in our country – LEED-IGBC and GRIHA. (igbc.in, grihaindia.org)) Both these rating systems are more or less similar to many other existing systems in the world. A green building is evaluated based upon certain themes which are almost the same; while weightage of themes vary from one system to other. (Fowler K M et al, 2006) A comparative study has been done and the themes which are evaluated are- Site and transport, Energy, Indoor Environment, Materials and waste, Water and Operations and maintenance. (Liu G, 2010) Figure 1 clearly shows that maximum emphasis is laid on energy efficiency.

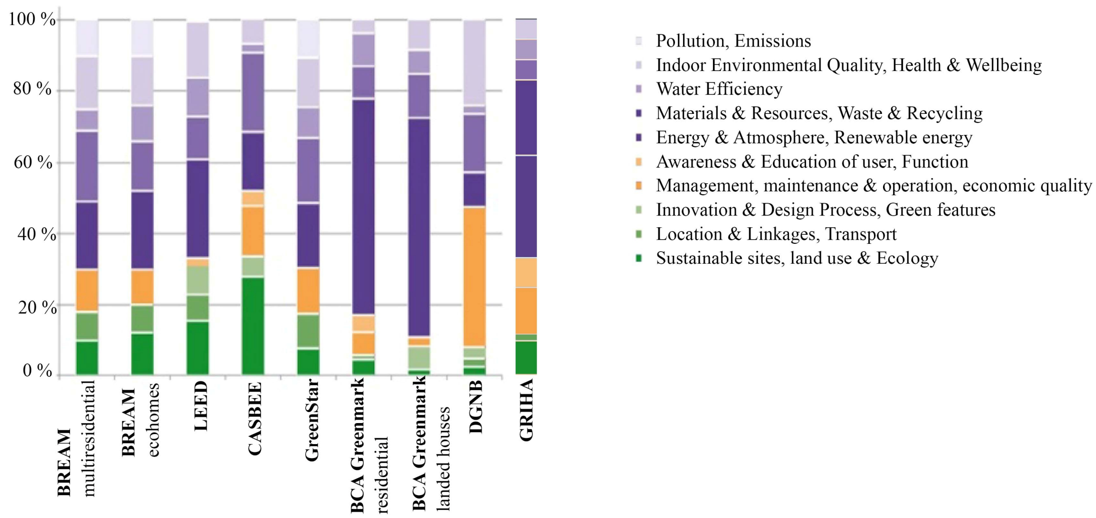

Figure 1 Comparative Chart Showing Weightage of Different Themes in Different Rating Systems across the World

While credits are given for innovation and design, quantitative assessment of design for achieving energy efficiency doesn't feature anywhere.(Happio A, 2008) For achieving a desired energy performance (whether prescriptive path is followed or performance rating method is followed) heads which are considered are- Building envelope, HVAC, Service Water Heating, Power, Lighting and other equipments. Building envelope focuses on Building Orientation, WWR, Fenestration design, type of glass being selected and opaque assemblies. (Fowler K M et al, 2006; Ballinger J A,1988) Once mandatory requirements have been fulfilled, overall reduction in energy consumption is calculated and credits awarded. In all this, capability of architectural spatial planning in bringing in substantial reduction to energy consumption has totally been ignored. (Cole R J, 2012) It is like creating a problem through design and then solving it through employing better systems. The issue becomes more important for a country like India where we have a variety of climates. (ECBC, 2007) All our vernacular buildings present efficient examples where only with the help of spatial planning and materials (building envelope), thermally comfortable indoor environments have been created. This approach is a preventive approach and also affects the stakeholder behavior.(Plessis C et al, 2011) The need here is to develop a parameter by which we can judge the effectiveness of any architectural design in any climatic context (normalization) in bringing in energy efficiency.(Haas R, 1997)

THE CHALLENGE

Aim of this research is to develop a tool by which effectiveness of an architectural design in bringing in thermal comfort (which leads to energy efficiency) can be evaluated using a single parameter.

Taking a look at how energy efficiency of a project is determined through whole building simulation. A base case is established as per a standard document or code; say ASHRAE 90.1 in case of LEED or energy consumption baseline in case of GRIHA. (ASHRAE 90.1, ; ECBC, 2007) Architectural design remains same for base case and proposed case. Energy Conservation Measures (ECM's) are then added to proposed case (which mainly comprise of alternatives of building construction/ building envelope and mechanical systems) and performance of building is evaluated. In this entire process, potential of a better spatial design's contribution towards energy efficiency is not being judged. Now if comparison of architectural design is to be done, what can be the base case? Since each building should respond to climate in which it is placed, the tool must have a tangible parameter through which effectiveness of architectural design can be evaluated.

SOLUTION FINDING

For evaluating effectiveness of architectural design towards creation of thermal comfort leading to energy efficiency, first solution that strikes is the use of thermal comfort indices for judging whether the design will be able to bring in thermal comfort.

Existing attempts

There are many thermal comfort indices which have been developed. To count a few popular ones- Effective Temperature, Corrected Effective Temperature, Operative Temperature, Equatorial Comfort Index, Bioclimatic Chart, Fanger's PMV, Tropical Summer Index etc. (Koenigsberger et al, 1973). Each whole building simulation program is capable of generating thermal comfort data usually based upon PMV.But there are some problems with this assessment as it is not a clear indication of efficiency of architectural design-

1. The building design which is simulated includes all mechanical, electrical and other systems of thermal comfort creation. Thus a impact of only space design cannot be seen.
2. Even if simulation is intended to be done only for building (devoid of any mechanical/electrical installation), the results can be deceptive. For example in case of a building situated in a temperate climate like Bangalore; it would have more hours falling under comfort range as compared to a building (though efficiently designed) in an extreme climate like Jaisalmer.

Besides using thermal comfort indices, another factor called Degree Days is also being used. But Degree Days help to normalize the weather variation which are used for simulation rather than normalizing the building's response to a climate.(Eto J H, 1988)

Thus the issue is of normalization of building's response to weather because a robust green building rating system has to be applicable to any part of the world. Hence thermal comfort indices cannot be used directly for assessing the effectiveness of space design for green building rating. A lot of efforts towards weather normalization has been made world wide. The prime objective however was to normalize weather to normalize variations in weather. The PRInceton Scorekeeping Method (PRISM)' which was initially created for calculating changes in energy consumption in a group of heated houses without cooling to individual houses (M. F. Fels et al. 1986), was developed to calculate energy consumption for individual house's cooling and heating without integrating the two (C. L. Reynolds et al 1988). PRISM considers weather conditions as an important parameter while calculating energy consumption but does not regard architectural design as a parameter. Building Energy Analysis Consultant (BEACON) system was developed by Haberl et al (1988), which is capable of continuously monitoring and diagnosing the operation and maintenance problems identifying the causes of abnormal energy consumption. In most of the models it is considered that energy use in any other year is simply the product of the appropriate degree-days in this other year and the weather-invariant parameters (Joseph H. Eto, 1988). So, Joseph H. Eto (1988) developed a simulation model which accounts for temperature forecasting based on weather conditions of a decade. Radu Zmeureanu (1992) presented a new method for weather-normalization to be used for energy consumed from all types of energy sources and considers weather as a factor contributing to energy consumption but lacks consideration of architectural design.

None of the weather normalization techniques discuss the impact of architectural design on thermal comfort normalized to the weather to which building is exposed. Hence a tool/parameter needs to be developed to evaluate thermal performance of building in response to climate it is being subjected to.

THE PARAMETER

The parameter uses Tropical Summer Index as the selected thermal comfort index for assessing thermal comfort creation. TSI has been chosen as the parameter is initially developed to respond to Indian subcontinent and TSI is the accepted thermal comfort index in National Building Code. The parameter is based upon the ability of building to convert uncomfortable hours outside in a selected climate into comfortable hours inside. Similar attempt (not to create a parameter but in approach) was made to compare passively designed office buildings in Germany. (Jens U et al, 2007) More is the number of such hours, more is the efficiency of design. Also the design has to be able to retain outdoor thermal comfort (when possible) inside the building.

Tropical Summer Index (Sharma M R, 1986; SP 41; SP 07)

TSI is defined as "the temperature of calm air, at 50 percent relative humidity which imparts the same thermal sensation as the given environment." The 50 percent level of relative humidity is chosen for this index as it is a reasonable intermediate value for the prevailing humidity conditions."

Mathematically, TSI (°C) is expressed as

$$TSI = 0.308T_w + 0.745T_g - 2.06\sqrt{V + 0.841} \quad (1)$$

Tw = Wet Bulb temperature in ° C, Tg = Globe Temperature in ° C, V = Air Velocity in m/s

For indoors, Globe temperature can be replaced with Dry-Bulb temperature. It is because Globe temperature takes into account Dry-Bulb temperature as well as effect of direct radiation also. Thus in the absence of radiation, globe temperature is almost the same as DBT. The environment was found comfortable between 25 to 30 TSI. It was tolerable up to 34 and down to 19. Lesser than 19, it was considered as too cold and beyond 34 it was considered as too hot. The TSI decreases further with increase in air velocity. (Table 1)

Table 1Decrease in TSI with Increase in Air Velocity

Air Velocity m/s	Decrease in TSI in ° C
0.5	1.4
1.0	2.0
1.5	2.5
2.0	2.8
2.5	3.2

THE PARAMETER – DUHOI

DUHOI – Difference in Uncomfortable Hours Outside vs Inside. As the title clearly states- parameter is the difference of uncomfortable hours outside against inside in a given climate. The parameter compares thermal comfort achieved inside the building through design and construction to climate outside for all hours in a year. Each building design will have one single value for DUHOI. However DUHOI can be calculated for extreme seasons like summers in hot-dry climate, winters in cold climates depending upon the criticality. Calculation of DUHOI is demonstrated using analysis of hourly data obtained through whole building simulation of a traditional haveli residence in Sikar district of Shekhawati, Rajasthan, India (AgrawalA, 2006). Figure 2 shows typical ground floor plan of the case with open to sky courtyard in the centre and double layered rooms all around. All windows and walls are shaded by sun shades and thick walls are made up of brick set in lime mortar. Haveli is simulated for one year and hourly data (Dry Bulb temperature, Relative Humidity and air velocity inside) thus obtained is used to calculate TSI for all habitable spaces in the Haveli. Air velocity inside could not be obtained through simulation, therefore excel sheet was prepared as per NBC 2007 manually which were further used to calculate TSI. After this DUHOI is calculated in the following manner-

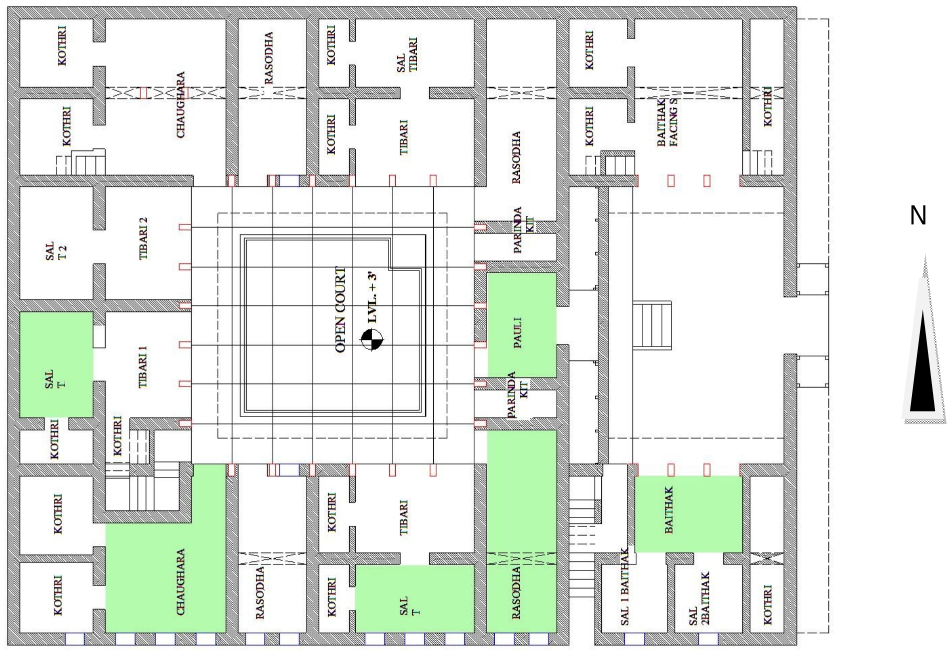

Figure 2 Upper Ground Floor Plan of a typical and Design Builder snapshot of modeled Haveli (Shaded areas are the ones which have ben simulated for calculations)

Methodology

DUHOI is calculated in a step wise manner as follows-

1. Calculate TSI for all habitable spaces and outside weather for entire year and all hours as per the formula of TSI stated above. (Table 2 – Because of limitation of space, calculations for only seven out of nineteen spaces have been demonstrated here)
2. Calculate the difference brought in TSI through design to each space. (When TSI inside is brought towards comfort it is counted as positive; if it is taken away from comfort it is taken as negative; based upon the comfort limits of TSI i.e. 25-30). (Table 3)
3. Overall difference brought in TSI (adding up positive and negative) is then averaged for the number of habitable spaces evaluated and number of hours for which evaluation is done. In case when TSI outside is already in comfort range say 29 and indoor TSI value also falls within comfort range say 25, such values will not be considered for calculations. (Table 3)

Table 2. Table showing Consolidated Thermal Comfort Data (TSI values) of Habitable Spaces in Simulated Haveli for few hours on one Typical Summer Day and TSI values Outside

Time	Baithak	Rasodha	Chaughara	Pauli	Sal 1	Sal T	TSI o
0:00	31.8	32.1	32.1	32.5	31.1	32.6	34.3
1:00	31.6	31.9	31.8	32.2	30.9	32.3	33.6
2:00	31.3	31.6	31.5	32.0	30.6	32.1	32.8
3:00	30.9	31.3	31.2	31.7	30.4	31.8	31.0
4:00	30.7	31.1	30.9	31.5	30.3	31.7	30.2
5:00	30.4	30.9	30.7	31.3	30.1	31.5	29.4
6:00	30.5	31.0	30.8	31.4	30.3	31.6	30.4
7:00	30.9	31.3	31.2	31.7	30.6	32.0	31.2

Table continues for 8760 hours.

Table 3. Table showing Difference of TSI Outdoors Vs Indoors for Uncomfortable Hours Outside

Time	Baithak	Rasodha	Chaughara	Pauli	Sal 1	Sal T
0:00	2.5	2.2	2.2	1.8	3.2	1.7
1:00	2.0	1.7	1.8	1.4	2.7	1.3
2:00	1.5	1.2	1.3	0.8	2.2	0.7
3:00	0.1	-0.3	-0.2	-0.7	0.6	-0.8
4:00	-0.5	-0.9	-0.7	-1.3	-0.1	-1.5
5:00	-1.0	-1.5	-1.3	-1.9	-0.7	-2.1
6:00	0.7	0.2	0.4	-0.2	0.9	-0.4
7:00	0.3	-0.1	0.0	-0.5	0.6	-0.8
	42.0	36.1	36.4	27.7	59.4	24.7

Table continues for 8760 hours.

$$\text{DUHOI} = (\sum dT) \div N*h$$

Where

$\sum dT$ = Summation of difference in TSI values of all habitable spaces to TSI Outside

N = Number of Habitable Spaces Analyzed

H = Number of Hours

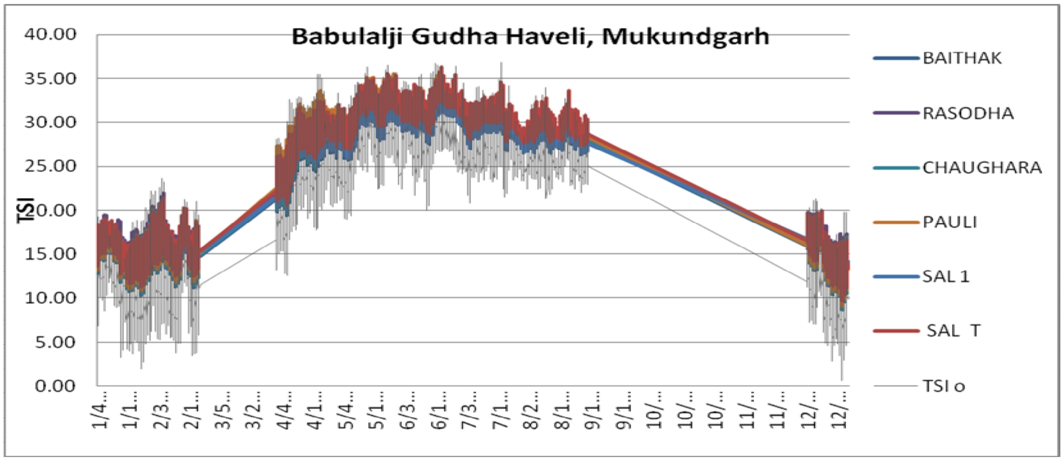
Conditions for calculation of DUHOI

Based upon logics and rationale, certain conditions have been set to calculate DUHOI.

1. Only habitable spaces are accounted for in this calculation. Service and ancillary areas such as circulation, toilets, machine rooms, kitchens etc are not included while calculating TSI and DUHOI.
2. If accessible open spaces have been provided in the building and schedule of activities suggests use of such a space during certain periods of the day, negative TSI difference values for those periods shall not be included in overall calculation of DUHOI. This is done in order to ensure that open spaces have been appropriately used. However for this option to be available, schedule has to be appropriately configured before simulating the building for its thermal comfort performance.
3. Building is assumed to be naturally ventilated without presence of any mechanical/electrical system in place. Natural ventilation schedule as perthe practice of opening windows during summer nights and winter day has been included.
4. Energy consumption for lighting and heat gain due to lighting is neglected for calculation of thermal comfort.
5. In case of large building complexes, such as campuses, mutual shading and local wind pattern of building complex will be accounted for in simulation.

Graph 1 plots hourly thermal comfort data for a Building. It can be seen that building is able to bring about positive changes in environmental conditions. Following the steps mentioned above to calculate DUHOI, difference brought is calculated using formula and the final value of DUHOI for the period simulated is calculated to be 1.41. This implies that building is able to convert uncomfortable hours into comfortable hours inside by 1.41 TSI on an average.

To know the performance of building in different seasons, seasonal DUHOI can also be found out and it can be ascertained that improvements are needed to bring down the temperature or to heat up a space. For the same building simulated here, DUHOI (summer) is 1.99 while DUHOI (Winter) is 1.32. This gives a clear picture that this building performs better in summers as compared to winter.



Graph 1. Graph showing Consolidated Thermal Comfort Data (TSI values) of selected Habitable Spaces in Simulated Haveli for an Year (excluding 3 months of March, half of September, October and Half of November) and TSI values for the same Outside

Advantages

DUHOI is a robust parameter which can be applied to any building in any climate and it has many advantages-

1. The need for a virtual base case has been eliminated. Weather of a place where building is situated acts as the reference and building is supposed to respond to weather only.
2. In this manner, any building situated anywhere in the world can be compared without making comparison of scale of building, typology and systems involved.

Application to Green Building Rating Schemes

Before DUHOI is included in rating schemes as a credit or a prerequisite, extensive base work needs to be carried out. For all climates of India and world, finest examples of passive designing (traditional and contemporary) can be picked up and DUHOI can be calculated for them. Based on this an acceptable range can be set for each climate and credits can be awarded. This would ensure that any building which is intended to be constructed as green building must have an architectural design which responds to climate of the place unlike current scenario. This way, newer green buildings based on DUHOI parameter will look local and respond appropriately to climate.

CONCLUSION

DUHOI is a robust and universal parameter which can be applied to green building rating systems. This would help in utilizing full potential of architects in making green buildings which would respond to climate as the first step towards building green. This move will have substantial effect in reducing energy consumption by buildings throughout the world.

GLOSSARY OF HINDI WORDS

Haveli	– Traditional courtyard type residence	Baithak	- Living room
Chaughara	- Largest bedroom in the corner of house	Rasodha	- Kitchen
Pauli	- Transition space from outer court to inner court	Sal	- Bedroom/ Room

ABSTRACT

Cities are complex systems rapidly evolving in a context of strong interweaving between problems and solutions especially in developing countries. The architectural design and the city management processes are renewed by the eruption of sustainable development. These processes are multi-scale: new geographical, temporal and political scales are emerging, calling for new tools for monitoring architectural and urban environmental changes, for implementing comprehensive plans, or for communicating between practitioners. Number of communities in developing countries has taken initiatives to develop tools based on sets of sustainability indicators. But are these tools really helpful during the architectural design or the urban management processes characterized by complexity, fussy or lacunar data, various time and space scales and multi-actors decisions? We will demonstrate in this paper, that these systems, aiming at "a posteriori" diagnosis, cannot be used directly during these fuzzy processes, especially during their early phases very critical with respect to solutions. By adjoining them multicriteria decision support techniques, they may become powerful tools for decision support. Architectural and urban designs may be evaluated using a set of weighted environmental criteria and methods to aggregate the various dimensions involved. Some Electre methods based on the comparison between pairs of solutions have been successfully used in that sense. A step further away may be performed from decision to evaluation support tools, by comparing ongoing urban designs against convolutions of systems of practitioners' values. This "value focused" approach, combined with the Electre-Tri method has been successfully integrated for evaluating the performance of urban projects, according to their distance to various user-defined systems of values.

INTRODUCTION

The urban development is characterized by various changes and mutations. The environmental impacts of urban designs may be numerous, diverse and sometimes conflicting. The magnitude of the relationship between these different impacts shows potential dangers from decisions related to a family of impacts: solving a problem often creates another.

In this context, a large number of communities have taken initiatives to develop a new understanding of how urban systems work and how they interact with their environment. These tools are mostly based on sets of sustainability indicators (Mori 2012). They are supposed to help urban practitioners to design and to implement comprehensive plans (Alberti, 1996; Briassoulis, 2001; Brandon, 2005). At the same time, specific international programs have been created to develop and

Luc Adolphe is a full professor at the Institut National des Sciences Appliquées de Toulouse, Tathiane Martins and Marion Bonhomme are Research fellows at the Laboratoire de Recherche en Architecture, in the Ecole Nationale Superieure d'Architecture de Toulouse, France. Catherine Dubois is a Research fellow at the GRAP laboratory, in the School of Urban Planning, Architecture and Visual Arts of the University of Laval, Québec, Canada. Benjamin Rousval is a Research fellow at the LAMSADE, in the University of Paris Dauphine, France.

harmonize urban indicators worldwide, such as UNCSD (Stiglitz, 2009), OECD (OECD, 2011), (UNU, 2012).

Simultaneously, the urban decision is renewed by the eruption of sustainable development, and virtually all communities share concerns for the state of their environment.

The architectural design and urban planning processes are critical to global sustainability, but there is no consensus on how to model this sustainability (Owens 1986; Newman and Kenworthy 1989; Adolphe 1995; Tanguay, 2010). During these processes, practitioners are looking for solutions based on “reasonable compromise” between non-homogenous constraints instead of collecting optimal but partial answers: a new culture of the consensus that aims at "un-optimizing" urban decisions.

A rising information level characterizes this process. In the early stages, the information available is low because it is impossible to apply straightfully all the constraints: design is a wicked problem (Conklin, 2005). Indeed, the early design stages of these processes have a hegemonic weight related with fundamental architecture, urban and technical choices. At the beginning of the process, the importance of design choices is maximum; at the end, it is minimum. This context of problem solving has been baptized “the paradox of the architectural or urban design process” (Adolphe, 1995) - see figure1.

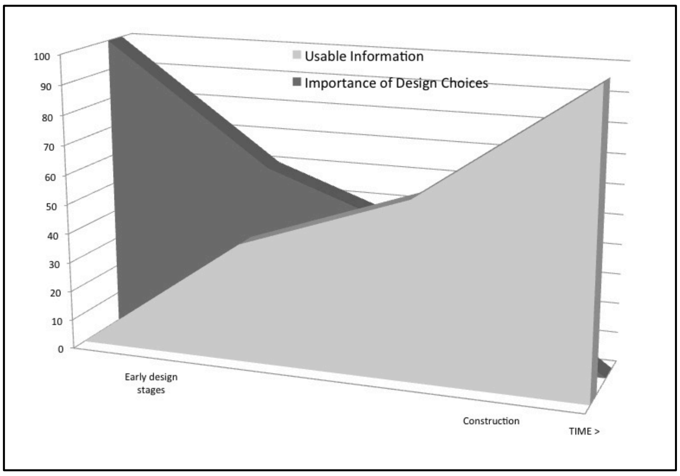

Figure 1 The paradox of architectural and urban design (Adolphe, 1995)

Therefore, the potential consequences of design support tools are highest in the early stages. They should rely on simplified but robust information on the design. The architectural design and urban planning processes are lacking for decision or evaluation support tools, especially during the critical configuration phases for the modeling process of cities. One of the main difficulties on building these tools rises with the simplification needed for modeling various urban elements and their relationships. In that sense, new research approaches have recently tried to fill this gap by improving validation on test cases, by integrating ranking between architectural variations in real practices (Adolphe, 1995; Fontenelle, 2012), or by a better integration of demand side management (Dubois, 2013). Therefore, it is necessary to develop assessment tools based on simplified models compatible with the level of information available during the various stages of the design process.

SYSTEMS OF INDICATORS FOR THE SUSTAINABLE DEVELOPMENT OF SETTLEMENTS

In this context, the most promising family of urban evaluation tools are based on systems of indicators able to integrate a wide variety of problems and the complexity of their interrelations in the space and the time (Adolphe, 2001; Josza, 2005 ; Adolphe, 2008; Adelle, 2009). The sets of urban indicators contribute to the building of systems in which development and environment are completely integrated. But currentlythese sets of indicators still remain very heterogeneous in terms of purposes as well as content.

But what is an indicator? Generally, indicators quantify information by aggregating different and multiple data. In short, “indicators simplify information that can help reveal complex phenomena”

(TERM, 2001). Compared to raw data used for example in the urban databases, single indicators are used to model the reality into decision support tools. These indicators would provide a representative picture of environmental conditions; being scientifically sound; being simple and easy to interpret; providing a basis for comparisons at various scales; integrating a target or threshold against which to compare environmental quality and performance (Alberti, 1999).

Therefore, how to build proper systems of indicators that exceed thematic, alphabetic, or just concatenated lists? How to interconnect indicators in systemic approaches characterized by strong interactions between subsystems?

Some characteristics of these systems are fundamental: 1) an indicator means nothing out of a system: there are strong links between indicators in a system; 2) a system means nothing elsewhere refering to fundamental issues. It is therefore necessary to build different systems for regulation compliance, decision support, simulation and evaluation; 3) a system means nothing without mixing physical, social, political scopes: each geographic scale or each actor may develop a specific system of indicators.

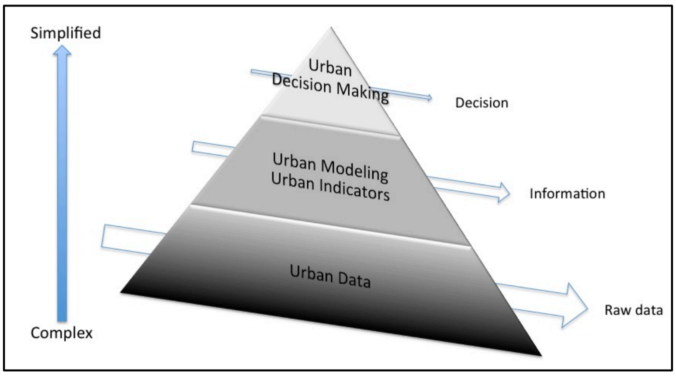

Figure 2 : Decision pyramid , from raw and complex data corresponding to real world, to simplified and abstract models useful in the decision process.

The first stage of building these tools is typically a structural stage. Some models have been developed to structure these systems: the PSR model "Pressure, State, Response" (RESPECT 2000) ; the DPSIR model : "Driving forces, Pressure, State, Impact, Response" (TERM, 2001); the DPSEER model : "Driving forces, Pressure, State, Exposure, Effect on Humans, Response" (Webster, 1996).

The second stage of constructing these indicators sets may rely on the aggregation of indicators into single index or composite indices. In the context of the sustainable development, one can say that this aggregation makes it possible: 1) simplifying, by reducing complexity, or simply reducing a great number of data into a smaller number of useful information for the evaluation; 2) quantifying, by modeling, simulating, and by building a comprehension of the phenomena and stakes; 3) communicating, by helping the decision makers to give their own opinion within the framework of a negotiation, an equitable exchange.

As a conclusion, the indicators are now popular and widely used in all organizations working on sustainable development. A consensus appears at least on the general characteristics of indicators. A good indicator needs to condense meaningful information into simplified, relevant, reliable, transparent, workable, synthetic, robust and correctly interpreted at the appropriate geographical scale. However, construction of current indicator systems suffers from serious methodological flaws.

The most important limitation of the current systems may be related to their construction method: these systems are based on a bottom-up approach, starting from the available data, without a global reflection about the goals to achieve. As a result, their gain to improve sustainability performance has been often limited (Alshuwaikhat, 2002; Seabroke, 2004).

The implementation of exhaustive top down approaches, starting from the fundamental concerns of the users of the system, to format and select the indicators could solve this problem. However, it should then iteratively combine with operational bottom-up approaches to reach a good compromise.

FROM SYSTEM OF URBAN INDICATORS TOWARDS DECISION SUPPORT TOOLS

To answer to this combined approach, we have moved off from this classical exercise of indicators concatenation, and to propose real decision support tools of the sustainable evaluation for urban projects, within an innovating morphologic and structural framework. This framework is based on the implementation, of multicriteria aggregation techniques. These tools allow to compare "the non-comparable", while implementing non-commensurable criteria or criteria which can get into conflict.

The main methods of multicriteria aggregation are primarily interested in alternatives or actions (Roy, 1985). They aim at putting forward the one or the better decisions to be taken, in comparison with the preferences of the decision-maker. These decision support tools are based therefore on a relative assessment: projects are compared to other ones in terms of sustainability performances. Some approaches are based on ELECTRE type methods, for ELimination and ChoicE Corresponding To Reality (Roy, 1993), and pairwise comparisons made without trying to bring the various criteria on the same scale value. They are able to manipulate complex concepts such as indifference, preference or veto thresholds to cope real-life decision context (Rousval, 2005; Fontenelle, 2012).

The multicriteria evaluation contributes to an exhaustive and synthetic census of information, while clarifying the results produced by the collections of indicators specific to each family of themes. The multicriteria evaluation is composed thus of two essential and indistinguishable aspects: the structuring model of information on the one hand and, the relative weighting of these criteria on the other (Adolphe, 2006).

The methods of partial aggregation are different from global aggregation ones mainly due to the three following aspects:

1) Data: evaluations of the indicators must be clear, probabilistic or fuzzy.

2) Operators of aggregation: the comparison of the evaluations of the criteria for each action can be performed by simple or complex fuzzy function (probabilistic or fuzzy evaluations). The over-ranking relationship between actions is established when a majority of criteria is better for an action than its competitor. The relations of indifference and incomparableness are also defined. The whole preference relations correspond to the criterion of over-ranking which constitutes the value of homogenization. Each preference relation represents the direction and the intensity of the preference between two actions.

3) Systems of preference: the decision makers define the weighting coefficients for the families of sustainability criteria.

This approach has been successfully used to evaluate the urban sustainability performance of urban designs at the district scale, in the SAGACITE Project (Adolphe, 2002). This project addresses the environmental influence of urban morphology at the neighbourhood scale. This work puts into perspective, objective indicators built from in situ measurements and environmental modelling, and subjective indicators related the perception of the users. The project is based on the simultaneous consideration of three concurrent areas: building, vegetation and transport. This resulted in the production of a decision support tool based on a Geographic Information System (GIS). This computing platform permits monitoring of existing urban projects (an “environmental dashboard”), comparison (intra or inter-urban) between sites, and scenario for urban spaces, taking into account environmental issues.

But the main limitations of this family of decision support tool are linked to the fact that they are based on relative assessment linked to partial two by two evaluations of actions. For most of the architectural and urban projects, practitioners are more obviously looking forward to compare their project with generic goals linked for example to its sustainability: this represents the shift between decision and evaluation support tools.

FROM DECISION TO EVALUATION SUPPORT TOOLS

"The evaluation process aims at quantifying and/or qualifying a system, thanks to all necessary information for building criteria allowing to attain the objectives concerning this system and pertinent in the framework of a wider activity but previously identified". Therefore the evaluation consists of "an assessment using criteria for achieving objectives or the degree of proximity of a project compared to a norm" (Abernot, 1996). Therefore, we distinguish the *decision*, for which we will compare several projects, based on a "relative" comparison (Roy, 1993) and the *evaluation* for which we will compare a project to goals or user's value systems, based on "absolute" comparison (Keeney, 1996).

The main motivations of these value focused approach are: 1) building a system of values as a reference for the evaluation; 2) knowing the reference system to understand the result of the evaluation; 3) explaining the system of values to justify the result of the evaluation; 4) communicating the system of values to build a consensus; 5) encouraging debate around the result of an evaluation; 6) monitoring the evolutions of the reference system for understanding the evolution of the evaluation.

In a first stage, we give privilege to the top-down approach, by defining the decision-makers' preoccupations for structuring the system of indicators, and by using a formal reconstruction system for the indicators selection.

When the object represents a major issue for the decision-maker concerning his position, it is a final objective, as opposed to the objective as a mean, which does not represent an end by itself for the decision-maker, but a means to reach a final objective. A strategic objective is a final objective that has the characteristic to be invariant during the time. A final objective can be decomposed; a means objective can be linked to various other ones (Fig.3-4). It is therefore possible to construct a structure (or hierarchy) of objectives for each decision-maker. To build the most exhaustive possible body of objectives, it is necessary to interview people representing each user group (Fig.5).

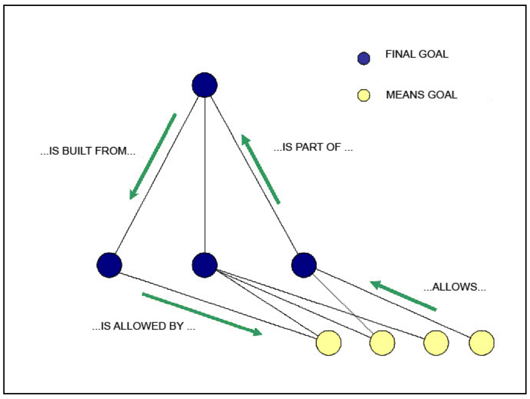

Figure 3 Relation between final and means objectives

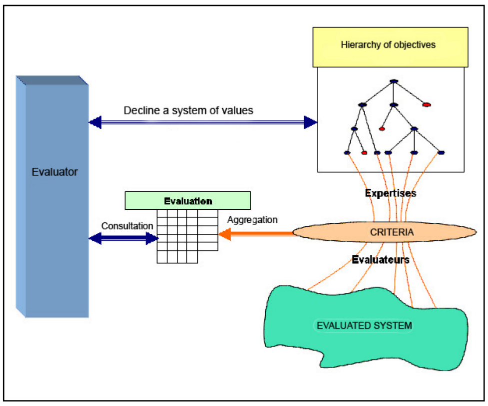

Figure 4 Application of the Value focused approach to our project (from Rousval 2005)

This value focused approach offers numerous advantages. It allows an interdisciplinary approach where the definition and the ranking of objectives structure the construction of the indicators system. It allows balancing objectives by propagating the weight in the hierarchy. Non-experts may use it to question and to structure the problems. At last it is easily applicable to wider contexts, such as sustainable development. The interviews are conduced in two stages. The first stage aims to define a first body of objectives. One lets the interviewee speak while asking non-directive questions. Taking some notes allows, then, to do a first census of objectives that appears along the interviewee speech. The second stage aims to explore the objectives that emerged from the interviews in the first phase. Thus, one can relate a means objective to an end objective while asking the question "Why this objective?". From a final objective, one can construct his superior hierarchy (bottom-up). To explore in depth the tree of the final objectives (top-down), one may ask "why this objective is important?" or "which facets of this objective are important?" (see Figure 5).

The last but not least advantage of the value focused approach is "the union" of several hierarchies, into a generic structure, while using a specific algebra (Keeney, 1992). One can thus structure the design of the system of common indicators for a population of decision-makers (Figure 6).

At last, we take into account the preferences of the decision-makers while using a multicriteria support method, the Electre-tri method (Yu, 2003). By using this method, it is proposed an ordinal evaluation of each objective.

- To master the environment
  - At the planetary scale
    - To preserve an environment in favor of human life
      - To limit the greenhouse effect
      - To limit the climatic change
      - To protect the ozone layer
    - To preserve the natural resources
      - To limit the extinction of natural types
      - To limit the extinction of natural environments
      - To limit the consumption of energy
    - To limit maritime pollution
    - To limit the production of persistent losses
  - At the local scale
    - Concerning natural environments
      - To limit impoverishment of landscapes
      - To limit the mineralization
    - Concerning human environments
      - Concerning public health
        - To limit the effects of the pollution of the air:
          - Of the peaks of pollution
          - Of mean pollution
          - To limit the effects of the accidents
        - To limit the effects of the noise on health
      - Concerning the life quality
        - To limit discomfort :
          - Due to noises
          - Due to smokes
          - Due to the odors
        - To improve the landscape
      - To improve cultural inheritage
      - To improve neighborhoods
      - To preserve the habitats from dust...

Figure 5 – Reduced and filtered hierarchy of objectives (from Rousval, 2005)

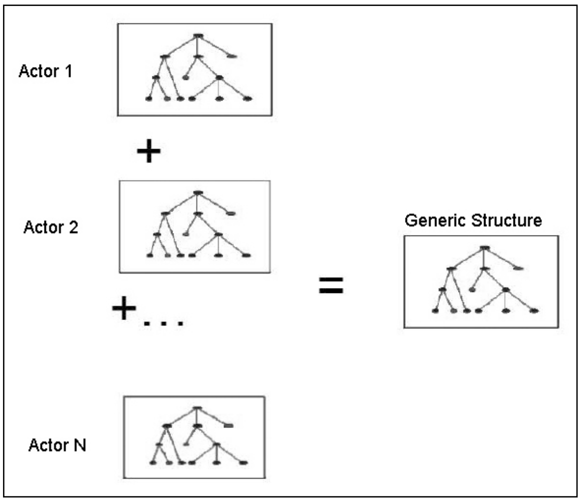

Figure 6: Union of deciders' hierarchies of goals into a generic structure (From Keeney, 1992).

This approach has been successfully used to evaluate the performance of urban sustainability of urban projects, in the PIE Project and to evaluation of sustainability of urban districts in developing countries (Adolphe, 2006). The "PIE" project aims to establish the specifications of a tool for the assessment of the environmental status of a geographical area selected in relation to the pressures (air, noise, water and soil pollution, impacts on space, on landscape, on fauna and flora, waste) enforced by the transport system. This tool for urban decision makers is based on sets of indicators structured by type of pollution. It enables a multi sectorial diagnosis from an aggregation of some (or all) of these indicators. These sets of indicators are based on two concurrent approaches: a top-down "back casting" approach based on concerns or objectives of decision-makers, and a bottom-up approach which starts from the operational constraints of the system. This tool uses multicriteria decision techniques allowing aggregation of basic indicators in sectorial indicators, and the construction of an operational approach for aggregating preferences of users of the system. This tool allows comparing the environmental impacts of different transport modes, technologies and policies.

The interests of this approach as well are numerous: the possible use of thresholds to consider the inaccuracy/uncertainty, the adequacy with the sorting approach, the comparison of the alternatives to a stable reference, the modularity, and finally, the incomparableness and no-compensation. The disadvantages are a weak readability and the lack of transparency. Possible applications of this method are the creation of a "global sustainability indicator", the support of activity-based "participative democracy" and the evaluation of "local and personalized follow-up".

CONCLUSION

Our work proposes a methodological framework for the decision and evaluation support of sustainable architectural and urban projects. The opportunities to use decision and evaluation support tools in the design or in the management process of architectural or urban projects are numerous. By simplifying a vast amount of information into a simple form, they make it much easier to read and understand complex reality and to help a new understanding of how urban systems work and how they interact with sustainable development at various scales (Alberti, 1999).

In a context where urban policymakers are, more than ever, challenged by the task of redirecting urban mutations into a more sustainable way, these new approaches are very challenging because they allow a good integration of the cultural or social dimensions of development. There is no point in building highly efficient cities, if they are not appropriate by their users, or if the spaces created do not meet their expectations or the representations of such places. “Sustainability, at the community level, is perceived as a holistic concept and not simply the sum of the environment, economy, society, and culture. The links among these components are established by the people and expressed in terms of people needs and aspirations” (Alberti, 1999).

We think that introducing these techniques into the design management process of architectural or urban projects brings new opportunities such as: 1) Avoiding to “bury” the practitioners in a proliferation of often conflicting and specialized information and constraints: help them keep up controlling the process that they are expected to master, so forth avoiding a divorce between design and production; 2) switching to a strategy of design “optimization” to a strategy of “reasonable compromise” between various constraints.

On the contrary, the limits and threads of these approaches are mostly linked to the context of sustainable urban development process itself. The decision is very complex and strongly context-related. Each new project is for example leading to a new set of indicators (Tanguay, 2010), and new user defines its own system of values (Kahn, 2006). These new tools are not designed for an automatic design but rather as a decision support in a specific governance context (Litman, 2011).

We have successfully integrated these various techniques to evaluate the performance of urban projects in developing countries in terms of sustainable development (Adolphe, 2006). The next step is to interbreed various themes simultaneously, such as building and transportation (Santos, 2013). Another development envisioned is to focus on the robustness of these systems, by testing the resilience of the threshold measurements. Even though this assessment presents difficult tasks, it is an unavoidable step in order to translate that new knowledge into effective policies.

ABSTRACT

The need for more environmentally responsible practices is unquestionable in the scientific community and the construction is responsible for a large part of energy consumption and consequently for the environmental degradation. It is the architecture`s duty to modify this panorama, intervening in a way that is conscious and alert, both environmentally and socially, following the development of societies and their emerging needs. This paper aims to develop an intervention strategy, in an underdeveloped region, more specifically, in Cunene in southern Angola, projecting a model of pilot schools, low cost and with low incorporated energy costs, duly adapted to the climate specificities. The Cunene is an Angolan region which obtained most of their livelihood over time with the livestock. However, like so many other places, it lacks of educational structures that enable its development and that provide higher levels of learning to the community. The project includes the use of local ecological materials such as earth and bamboo. Enabling people to participate in the entire construction process, by moving knowledge to enable the development of the local economy, particularly in the production of adobes. Therefore, the community and the man have an active key role throughout the project. The land is withdrawn from a nearby project site, by appeal to human labor instead of the machine. In the case of bamboo, it is anticipated planting a species that best suits the local climate and construction. The whole proposal is designed so as to respect the three basic pillars of sustainability: economy, environment and society. Allowing these locations to progressively develop and so that social justice can be found.

INTRODUCTION

The present case study is located in the Cunene region, in the southern border of Angola. This choice is directly related to the evident lack of educational infrastructures in the region, as well as the high number of children outside of the school system and with the conviction that it is fundamental to invest in education in order to develop populations that reside in remote locations. It is essential to the decrease of illiteracy among its people and vital to the local and regional development.

According to various studies, most of the poor population on earth lives in rural settings. In this sense, the education of the population becomes extremely important and the community must participate in this process, becoming the foundation of the local development, while promotion civic and educational developments.

GENERAL FRAMEWORK OF THE ANGOLAN TERRITORY

Angola is located on the west coast of Southern Africa, bordered by the Republic of Congo to the north, to the east by the Democratic Republic of Congo and Zambia and Namibia to the south, making a land border of 4690 km. To the west it is bordered by the Atlantic Ocean shipping line corresponding to 1650 km long. (1)

The Angolan territory corresponds to a total area of 1,246,700 km2, dividing them into 18 provinces, which in its turn are divided into 163 municipalities subdivided into communes.

The official language is Portuguese, spoken mainly in the cities. However there is a panoply of other languages used by its inhabitants, being distributed by well-defined geographical areas. The better-known languages are Umbundo, Quimbundo and Quicongo.

According to the last census in Angola, which dates from 1992, it was estimated at 10.31 million inhabitants, mostly from rural areas - about 6.159 million inhabitants - which corresponds to 59.7 % of the total population.

The oscillations of the population have always been a constant in Angola, especially during periods of civil war, that caused constant displacement of the population, migrating to cities or emigrating to neighbouring countries.

Currently there is a steady exodus of younger people from rural to urban areas, in search of better quality of life, particularly due to the growing job search. So it becomes even more evident the need for emergent interventions in remote areas, unprotected and devoid of infrastructure resources, as well as becoming increasingly depopulated. This migratory population exacerbates already serious problems of uncontrolled growth in the suburbs, where extreme poverty is evident, showing serious housing, health, employment and illiteracy issues.

Several studies show that the majority of the African population is young with low education levels, a result of various factors - including the Civil War action - as well as economic and social factors, on which the action of the state is not sufficient to meet the current needs.

The climate in Angola is divided, generally, into two seasons: wet and hot summer, corresponding to the months from October to April and winter (known as *cacimbo),* corresponding to the months of May to September, dry with lower temperatures.

The morphology of the Angolan territory develops about 60% in highlands, which naturally influences regional climates. Cumulatively, we can see the influence of the cold Benguela current and the coastal breezes. All these factors are responsible for small local variations in climate, although the average annual temperature is high throughout the country.

Education in Angola

Focusing this document in our area of research: primary schools in remote environments, more specifically in the Cunene region, we realize the organizational logic of education in Angola.

The Angolan education system is divided into three levels: primary, secondary and tertiary. However, in order to reduce the deep levels of illiteracy and lack of education of a large population, noted mainly in rural areas, the subsystem of adult education emerged.

According to Trade and News Magazine, *"22% of Angolan children of school age are out of school in urban areas. In rural areas, the estimate is 44%. Failure at school measured by the sum of the rates of repetition and dropout is extremely high, reaching figures of around 50% for 1st and 2nd grades. 42 % for 3rd level of Regular Education. Regarding the dropout rates, the statistics presented indicate that 12.5% of children drop out of school in urban areas and 25 % in rural areas (...) "* (3)

It is noteworthy that the few schools operating in remote areas, hold serious construction problems, not being provided with the basic conditions for an adequate level of education. Many of these classrooms are constructed using solutions of "wattle and daub", using only local materials easy to obtain. However, the lacks of constructive knowledge, either endogenous or technical, have limited the quality and number of suitable classrooms.

Serious socio-economic problems, seen in this country, such as extreme poverty and social inequality are due largely to an inadequate education system, the result of prolonged civil war, and also due to the lack of physical structures and educational resources that enable a way of integrating active citizens in local and regional growth.

Figure 1 Classrooms at the Catholic mission of Okaunatoni, Cunene, in May 2013.

The lack of adequate primary schools subsequently condemn the formative and educational capacity of its citizens and inherently stall the growth of the country.

In remote or rural settings, this reality accentuates migration to the big cities, forcing this population to survive in the suburbs, deprived of employment opportunities or minimum health conditions, whereas if provided with adequate training in their unique environments they could secure better livelihoods and resiliency within their communities, thus enabling local development of consistent and sustainable manner as an alternative to migration to cities.

IMPLANTATION OF THE PILOT PROJECT

The proposed project intends to develop as a model for regions with the same geomorphological, social and human characteristics, duly adapted to the constructive specificities of each place.

It is located in the Catholic Mission of Okaunatoni in Cunene, southern Angola. And due to its difficult access, where most of the roads that connect to the mission are made of sand and because it is situated about 30 kilometers from the nearest locality - Xangongo, the resources and labor become scarce and difficult to obtain; there is an absence of construction companies operating in the local, or the ones that eventually mobilize to these places present honorary fees incompatible with the most disadvantaged populations. These factors, in addition to those that will be mentioned later in this article, reinforce the need for a project made by people, using locally available materials and easy construction.

Figure 2 Location of project implantation and current location of the classrooms at the Catholic mission of Okaunatoni, Cunene. No scale.

The considerations / limitations with the surroundings of the project, with local populations or climate conditions are some of the criteria to be taken into account in formal conceptualization of the design solution. We intend to develop a solution that is functional, educational and acts as an empowering tool for a constructive change paradigm based on locally available materials.

We intend to use locally extracted materials, with local labor, and give men and women leading roles throughout the construction process, contributing to a more active and participatory architecture. Therefore, the communities will be taught new valances that will enable them, in the future, be able to build their own houses as well as doing its maintenance, without being limited to the will of the government, which little supports these more remote communities.

The architecture has a key role in developing a methodology grounded in research and construction methods validated laboratorially, which will optimize techniques and local resources to build sustainable buildings at a low cost, such as the present study. The construction of pilot schools, with subsequent measurement and validation will ensure access, quality and educational equity to local populations.

The architect gains a role on this project that becomes more than an agent of change, beyond the designer role, contributing to the socio-educational integration of people and hence the sustainability of the most remote locations.

The aim of this work was to define innovative principles and essentially structural design recommendations for building cost-effective pilot schools for the regions of sub-Saharan Africa, anchored in bioclimatic principles and constructive, economic and environmental sustainability, addressing the specific conditions of each target region.

Main Planing Principles | Case Study

In this proposal we develop a series of bioclimatic principles that claim, through a rational use of natural resources, to better integrate the school building on site as well as reduce the costs of future maintenance of the same, ensuring comfortable and properly balanced environments, adapting available to local and improving their technical reality resources, so enabling them to prolong the life of the buildings.

Immediately we will consider the actual shape of the building, including its design. The solar orientation, natural ventilation and the correct choice of materials are essential principles for an integrated and properly adapted architecture.

The program of the proposed building is relatively simple, consisting only of two blocks of classrooms and a separate block with their sanitary facilities and a covered outdoor living space. Trees are to be planted in the patio, so as to ensure greater shading of buildings and, on the other hand, to ensure a slight cooling of the temperature. The shape of it will also be a simple consequence of the program itself and the choice made on the construction of the building: local materials and local labor.

The buildings will be deployed on a slightly raised platform floor level, thus protecting them from the risk of flooding - very common in the region - and secondly, to avoid the excessive wear and degradation caused by the action of water on the foundations and walls of adobe. This way the foundation and plateau will be built, if possible using stone, and in its absence, using repellent mortar in order to consolidate and stabilize, if exceptional circumstances of flooding may occur.

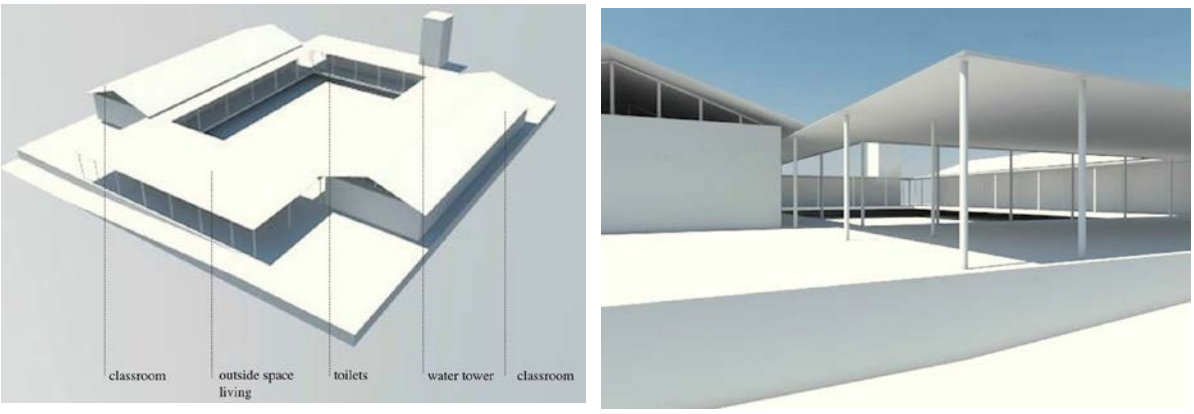

Figure 3 Organizational schemes of pilot school, Cunene, Angola.

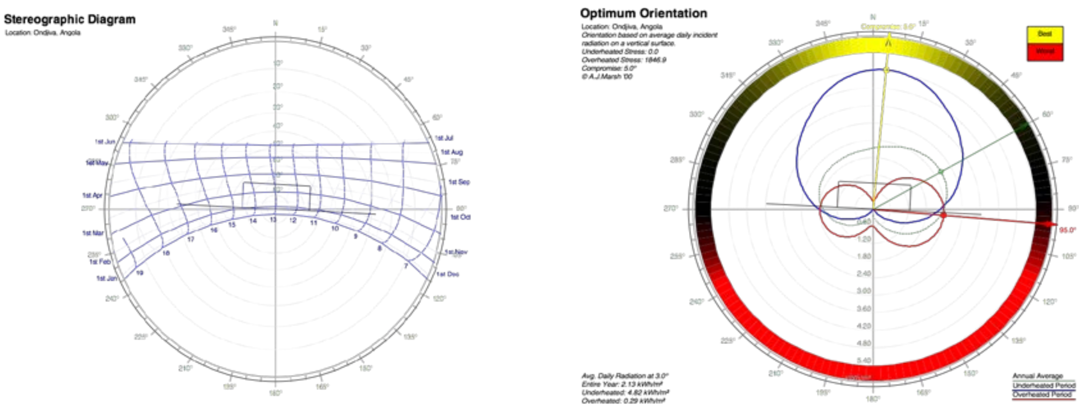
Figure 4 - Angola' s map - Ondjiva (17°01'40.4"S 15°03'06.6"E)

The walls in raw ground work as support to a structure of bamboo which will anchor the coverage of the building, coated by sheet metal. Adequate ventilation of the building will be ensured by gables, releasing the wall of the casing, thus contributing to the cooling of indoor spaces and to reduce moisture levels, asserting the air quality and comfort.

The school will be located under the guidance recommended in Figure 5. These studies as well as showing the solar path in Ondjiva, during different periods of the year, show us which is the optimized solar orientation for this region.



(a) (b)

Figure 5 - (a) "stereographic diagram for Ondjiva, showing the solar path in the various periods of the year" (b) optimized solar orientation for Ondjiva (5 º C) " (4)

The special configuration responds to the better orientation of classrooms, oriented in east / west direction, with the biggest facades turning to north and south, getting the best sun protection as well as lighting. Similarly, the toilets are placed intentionally so that setting the assembly to solar radiation throughout the day and year, as it may function as a natural sterilizing action of such areas that require greater care and control of fungi. It was also ensured a covered patio to the east, as well as outdoor galleries to ensure sheltering from rain and solar radiation to users throughout the year.

As mentioned earlier, this study serve as a prototype intended to be "replicated" in other places, with human, social and economically similar characteristics. Most importantly, we must bear in mind that "new projects" have to meet with the real needs of populations and adapt to the context in which they are entered, including solar orientation, the wind regimen, the labor and locally available materials. Therefore, it will be enabling a better adaptation of the shape / design of the place where the constraints will be installed.

Applied Materials

The earth as a building material has been the subject of some reluctance in the target countries of study, as its use is associated with a stigma of poverty and insecurity that people want to avoid. However, it is essential to realize that this preconceived idea is anything but reasonable and realistic. Initiatives to improve these communities should meet their needs, and earth is a material that fully meets the needs of the community, with economic and environmental advantages and ease of application with hand-local labour benefiting from this.

It is a local, natural, recyclable, non-polluting and foremost reusable material. A building on earth can simply stop being and the material returns to its origin being returned to nature without intervention or expenditure of energy or human action, characterizing the earth as a material with a closed cycle. Although besides these qualities, many other criteria lead us to choose the land to the detriment of other materials.

In hot climates, such as Cunene, issues relating to thermal inertia of the materials are very relevant and should be taken into account when designing a school building. The earth has the ability to regulate and smooth the external temperature fluctuations, maintaining the coolest spaces in warmer periods and in turn, maintaining milder temperatures when the weather cools, particularly during the daytime and night time periods.

The soils in Cunene region are very sandy and as such they require a binder material that unifies the mixture and makes it cohesive, capable of being used for construction. Consequently the addition of other materials in order to correct this situation is required. It is expected to be mixed lime or cement, whichever is easier and convenient to purchase on site.

Despite the obvious durability that buildings have on earth, simply because there buildings constructed with use of this material continue to leave your testimony in our landscapes, studies have been shown that the addition of other stabilizing components prolong their good conservation and avoiding construction issues, their natural erosion, particularly that caused by water.

Figure 6 "Stretches of rammed earth walls exposed for 20 years to atmospheric agents: (a) wall, stabilized with 5% lime earth; (b) on the ground without wall stabilization (mixed soil); (c) Wall ashore without stabilization;" (5)

The study corresponding to Figure 6, aims to demonstrate that the addition of stabilizing elements, such as lime, protects the walls exposed to weathering, from the erosion that is naturally subject. Consequently the stabilizer prolongs the good condition of the building, providing more stiffness and durability.

Since the buildings on earth are already being disseminated in much of the territory and becoming a current practice in these environments, it is intended that the community re-acquires the right knowledge, and adjusts its implementation and that consequently there is a constructive improvement of these practices. It is not intended that these techniques are vernacular revival, but rather, to adapt to new realities to constructive development. For all that, and the current resistance observed in these locations due to the onshore construction, we propose the application of plasters in order to address the weaknesses of the material.

Traditionally, in Angola earth constructions are already built with thatched roofs, but this material presents some weaknesses at the expense of others, especially in their natural susceptibility to the possibilities of fires. Cumulatively, the use of the stem for several years, has led to its gradual disappearance, not being available in construction sites, implying major shifts to its acquisition. Still contributing to the cause of the abandonment of this material, the current population has new rhythms of life that does not allow them to do the right and necessary maintenance to keep the stem is in good condition.

In contrast to stem use, we propose the use of sheet metal. This material allows for a lighter support structure, since the material itself has little weight. Its displacement and application is relatively simple and does not require maintenance during the lifetime of the building.

Even though it is not a local material and considered sustainable in origin nor incorporation associated with energy, it is affordable, durable, lightweight, flame retardant, low cost and easy to transport. The application of the coating material enables to lighten the supporting structure and by their individual dimensions of each sheet cut together, the weak points of rain and wind action.

To the support structure it will use the coverage at the expense of the bamboo wood, commonly used in the region. The bamboo has a relatively rapid growth compared to other materials, within 2-3 years it can be extracted from the site and is mature enough to be used in construction. We intend to proceed with the planting of a species in a nearby location that best suits the local weather conditions and has the height, diameter and thickness suitable to be used in the construction of the building.

Unlike wood, which requires a much longer process of growth and still requires the use of machinery to cut and modelling, thus incorporating more energy in its transformation and the consequent need for more expensive and complex equipment, bamboo uses are very simple, economical and without the need of power tools, verifying a minor impact on the environment.

After the extraction of the material - and this is in the place where it will be used - there is a mechanism of preservation, which in addition can prevent rapid degradation, since the material has little resistance to micro-organisms and insects, it will increase its durability. This process can be done in two ways: by chemical or non-chemical methods. In this proposal we will use a non-chemical process where the bamboo is stored in tanks of water and could thus decrease its starch content, which will consequently make the plant more resistant to biological organisms and increase its durability. This technique of leaching of bamboo is an ancient method and used for several years in different communities to protect the material from the draining action of organisms. However, its variation is directly dependent on the durability of the species concerned and it might turn this treatment insufficient and it is necessary to add a chemical components into the water so as to make tougher materials.

One of the objectives pursued, when the choice of materials is bamboo, is to introduce new materials, with easy extraction and handling, responsive to the needs of these communities. Since there is still a profound lack of knowledge about these techniques, the population tends to reject it, even if unconsciously, so you will need to "democratize" and promote its use throughout a process of adaptation to the material, instructing the local population so it will benefit from constructive greatness of it, as well as the possibility of its using in other capacities - not only construction, but also with applications in woodworking and carpentry, with the construction of furniture.

There are already some examples of buildings in remote means, which involve the use of bamboo to make the structure of your toppings. Among them, we highlight the Handmade School in Bangladesh by

the architect Anna Herringer and the Habit Initiative Cabo Delgado in Mozambique, by the architect Roswag Ziegert. (figure 7)

(a) Handmade School | Bangladesh (b) Habit Initiative | Mozambique

Figure 7 Bamboo structure construction by the local population

CONCLUSION

Local interventions of apparently little scale have global repercussions. It is vital that we intervene locally so that the long term scenario is different, dignifying the most disadvantaged communities.

However it is essential that the scientific community realizes that behind the choice of certain materials are rooted local prejudices that must be understood and taken down or assimilated and managed for an innovative solution that can be attractive and harmless on local traditions. The blind imposition of new solutions seen as superior risks the non-assimilation and not being fully understood by the target population. All communities have their patterns and desires that must be respected and reconciled in the intervention. Concessions on certain points of intervention should be taken into consideration, as the scientific community should cooperate and not solely teach, share knowledge and not just impose.

Photographic examples of schools considered "bio" and "eco" in remote environments advertised as examples for the scientific community are constant in failure in their places of deployment, for they were not assimilated by the population, resulting in innocuous buildings without result in pilot examples for the region. Certain orthodox and rigid solutions without added local inputs resulted in unique and beautiful examples, but not replicated, either by training difficulties of the population, or simply by their lack of identification, assimilation and understanding of forms of use, habits and customs.

It is our understanding that a sustainable conceptual solution for the measurement and scientific validations should be downstream of understanding anthropological and socio-cultural assimilation, and incorporate local religious architecture in the draft. This should just be a reflection of local and scientific assignments and reconciliations.

Acting locally avoids successive massive displacement of populations to cities and consequently decreases the informal, illegal and uncontrolled development in the outskirts of cities. Remote, inhospitable and prone to decay stands can gain new lives with this kind of interventions, that are beyond architectural, becoming social and economic transformations.

ABSTRACT: Is India on a sustainable road or not? Between April 2012 and January 2014 the authors have conducted a quantitative paper and online based user survey on energy awareness and attitudes in Mumbai, Bangalore, Chennai, Delhi, Pune, Hyderabad, Ahmedabad and Kolkata. The survey was part of the project "Clime Related Energy Efficient Design - Product Solution (CREED-PS)" first funded under the aegis of Germany India Year 2011-2012 "Germany and India: Infinite Opportunities" with a focus on "City Spaces" and then as part of the project "DWIH Excellence on Tour. 2013-2014." More than 2000 visitors were interviewed during the events about their individual energy consumption, their knowledge of selected energy issues and energy efficient building design and their sustainability attitudes. The majority of the visitors are part of the academic middle class group in India's Megacities, as a limited group of India's society. One of the main results are that living in energy efficient residences is very important for most of the respondents, although two third don't know exactly the energy consumption of their household. Yet, most of the respondents are willing to spend more money in energy efficient and energy saving building devices and household equipment. Summing up one can say that the interviewed middle class group (Shukla, 2005, Mawdsley, 2004) is on the sustainable road, although we have identified several inexplicable contradiction in knowledge and awareness as topics for further research work that are relevant for building and product design. This paper illustrates on the one hand the use of survey as part of an integrated design process and suggests on the other hand collaborative approaches to educating architecture and design students about sustainability in building and product design.

Keywords: India, Energy consumption, Energy saving, Energy efficient building design, Sustainability, Standards of housing

INTRODUCTION

Today India is an emerging country with a 1.3 billion population (MHA, 2011) and a rapidly growing economy. The census 2011 estimated 168 million households in rural areas and 79 million households in urban areas. Most of Indian families and individuals still live in traditional rural houses or in buildings that are older thirty years. Yet, the economic boom since 2001, a growing middle class in Indian cities and the migration of people from rural areas to urban areas has accelerated a tremendous construction and investment boom in rapid sprawling metropolitan areas. According to the report of Global construction perspective Ltd. (2011) between 2013 and 2020 India will become, behind China and US, the third biggest construction market in the word with an annual growth rate of 8 %. It is more than evident that India with its high demand of construction material and energy consumption moves straight to a critical resource shortage and carbon emission collapse, if the government and the society do not counteract with sustainable strategies and action plans for energy efficient building design and energy saving technologies. With about 39 % of the total national energy consumption the construction and building area is the major energy consumer (de la Rue du Can, 2009).

In many discussions with Indian architects, scientists, energy experts and organization, e.g. the Bureau of Energy Efficiency (BEE) and the India Green Building Council (IGBC), it was mentioned repeatedly that the awareness and knowledge of stakeholders, investors and users plays a central role in the change process to more sustainability.

In general only few studies and publications about the mindset of the Indians on energy concerns are available. Alam, Sathaye and Barnes (1998) reported in an older survey of household energy use in the city of Hyderabad. The survey revealed the fuel transition from biomass-based fuels to modern fossil fuels and electricity in cities. Reddy (2004) using the data from the National Sample Survey (1983-2000), analyzed the dynamics of energy end-use in household sector in India. The paper reported that large variations in energy use exist across different sections of households urban/rural, low/high income groups, etc.

In 2011 the Mercom Capital Group (2011) conducted a survey on renewable energy awareness in the area around the cities of Bangalore and Mysore in Karnataka State. The limited survey based on 101 respondents of the rural area, 204 respondents of residential and 204 of commercial/industry. Overall findings of the survey were that a "general lack of education and understanding about renewable energy, though the people surveyed were very enthusiastic about renewable energy concepts". Only 39 % of the rural respondents have heard the term „renewable energy" or „clean energy", in difference to 61 % of the residential/commercial/ industry respondents. About 32 % of residential and commercial/industry respondents answered that they have installed solar water heater, 6 % have installed solar panels, 1 % used wind turbines, 2 % biomass and about 60 % had no application of renewable energy installed (Mercom Capital Group, 2011). Likewise interestingly is that 46 % of all respondents don´t plan to install any type of renewable energy in the near future and 62 % were not aware (rural 80 %) of any government subsidies for renewable energy.

In another national survey on "Climate change in the Indian mind" by the Yale University, GlobeScan Incorporated, and C-Voter 4,031 Indian adults were interviewed, using a combined urban (75 %) and rural (25 %) sample. This "study was designed to investigate the current state of public climate change awareness, beliefs, attitudes, policy support, and behaviors, as well as public observations of changes in local weather and climate patterns and self-reported vulnerability to extreme weather events." (Leiserowitz, 2012). The key findings concerning climate and energy policies were: "41 % of respondents said the government of India should be doing more to address global warming; 54 % said that India should be making a large or moderate-scale effort to reduce global warming, even if it has large or moderate economic costs; 38 % said that India should reduce its own emissions of the gases that cause global warming immediately, without waiting for other countries; 70 % favored a national program to teach Indians about global warming; 67 % favored a national effort to help local communities build check dams to increase local water supplies; a majority of respondents favored a variety of policies to waste less fuel, water, and energy, even if this increased costs; 53 % said that protecting the environment is more important, even if it reduces economic growth, while 28 % said that economic growth is more important, even if it leads to environmental problems" (Leiserowitz, 2012).

AIM AND OBJECTIVES AND HYPOTHESES

The survey aims to assess energy efficiency awareness of the users in India and potential for integrating the same in building and product design.

Overall objectives

The survey followed some overall objectives related to the described target group:

1. Identification of knowledge, attitudes, awareness and behavior on energy issues to develop new concepts for energy efficient buildings in India.
2. Identification of different climate-related and city-related life-styles, housing, and amenities demands.

3. Identification of awareness/needs/methods/approaches to improve the efficient building design for investors and the energy saving behavior of urban dwellers.
4. Involving businesses and corporate social responsibility for promotion of energy efficiency and sustainable consumption.
5. Identification of energy efficiency related topics for information and education programs.

Research hypothesis

The survey is based on the following hypothesis that should be proofed:

H1: Higher educated people of the new middle class in urban areas have a clearer awareness and higher needs on energy-efficient lifestyle than lower educated people.
H2: The higher the income of people the lower the awareness of energy issues.
H3: Females are better informed on energy saving and efficiency than males.
H4: Younger dwellers are better informed on energy saving and efficiency than older dwellers.
H5: People with high individual energy consumption are willing to spend more money for energy saving activities.
H6: A good residential place has a higher priority than the distance to the working place.

METHODOLOGY

The survey was conducted in Mumbai (April 2012), Bangalore (June 2012), Chennai (August 2012), Delhi (October 2012), Pune (January 2013), Hyderabad (April/May 2013), Ahmedabad (November 2013) and Kolkata (March 2014) during the events "Germany and India: Infinite Opportunities" and "DWIH Excellence on Tour. 2013-2014." The majority of the visitors are part of the academic middle class group in India´s Megacities, as a limited group of India's society. More than 2000 paper-based questionnaires (250 for each location) were disseminated and collected. All filled out paper-based questionnaires were captured automatically with a scanner. The statistical evaluation of the questionnaires was conducted separately for each city and altogether for all cities. In total more than 2000 visitors were interviewed.

The paper and online-based (CREED) questionnaire in English language was created with the web-based software (EvaSys)˙ Altogether the questionnaire was divided in 6 sections: (1) personal details, (2) mobility, (3) environment, (4) aspects for choosing the apartment/house; (5) environmental aspects, (6) general aspects. Questions were created in different formats (scale, single- or multiple-choice, and open).

In all automatically generated pdf-reports with EvaSys the case numbers were indicated for each question. Single-choice-questions and multiple-choice-questions were generated as a bar graph. Scale questions were generated as a histogram with average values, median values, and standard deviation. Additional the scale questions were diagrammed as a profile graph. Open questions were automatically identified and copied in the report as a picture-file. In the online-version open questions were recorded directly. For further statistical analyses the raw data were converted to an SPSS-file. The analyses were done with the statistical package SPSS version 20. In order to find out pattern in the data with a very strong correlation (r-value) and a very high significance (p-value) we conducted cross tabulation of age, sex, income, and occupation for all variables (items) in the questionnaire.

SURVEY RESULTS

General and Personal Data of the Respondents

More than one third (38.8 %) of the respondents live in a typical middle-class household with 4 persons. Nearly half of all respondents (45.3 %) were aged between 20 and 29 years. Only a small number of respondents (6.3 resp. 3.3 %) were older than 50 years. The majority of the respondents (77.7 %) were males. 65.5 % of the sample has a bachelor or master degree. This high %age depicts a strong focus on respondents with an academic background. The monthly income of the respondents is likewise nearly equally distributed. Probably the income group below 20.000 Rs. (37.7 %) consists predominantly of students, freelancer or housewives. 27.7 % belong to the lower middle class has a monthly household income between 20.000 and 40.000 Rs.. 34.6 % belong to the upper middle class has an income above 40.000 Rs. (Meyer and Birdall, 2011).

Priorities of Housing Standards

In the first part of the survey the respondents were asked about the most important factors for choosing a new residence as an indicator of life-style, social priorities and sustainability awareness. Fourteen (14) social related, building related, life-style related and energy related questions were provided. The highest priority to choose a residence was a high performance of the location (73 %) followed by security of the location (70 %).

Figure 1 depicts the confirmation resp. the importance of the fourteen (14) investigated factors on living standards in the eight included Indian cities. The respondents could answer between "very important" and "unimportant".

Q: To choose a residential for me is very important ... (% of respondents)

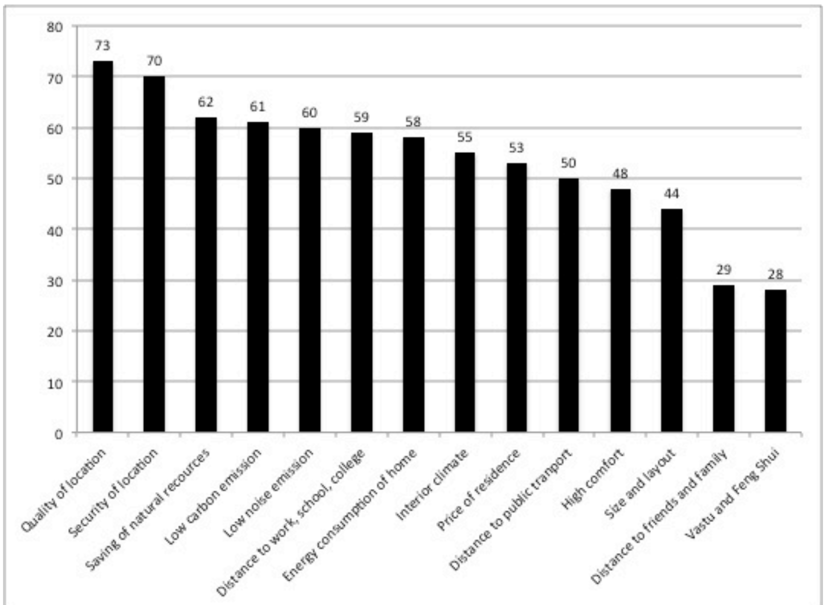

Figure 1 Overview of living standard priorities

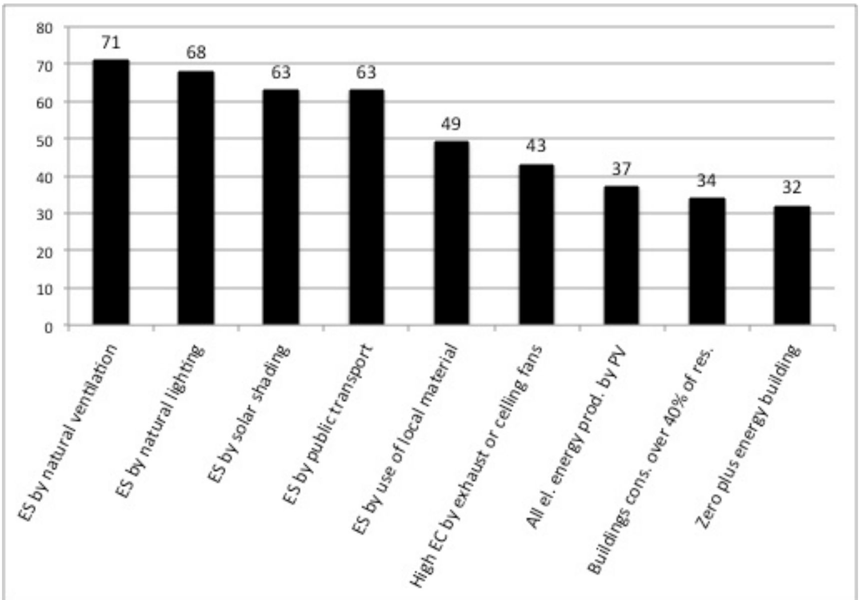
72.5 % of respondents consider a high priority of the location (district/quarter/street) for the apartment or house. This criterion of living standard has been the highest value of confirmation with an average value of 1.4 and a median of 1.0 with a deviation of 0.8. Because, this criterion implies a lot of sub-criterions like social and ethnic structure, population density, security, infrastructure (water and electricity supply, sanitation, garbage collection etc.), shopping opportunities, access to public transport, proximity to schools and kindergarten, cultural amenities, medical care and hospitals etc. The lowest confirmation of living standards of the respondents has "vastu" and "feng shui" with 27.9 %. A nearly equal share of 31.4 % find that unimportant. The age group above 60 years gives more importance to "vastu" and "feng shui" compared to other age group under consideration. The income group of 20,000 – 40000 Rs. places higher importance to "vastu" and "feng shui" in comparison to lower and higher income groups.

Other factors like saving of natural resources, low carbon emission, low noise emission, distance to work etc. and further investigated factors lays close behind the two top priorities. Amount of energy consumption, interior climate, price of residence, distance to public transport, home size and layout are less important factors to the respondents.

Environmental Knowledge and Attitudes

In the second part of the survey the knowledge and attitudes on building and product design issues should be identified. Nine (9) questions of use of material and electrical home equipment were provided.

The following Figure 2 depicts the knowledge and attitudes of the respondents on the nine energy related fields. The respondents could answer between “very familiar with …” and “not familiar with …” (% of respondents).



Legend: ES = Energy Saving; EC = Energy Consumption; PV = Photovoltaic´s

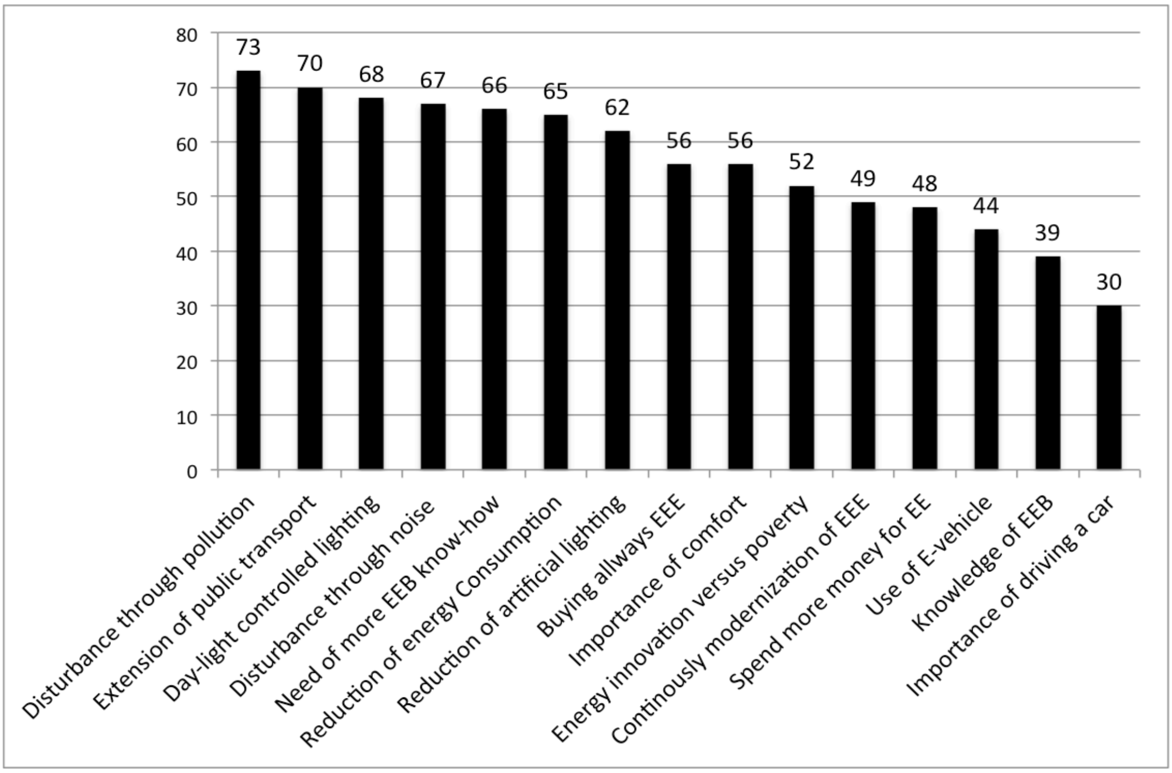
Figure 2 Overview of environmental knowledge and attitudes

71.1 % of respondents were very familiar with the fact that natural ventilation contributes to energy saving. A similar high confirmation of energy saving measure we have seen by the items of natural lighting (68 %), solar shading (63 %), and public transport (62 %). Saving energy by using local material (49 %) was not aware by nearly half of the respondents. Only 34.2 % of respondents were very familiar with the fact that buildings consume more than 40 % of all resources; 18.6 % were not familiar with this fact. 31.5 % of respondents were very familiar with the fact that buildings can produce more energy than they consume; 23 % were no familiar with this fact. As well only 32 % of the respondents knew that Zero Plus Energy Buildings could produce more energy as they consume. All in all these results shows a widely superficial knowledge of the respondents in the field of energy efficient building designs since the users are well aware of the basic energy saving measures like natural ventilation and lighting but they are not aware of the state of the art of energy savings strategies like zero or plus energy buildings.

General Attitudes of Housing

In the third part of the survey the general attitudes of housing related to building and product design was investigated. Fifteen (15) questions related to energy consumption attitudes were provided. The extreme poles of this question battery were on one hand side disturbance through pollution (73 % agree strongly) and on the other hand side importance of driving a car (only 30 % agree strongly).

Figure 3 depicts the general attitudes of housing in the fifteen items. The respondents could answer between “I agree strongly with” … and “I disagree strongly with …” (% of respondents) on Likert scale.



Legend: EEB = Energy Efficient Building; EEE = Energy Efficient Equipment

Figure 3 General attitudes of housing

The most important issue of the respondents is the air pollution. 73 % of respondents assert that air pollution is a very disturbing issue for them; for 91 % it is disturbing and very disturbing. The second important opinion focused on the extension of public transport (70 % agree strongly). In the following ranked items we found in general a linear decline of agreements. Yet, concerning the consuming attitude of the respondents one can consider a significant difference between the age groups. In general the older the respondents the more they have the attitude to buy energy efficient building equipment or amenities. In general one can assess a trend the higher income the higher are the tendency to buy always energy efficient equipment.

Interestingly, the alternative question that in the long term perspective innovation in energy saving is more important than fighting against poverty was strongly agreed by 52.3% of the respondents. This phenomenon is probably strong related with the particular structure, occupation, income, education, attitudes and behavior of the Indian middle-class. “It is by reckoning the most polymorphous middle class in the world.” (Beteille, 2001).

Concerning the knowledge about energy efficient buildings is was intended to measure the level and intensity of knowledge and information of energy efficient buildings. These values inform about the relevance of the topic for the respondents and for further information and promotion campaigns. 39 % of respondents assert strongly that their knowledge about energy efficient buildings is good, 70.3 % answer “I agree“ resp. “I strongly agree“. Between the age groups one can consider a tendency of higher knowledge in the age group 20 to 29 years and in the age group above 60 years.

48 % of respondents assert that they would spend more money for an energy efficient home, 79 % agree and strongly agree. The age group of 50 to 59 years has higher percentage of people who agree strongly for energy efficient homes. The group with higher income > 40000 Rs. place higher importance to energy efficient homes.

A deeper look into the age groups shows, that the high confirmation of the group above 60 years is very conspicuous and the increase of confirmation in the younger groups. The highest rejection one can see interestingly in the group below 19 years. Concerning the income groups there are no significant differences in confirmation or rejection. Merely in the income group 20.000 to 40.000 Rs. one can assess a higher value of rejection. Interestingly, in this question the “neither nor“ group is especially wide. All in all one can suppose a difference between to own a car as a status symbol and to drive a car actively under the current traffic circumstances.

CONCLUSION

In this article a selection of assessments of attitudes and awareness of energy consumption is shown and discussed. The hypothesis H1, H2, H3, H4 cannot be confirmed. In most of the measurements all respondents with a tertiary education have a clear awareness and a high demand of energy-efficient lifestyles. Females and males as well as older and younger respondents show no differences in the level of information of energy saving and energy efficiency. H5 and H6 can be confirmed. Respondents with higher energy consumption and a higher income are willing to spend more money for energy saving activities and a good residential place has a higher priority than the distance to the working place, although for choosing a residential place the proximity to the workplace or the college is very important.

Between the eight investigated cities the survey found no significant differences in attitudes and awareness of the respondents. The quality of the location and the security of the location have the highest priority. Air pollution is one of the most important disturbing factors. We assess a clear attitude for an energy saving and energy efficient residential place. Most of the respondents vote for a strong extension of the public transport system.

This survey shows a picture of attitudes and awareness of a selected population segment with mainly tertiary education. Although this group is very important for the economic and social progress in India, more data and information of urban population with low income and low education, and from people from rural areas with lower income level is needed. With this data it would be possible to get a more holistic picture of attitude and awareness of energy saving and sustainability. For that purpose further research is needed, particularly for the transmission to a deeper eco-friendly education and knowledge-building and pro-environmental behavior (Vlek and Steg, 2007, Steg and Vlek, 2009, Geller 2002, Altomonte et. al., 2013). The usefulness of the value-belief-norm (VBN) theory for pro-environmental behavior analysis has been successful tested and disseminated in the psychological literature (Stern et. al., 1999).

ACKNOWLEDGMENTS

The authors would like to thank the German Federal Ministry of Education and Research (BMBF), the German House of Research and Innovation (DWIH – New Delhi) and the German Embassy in New Delhi for their generous support to conduct the survey in India between 2012 and 2014. As well we thank our academic colleagues and their students, official authorities and CEO´s in India for the brilliant interaction, knowledge sharing and feedback. An outstanding technical support for the preparation of the questionnaires and as well as for the data analyses with EvaSys comes from Sabine Sommer, Ostwestfalen-Lippe University of Applied Sciences, Department for Statistical Analysis.

ABSTRACT

According to the adaptive hypothesis, contextual factors and past thermal history modifies building occupants' thermal expectations and preferences. This paper cites the findings of a research that was based on a field investigation, for a detailed understanding of perception of thermal environments, by students, inside typical classrooms of Dhaka, Bangladesh, during the pre-monsoon (hot-dry) and monsoon (warm-humid) seasons of a year. One hundred individual responses, by subjects in naturally ventilated classrooms, provided comprehensive data, through a standard questionnaire survey, which was then used for analysis of their responses and preferences, with respect to the measured indoor thermal environment. This research revealed that thermal adversities, encountered in summer, are quite well tolerated by the acclimatized and adapted students, of Dhaka city. The findings reconfirmed that sensation, comfort and preferences about air temperature, inside classrooms of this tropical country, are markedly different from set international standards. The 'neutral' temperature of the students was identified, which was found to be much higher than the international standard. Therefore, if thermal comfort standards are contextualized, for naturally ventilated classroom spaces in Bangladesh, it is likely to minimize the pressure on energy and allow for more sustainable architecture.

Keywords: Perception, Sensation, 'Neutral' temperature, Adaptation, Classroom environment

INTRODUCTION

Any comfortable environment is a holistic phenomenon, involving synergy of thermal comfort, indoor air quality, other environmental factors, such as, the type of building and its psychological relevance for the occupants (Croome, Gan, and Awbi, 1992). According to ASHRAE 55-2004, thermal comfort is a subjective response, and is defined as the state of mind that expresses satisfaction with existing environment (Brager and Richard, 1998), which is widely driven by perception and expectation of the occupants. Therefore, the same thermal environment may be perceived differently by different occupants, or different occupants may perceive the same thermal comfort sensation for different thermal environments (Brager & Richard, 2002), (Auliciems, 1981), (Rajasekar & Ramachandraiah, 2010). While the idea of a comfortable environment for all, would involve the consideration of individual preferences, there is a set of general conditions of air and radiant temperatures, airflow, humidity, etc, in which a majority of the people would be at ease (Mallick, 1994). Thermal comfort is a key component for quality of indoor environments (Appah-Dankyi & Koranteng, 2012). Methods for defining a 'comfort zone' or 'comfort range' of acceptable temperatures are based on associating ideal conditions with a feeling of neutrality, or on conditions that are totally unnoticeable (Brager & Richard, 2002). ‘Thermal neutrality’ for a person, is the condition in which the subject would prefer neither warmer, nor cooler, surroundings (Fanger, 1972).

According to the adaptive hypothesis, contextual factors and past thermal history can modify building occupants’ thermal expectations and preferences (Brager & Richard, 1998, 2000 and 2001), while people with environmental control options, are more easily thermally satisfied, than when they perceive not to have control. Temperature and Humidity are two of the prime indicators of thermal comfort. International standards and related predictive models predict that subjects in cool climates, from where the standards have originated, feel much warmer than subjects in naturally ventilated buildings in warm climates (Tablada, Peña, & Troyer, 2005). Therefore, occupants in naturally ventilated buildings of tropical countries are tolerant of a significantly wider range of temperatures, explained by a combination of both behavioural adjustment and psychological adaptation (Brager & Richard, 1998). Such results can form the basis of indoor temperature standards, more elevated than standards set for cooler climates.

Institutional buildings mainly operate during the hottest part of the day, with young adult occupants. Research findings indicate that the thermal sensation of the younger subjects (age 22-25 year) is, in general, 0.5 scale units higher in comparison with their elderly counterparts (age 67-73 year) and that young adults prefer a lower temperature in comparison with elderly persons (Schellen, van Marken Lichtenbelt, Loomans, Toftum, & de Wit, 2010). Therefore, if the indoor environment is found comfortable for fit young adults in the summer season, then the rest of the older population will also find it to be comfortable. So, efforts should be made to predict the temperature, or combination of thermal comfort variables (air temperature, relative humidity and air velocity) which will be found comfortable in classroom environments of Bangladesh, in order to set contextual local standards.

Figure 1 Naturally ventilated classroom environments in Dhaka

The study of thermal comfort in classroom environment is very important because it directly affects students’ health and also energy consumption of the building (Markus & Morris, 1980). This paper cites a study of the classroom environment of undergraduate students in Dhaka, Bangladesh, aimed to investigate thermal sensation, acceptability and preference of indoor climatic conditions by students in naturally ventilated classroom environments, **as shown in Figure 1**, during the hottest period (April-July) of the year. During this study, five naturally ventilated classrooms were investigated on six separate occasions during the selected critical period (April-July), and the environmental data were recorded, along with responses, through questionnaires, of the subjects to these conditions. The responses were correlated with the corresponding recorded environmental data, to identify the acceptable air temperature range, along with the ‘neutral’ temperature.

Findings of such studies can lead to formation of local standards of thermal acceptability, which can result in reduction of building energy consumption.

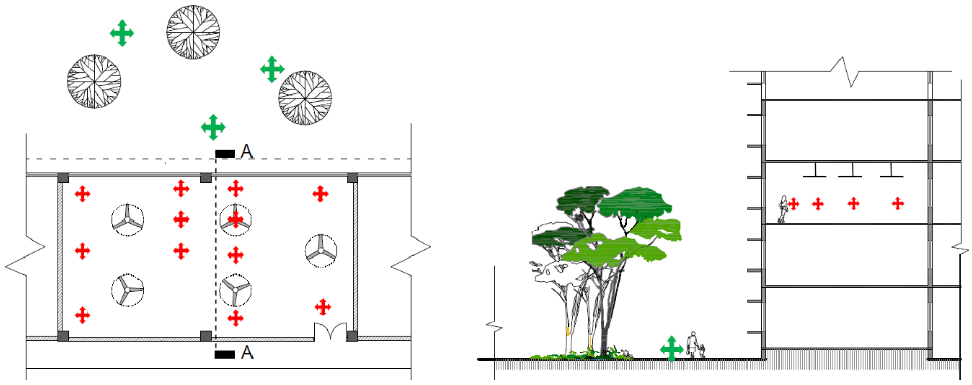
RESEARCH METHODOLOGY

Field investigation in multiple-cases, with a structured questionnaire, and measurements of simultaneous environmental conditions, was adopted as a methodology, to produce primary data during this research.

A total of 100 subjects, in naturally ventilated classrooms, of five institutions, provided comprehensive data through a questionnaire survey, on six occasions during the survey period, for the analysis of indoor thermal condition and their preferences. Transverse surveys were conducted in April, May, June and July (2013) in Dhaka, located in a tropical climatic zone.

All the selected students, aged within 18-25 years, were engaged in sedentary work, and wore summer clothing (between 0.35-0.5 clo), while all the selected classrooms had similar options of adjustment to neutralize the physiological factors affecting their thermal condition. Students had similar types of social class, as they came through the same type of educational background and set up. Naturally ventilated institutions were selected with similar materials (brick and concrete) and classrooms having glass openings were selected to get similar type of micro environment of building design.

The micro-climatic parameters were measured simultaneously during questionnaire survey, in order to relate these to the thermal responses. A Digital Thermometer Hygrometer (Zeal PH1000) was used for measuring air temperature (indoor/outdoor temperature) at positions, **as shown in Figure 2**. The airflow, mainly generated by running ceiling fans, as is common in Dhaka, was found to be on average, 0.475 m/s.



Conceptual Plan

Conceptual Section (AA)

	outdoor air temperature, relative humidity, air velocity (at 01 m above ground level)
	ceiling fan

Figure 2 Positions of taking measurements of environmental variables

Table 1. Thermal sensation scale (ASHRAE Scale and modified used in this research)

	thermal sensation						
ASHRAE SCALE (Fanger's Scale)	very cold	cool	slightly cool	neutral	slightly hot	hot	very hot
	-3	-2	-1	0	+1	+2	+3
Modified ASHRAE SCALE			slightly cool	neutral	slightly hot	hot	very hot
			-1	0	+1	+2	+3

Sensation Scales

A modified version of ASHRAE Scale was used (ASHRAE, 2005), **as shown in Table 1**, for measuring thermal sensation, and answering the question: ***How are you feeling (Thermal sensation)***

inside the classroom? This was because previous studies show that 'cold' discomfort is not an option in the warm seasons of Dhaka, and therefore, the options of 'cool' [-2] and 'very cold' [-3] were not mentioned in the questionnaire.

Comfort voting

The voting scale**, as shown in Table 2,** was used, to assess 'comfort', and answer the question: ***How does the classroom feel like to you (air temperature)?***

Table 2. Comfort voting of air temperature, relative humidity and air velocity

comfort voting						
uncomfortable			neutral	comfortable		
-3	-2	-1	0	+1	+2	+3

Preference Scales

To cross match comfort with preferences about air temperature, the 'McIntyre preference scale' was used (McIntyre, 1980), **as shown in Table 3**, answering the question: ***What change in the temperature do you want in the classroom?***

Table 3. Preference Scale of air temperature used in this research

thermal preference						
extreme cold	much cooler	slightly cooler	no change	slightly warmer	much warmer	extreme hot
-3	-2	-1	0	+1	+2	+3

The subjects also voted on their assessment of the environmental acceptability on subjective scales, **as shown in Table 4**, by responding to the question: ***How do you rate the overall acceptability of the thermal environment at this moment?***

Table 4. Subjective scales of 'acceptability' used in this thermal study

acceptability					
not acceptable			acceptable		
-3	-2	-1	+1	+2	+3

ANALYSIS AND RESULT

A total of 600 responses (100 students for 6 times) were investigated during the survey period, of which 251 (42%) were male and 349 (58%) were female. The measured indoor environmental parameters during the study period (April to July, 2013) are **shown is Table 5**.

Table 5. Measured indoor environmental features of selected classrooms

Measured indoor environmental features	range
Range of Mean indoor AT (ºC)	27.95 - 32.6
Range of Mean indoor RH (%)	52.5 - 80
Range of Mean indoor AV (m/s)	0.05 - 0.9

Comparison of indoor and outdoor environmental conditions

The outdoor temperature, measured at one meter (01m) above the ground level outside selected classrooms, is compared with simultaneously measured indoor conditions, **as shown in Figure 3**, showing a strong correlation, increasing and decreasing in a similar pattern.

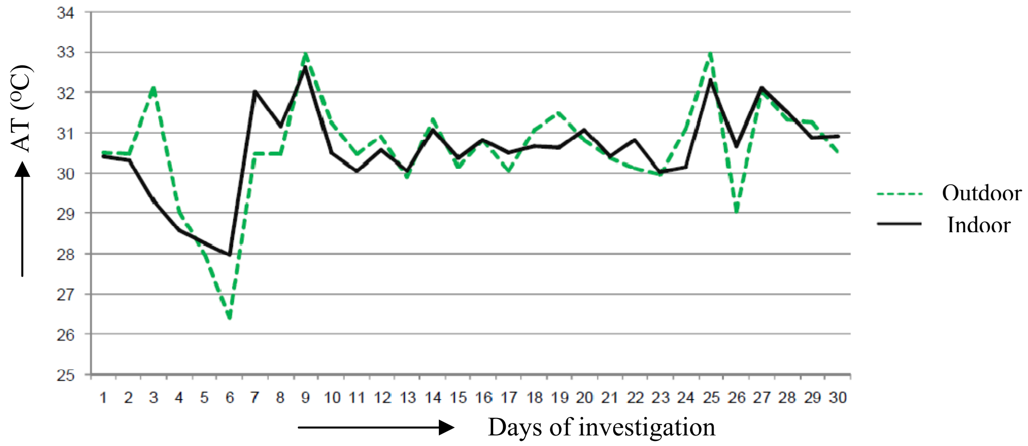

Figure 3 Comparison between indoor and outdoor air temperature (Mean)

Thermal acceptability of classroom conditions

Regarding thermal acceptability, it was found that only about 43% of the responses (257 out of 600 respondents) 'accepted' their immediate classroom environments to be comfortable. But about 73% responses lie within inside the three central categories [vote = -1, 0, +1] of the sensation scale, which imply acceptability (ASHRAE Standard 55, 2004), showing that though the respondents were not in absolute thermally acceptable conditions, the conditions were, nevertheless, close to acceptability. The mean value of thermal sensation vote (TSV) was found to be 1.003 which lies very close to the 'slightly warm' vote category [vote = +1]. But since the three central categories imply acceptability, it can be said that, in general, students are reasonably satisfied with the air temperature of their classroom.

Comfort Votes on air temperature

In order to cross check the responses of the thermal sensation scale, a question, ***How does the classroom feel like to you (regarding air temperature),*** was included in the survey, about the comfort sensation regarding the temperature experienced in the class, which varied between 27.95-32.6 ºC. For the response, a 3 point rating scale was used: Uncomfortable, Neutral and Comfortable. In this question regarding the indoor air temperature, 55% responded that their classroom condition is 'uncomfortable'. This contradicts the voting mentioned previously where 73% found conditions acceptable (voting between the -1, 0, +1 range).

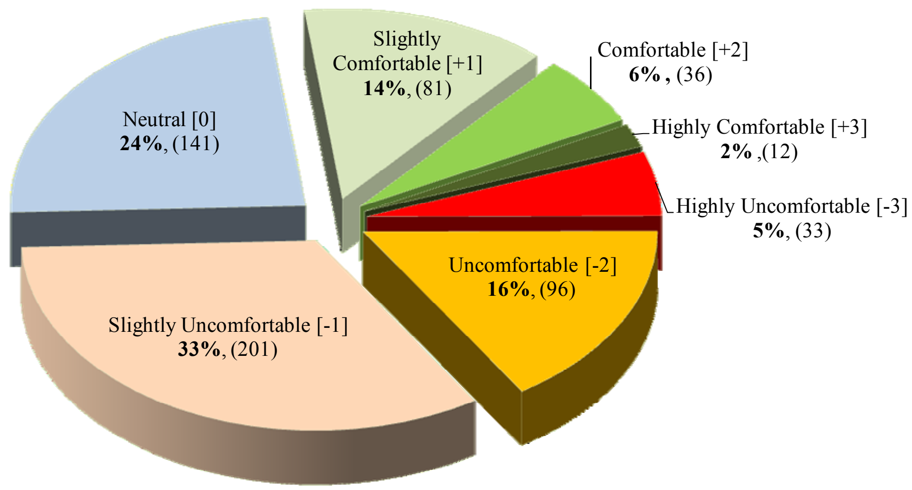

Figure 4 Comfort voting (with rating scale) regarding air temperature

But voting against a question, ***How does the classroom feel like to you (regarding air temperature),*** on a 7 point rating scale: uncomfortable degrees of -3,-2 and -1, neutral (0) and comfortable degrees of +1, +2 and +3, reveals that 71% responses were in the acceptable comfort conditions of air temperature, the students voting in between the -1, 0, +1 range**, as shown in Figure 4**.

Therefore, compared with the acceptable thermal sensation votes (73% between -1, 0, +1) and 'comfort' votes (71% within the acceptable -1, 0, +1 range), there is a close similarity between 'thermal sensation' and 'thermal comfort' due to air temperature, among these students. Moreover, on cross checking, it can be concluded that the students are aware of their environment, and that their responses to it are consistent.

Correlation between thermal sensation votes and air temperature (Mean)

The six hundred thermal sensation responses were plotted in a scatter plot diagram, against the simultaneously measured air temperatures**, as shown in Figure 5**.

The slope of this plot, generated through the computer software, reveals certain dependence between these two variables. The low R^2 value is considered indicative of the wide variability of the perception of thermal sensation vs. the actual air temperature, which is not uniform, particularly in naturally ventilated tropical spaces.

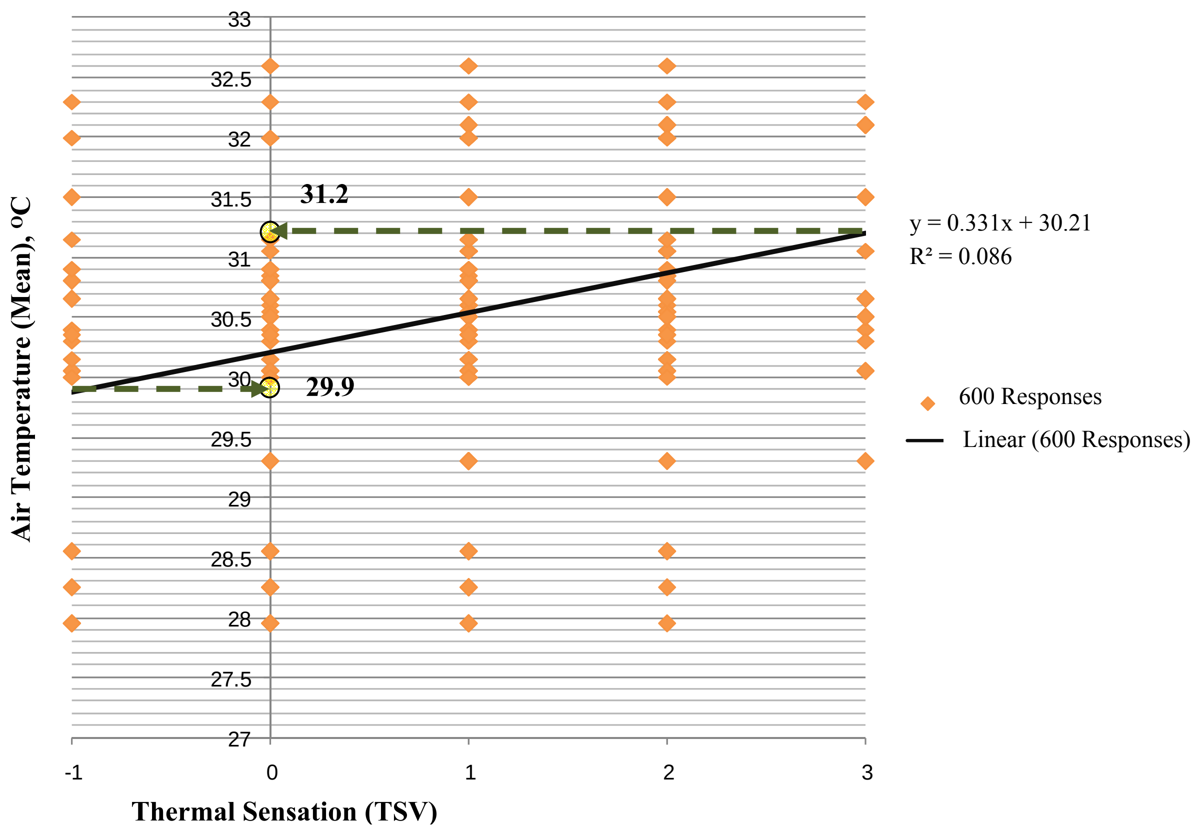

Figure 5 Thermal sensation votes VS air temperature (Mean)

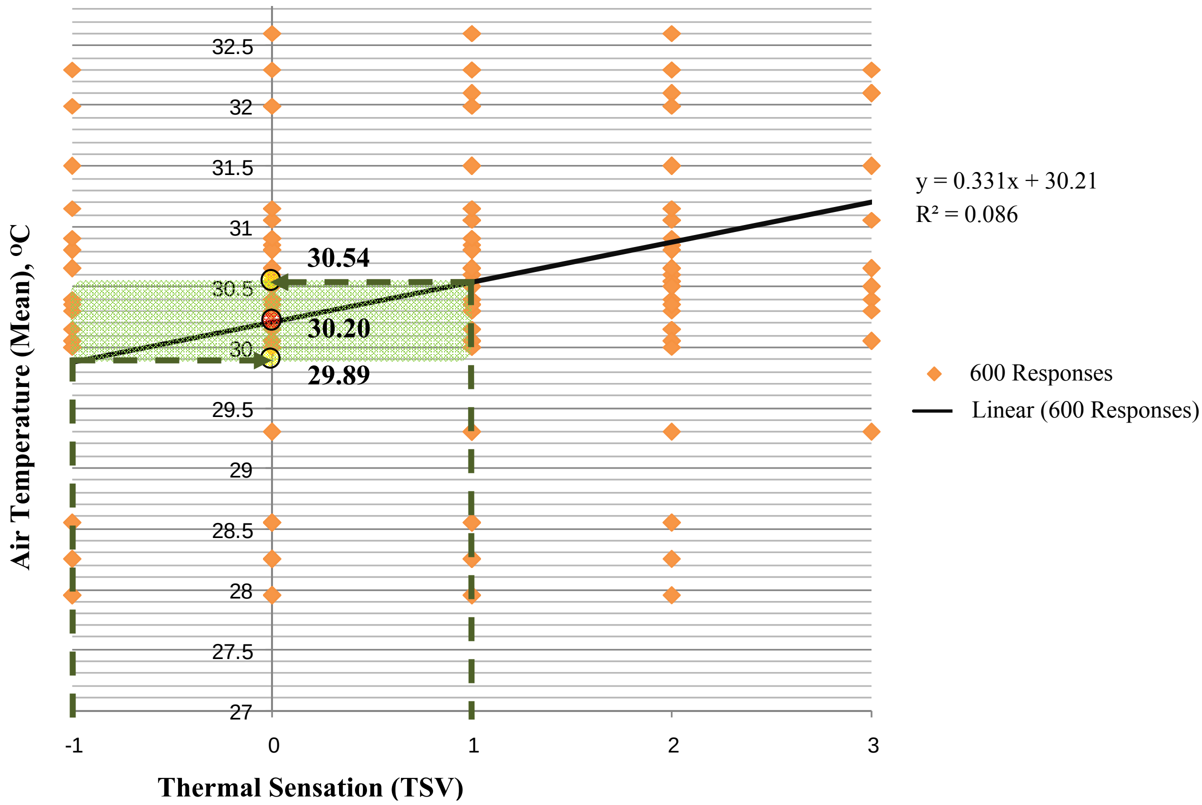
This figure shows that the higher the air temperature, the higher the thermal sensation vote (TSV).When the air temperature (Mean) is 29.9 ºC, the TSV is 'slightly cool' [-1], and as the temperature rises up to 31.2 ºC, the thermal sensation vote indicates the 'very hot' [+3] condition.

Through the graph**, shown in Figure 6**, it was possible to identify a 'neutral' air temperature which may be perceived as 'neutral' by the undergraduate students (age 18-25 years) of Dhaka, Bangladesh.



Measured environmental variable during voting	Range
Range of Mean indoor AT (ºC)	27.95-32.6

Figure 6 Identification of 'neutral' temperature

The temperature range between the two lines of 'slightly hot' [+1] and 'slightly cool' [-1], forms the acceptable temperature range, (ASHRAE Standard 55, 2004), i.e. 29.89 ºC to 30.54 ºC. The intersection of the TSV Vs the Mean air temperature slope with the '0' TSV, has been identified as the 'neutral' temperature, i.e. 30.20 ºC, where the thermal sensation is 'just right'. This figure is undoubtedly much higher than that acceptable according to published international standards.

Also the very narrow acceptability range of only 0.65 degC is surprising, where thermal studies in cooler climates have revealed acceptable ranges of ±2 degC (Fanger, 1972). The reason for this is probably the high level of the neutral temperature and the state of acclimatization for the tropical population in naturally ventilated buildings.

RECOMMENDATIONS

This research concludes that, thermal adversities encountered in summer are quite well tolerated by the acclimatized and adapted students of Dhaka city. It is essential to provide a comfortable and healthy indoor environment to its dwellers in various seasons to perform their works effectively (de Dear, Fountain, Popovic, Watkins, Brager, Arens, & Benton, 1993). The neutral temperature was established at a value of 30.20 ºC, which is much higher than international standards. The findings reconfirmed that sensation, comfort and preferences of this tropical country, along with the acceptable range of temperature, are markedly different from set international standards. Therefore, developing a more relevant and contextual thermal comfort standard, for naturally ventilated spaces in Bangladesh, is an imperative, which will also accommodate different expectations, preferences and adaptation means.

Relevant thermal standards for indoor thermal conditions of Dhaka should be set on an urgent basis. As there is a very close relationship between internal temperature standards and energy usage, setting a higher acceptable temperature value will allow greater energy savings, thus allowing for a more sustainable energy balance in the country.

ABSTRACT

Studies of thermal comfort in open spaces in various climatic and cultural contexts, seek to create design guidelines for attractive outdoor environments, which improve the quality of urban life. In general, these studies characterize microclimates and define the conditions for actual and/or calculated thermal comfort by predictive indexes in streets, squares and parks. In this context, this pilot study aimed to characterize the thermal perception of users and changes of the range of PET (Physiological Equivalent Temperature) for thermal neutrality according to the age of visitors to a park in the city of Bauru, State of Sao Paulo, Brazil. The study was conducted through microclimate monitoring and structured questionnaires to users in warm weather conditions. Results showed higher frequency of thermal sensation between comfortable and warm; a differential thermal preference according to the major microclimatic variations observed between morning and afternoon; little tolerance to the effect of direct solar radiation and minor differences of PET index between the age groups of children and teenagers and greater variations between these groups and adults/elderly.

INTRODUCTION

The open spaces have several ways of daily use in the city and, therefore, an important aesthetic and recreational function (Raja & Virk, 2001). Chen and Ng (2012) advocate that open spaces are key to more sustainable cities because they accommodate pedestrian traffic, the outdoor activities and contribute to the livability and urban vitality. Thus, they encourage more people to attend the open spaces in the cities benefitting their physical, environmental and socio economic dimensions.

The quest to create the most attractive open environments has contributed to the growth of research in open spaces, focused on different aspects, including thermal comfort. In this approach, the pioneering studies investigated the thermal environment, the human comfort parameters (Nikolopoulou, Baker & Steemers, 2001), the characteristics of space usage (Zacharias, Stathopoulos & Wu, 2001), the relationship between comfort psycological adaptation (Nikolopoulou & Steems, 2003), and thermal comfort and behavior patterns of users on streets, squares and parks (Thorsson, Lindqvist & Lindqvist, 2004).

These researches show the complexity of the evaluation of comfort in open spaces and proved that there is a close relationship between the thermal environment and the number and distribution of users, and also between the behavior of people in open spaces. These findings significantly influenced the development of research on the conditions for thermal comfort in open spaces in different climatic and cultural contexts (Katzschner, 2006; Thorsson, Honjo, Lindberg, Eliasson & Lim, 2007; Eliasson, Knez, Westerberg, Thorsson, Lindqvist & Lindqvist, 2004; Lin, 2009; Dacanal, Labaki & Silva, 2010; Labaki, Fontes, Bueno-Bartolomei & Dacanal, 2012 and Fontes, Nishimura, Sebastião & Faria, 2012; Lin, Lin & Hwang, 2013).

In general, these researches seek to analyze the thermal quality of open spaces, based on qualitative aspects (thermal perception of the users) and quantitatively with the use of different predictive indexes of comfort, such as the Physiological Equivalent Temperature - PET (Mayer & Höppe,1987; Höppe, 1999), to define the limits of thermal comfort. The aim is to create design subsidies that favor the creation of pleasant microclimates for human society and, consequently, contribute to the increment the daily use by the population.

So it is important that architects and landscapers use tools that have been developed from research in the area, with the goal of designing open spaces with adequate comfort conditions. Considering especially the effects of expanding cities adversely affect the microclimates of these spaces, because of the significant heat islands effects (Lin et al. 2013).

In this context, this research shows results of a pilot study investigating microclimates and thermal perceptions of users of a park located in Bauru, midsize city of São Paulo State, Brazil. However, the difference here presented, in relation to other similar studies, is to attempt to identify possible variations of PET for thermal neutrality according to the different age groups of visitors.

MATERIALS AND METHODS

Characterization of the study area

The study area is the Municipal Zoo of Bauru (Lat. 22 °18'54" S, Long. 49°03'39" W and average altitude of 530m), medium-sized city in the Midwest of São Paulo state, Brazil. According to Köppen climate classification, the local climate is Aw - tropical climate with summer marked by high temperatures and rainfalls and mild and dry winter. Figure 1 shows the thermal range of the city, from the analysis of historical data of air temperature over the period of ten years (2001-2010). The table also includes the minimum and maximum temperatures of two days of field survey in the months of October and November 2013.

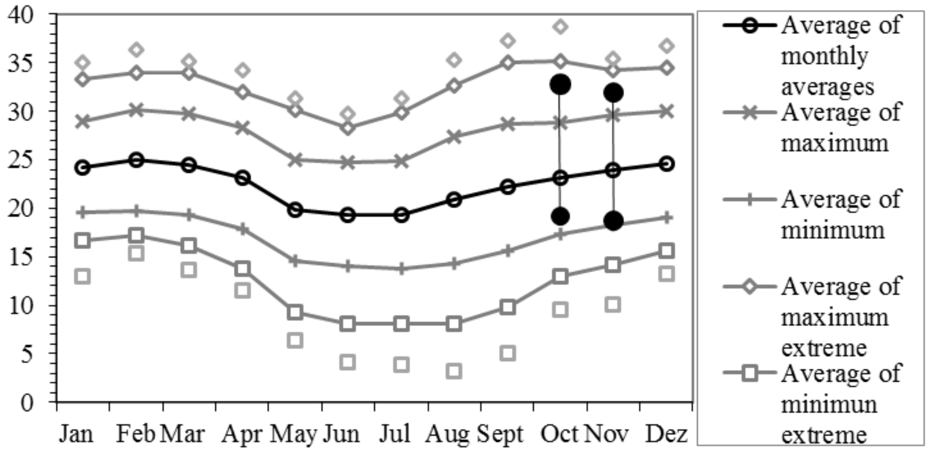

Figure 1 *Statistics of thermal data of Bauru (SP) over the period 2001-2010. Source: http://www.ipmet.unesp.br/*

The Zoo is an important recreational space for the city and region, comprising an area of 20 acres inserted into a region of cerrado vegetation of more than 200 acres (www.zoobauru.com.br). Its inner space consists of totally unshaded areas of direct solar incidence, areas partially shaded by vegetation and areas shaded by built covers, as can be seen in Figure 2 respectively.

To analyze the thermal perception of the users, one of the areas of longest permanence time within the park, "the Food Court" (Figure 3) was chosen. This place is quite shaded by vegetation and is used for relaxation and meals by users who have family picnics or to school tours. The permanence time at the site varies from a few minutes to two or three hours.

Figure 2 *Different areas of the Zoo: a) Area of felines (left) and circulation spaces, unshaded sites of direct solar incidence; b) Area of birds and local open spaces of permanence (center) partially shaded by adjacent vegetation; c) Area of primates, reptiles and penguins (right), areas shaded by built covers.*

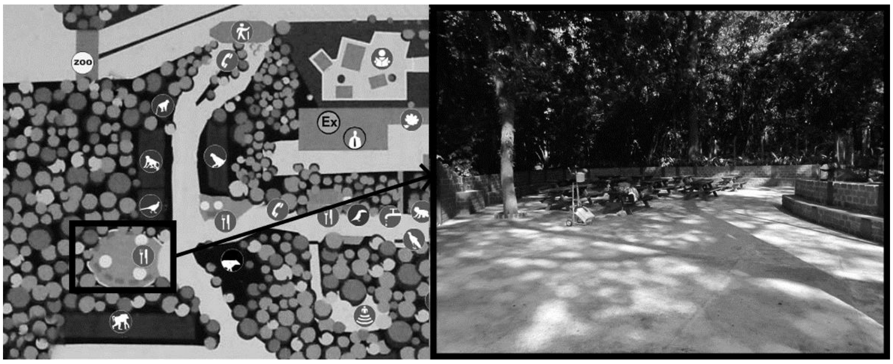

Figure 3 *Partial internal map of Bauru Zoo, especially the Food Court, site of the data collection. Adapted from www.zoobauru.com.br.*

Microclimate Monitoring

To monitor the microclimate in the food court, a mobile weather station was used with the following sensors: 1. Globe Temperature Sensor (Model 1: 0613 1712; manufacturer: Testo), built with official ping pong ball painted in gray-bourgeois (emissivity 0.9, solar reflectance 0.3); 2. Temperature and Humidity Data Logger (Model: Testo 175-H1); 3. Heated Sphere Omnidirectional Anemometer (Ø 3 mm, Model: 0635 1549; manufacturer: Testo); 4. Net radiometer (Kipp & Zonen manufacturer).

As this is a pilot study, with the aim to asess methodology for a larger project, the monitoring was carried out in just 2 days in warm weather conditions (October 26 and November 3, 2013), from 9 am until 4 pm, at intervals of 5 minutes. This Corresponds to 1 hour after the park opening team and one hour prior to its closing, During Which there is a greater number of people visiting the park.

Structured questionnaires

Structured questionnaires were applied to a sample of 115 users simultaneously to the monitoring of the microclimate. The questionnaire (Figure 4) addressed a question about the Actual Sensation Vote (ASV) on a 7-point scale, and questions about thermal preference, feeling about the wind and relative humidity. Personal data of each user were also collected: age, gender, weight, height, clothing, activity developed.

In the questionnaires, users were divided into 3 age groups: children (under 12 years), teenagers (13-20 years) and adults/elderly (over 21 years). In this division, children had some difficulty in understanding the questions and required further explanation of each question so that they could give a response that reflected their real thermal perception.

This study was unable to establish an optimal sampling in view of the lack of quantitative survey of visitors by park management. Moreover, the greater permanence space analyzed is used only by part of the users and not all park visitors. Thus, the option was to interview the maximum number of people available, coming to a final number of 115 respondents.

At the moment, what is your thermal sensation?

Very cold	Cold	Little cold	Neither cold nor warm	Little warm	Warm	Very warm

At the moment, what is your thermal preference?

Colder	Same temperature	Warmer

At the moment, what do you think about the wind?

Windless	Neither little wind nor windy	Windy

At the moment, what do you think about the humidity?

Dry	Neither dry nor wet	Wet

Do you feel comfortable?

Yes	No

Figure 4 *Part of the questionnaire applied.*

Thermal Comfort Index

In-loco surveys were used as input data of RayMan software (Matzarakis, Rutz & Mayer, 2007), to calculate the index PET (Physiological Equivalent Temperature), developed by Höppe (2002). This index is widely used in Brazilian studies (Dacanal et al., 2010; Fontes et al., 2012; Labaki et al., 2012, among others), due to the representativeness of their results, and also the ease of use by RayMan software.

For the insertion of data in the software, it was necessary to calculate the mean radiant temperature with Software Comfort 2:02 (Ruas, 2002) and also the body surface of each user, using the formula of Dubois (http://www.sbn.org. br/equacoes/eq6.htm) for the conversion of metabolic rate in W/m2 for W. Thus, the PET index was determined for each user and the following analyzes were performed: 1. Distribution of the thermal sensation frequency (ASV) and the thermal preference of users (for all users and by age group); 2. Frequency of users' thermal sensation in relation to ventilation and relative humidity; 3. Distribution of PET range for users in general and for different ages.

RESULTS AND DISCUSSION

During the fieldwork (October 26 and November 3, 2013), the data from the local weather station (IPMet) characterized the weather as hot and dry, with temperatures above the historical average for the months in question. In those days, the mornings were mild, with temperatures ranging from 23.8 ° C to 24.9 ° C at 9am in the early surveys, and reached 31.5 ° C at 4pm, end of microclimate monitoring. The relative humidity reached the highest value of 73.7% and the lowest 40% in the afternoon.

The data collected in the Food Court showed more pleasant microclimates observed in the IPMet, due to the fact that it is a place partially shaded by vegetation. The difference in air temperature in these two sites got an average of 1.4°C and reached the highest value of 2.8°C at 10:15am of the second day.

Regarding the relative humidity data the values mean monitored in zoo were until 8.7% higher than values observed in IPMet.

Figure 5 shows the behavior of the temperature and relative air humidity over the two days of measurement at fixed measuring point in the park. The air temperature ranged from 22.6 to 31.9°C and relative air humidity from 41.9 to 75.2%. The graphs show the high temperatures and low humidity in the afternoon. These data contributed decisively to thermal perceptions in this period compared to those observed during the mornings.

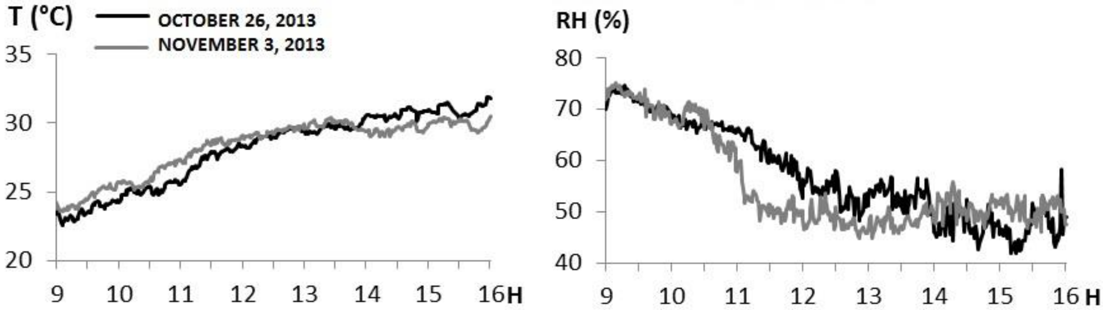

Figure 5 *Temperature and relative air humidity during the measurement days in Bauru.*

Regarding the questionnaires, the profile of the respondents had similar numbers between the genders, with 52% male and 48% female. As to age, 39% were children under 12 years, 18% of young people under 20 years and 43% of adults and elderly, with almost all wearing light clothing in view of the high temperatures of the period. 70% of the respondents were from cities in the region or further afield and only 30% were local residents.

Users proved tolerant to high temperatures, since 87% of respondents stated to be feeling comfortable (thermal satisfaction), although the thermal sensation was "little warm" or "warm." This difference between satisfaction and thermal sensation is due mainly to the influence of psychological aspects, since that was a moment of leisure in an environment surrounded by greenery. However, users have shown little tolerant to solar incidence, avoiding some of the circulation spaces with great exposure of direct sunlight. There was a tendency for users to take shelter in places shaded by vegetation, such as the Food Court, and also in areas with built roofing, instinctively seeking milder microclimates.

During the afternoon, with increasing temperature around 32°C, many users felt uncomfortable, and indicated thermal sensation of "warm". Figure 6a shows the frequency of the Actual Sensation Vote (ASV) for the period, where it is possible to observe a significant number of people in a comfortable situation, but a greater number of people feeling uncomfortable by the heat (+1, +2 and +3).

Regarding thermal preference (Fig.6b), users preferred cooler temperatures (52.2%); the same temperatures (33.9%) or warmer (13.9%). There were differences in thermal preference in relation to time of day. In the morning the users preferred the same temperature or warmer. During the afternoon, the user preference was for lower temperatures.

As for the relative air humidity, 53% of users were satisfied, 31% considered dry and 19% wet. The analysis of the periods (morning and afternoon) shows that the perception of "dry" weather was concentrated during the afternoon (42-50%) and "wet" in the morning (50-75%). However, on this variable, users were satisfied throughout the day.

In relation to the wind, 57% of users said they felt satisfied with the condition of the moment and 43% thought there was little wind. The air velocity measured was low and varied from 0.2 to 2.4 m/s. This aspect can be attributed to roughness of the vegetation. This behavior was also found in research in the woods of the city Campinas-SP, Brazil, developed by Dacanal et al. (2010). The responses on this variable showed to be very subjective. There is no clear relationship between air velocity and thermal perception of the user.

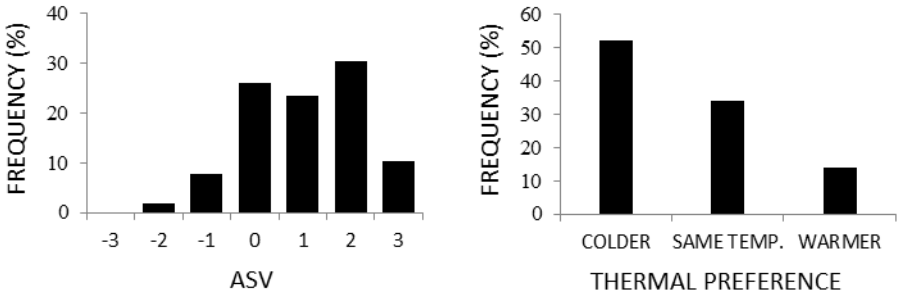

Figure 6 *Frequency of ASV and Frequency of Users' Thermal Preference, respectively. ASV.scale: -3 = very cold, -2 = cold, -1 = little cold, = 0 indifferent, 1 = little warm, 2 = warm, 3 = very warm.*

Figure 7 shows the ASV analyzed by age group (children, young people and adults/elderly). The total number of children interviewed was 45 and ASV this age group was distributed between "a little warm" (28.8%), "neither cold nor warm" (26.6%), "warm" (15.5%) 13.3% "very warm" and 2.2% "a little cold." Among young people (21 respondents), the highlight was the "hot" ASV (42.9%) and "neither hot nor cold" (33.3%). The "a little warm" scale appears with values of 14.3% and "a little cold" with 9.5%. Among adults/elderly (49 respondents), the most prominent feeling is "hot", with 38.8%, followed by "neither cold nor hot" and "a little warm", both with 22.4%. The remaining reached 4%.

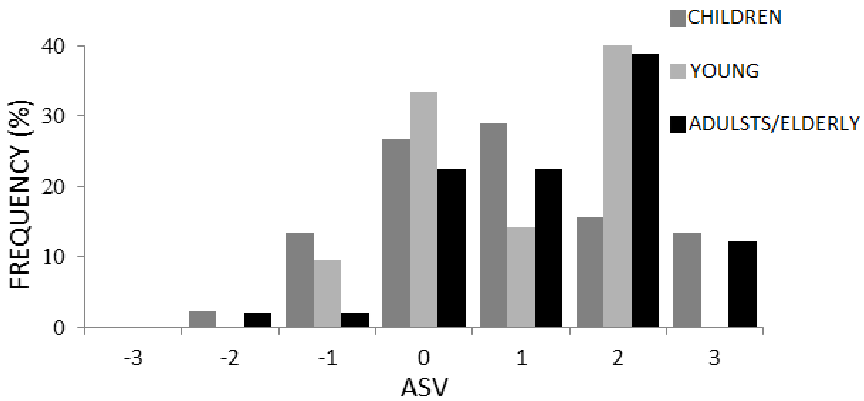

Figure 7 *Comparison of actual thermal sensation ASV between age groups.*

To define the range of comfort, the set of values of PET for each vote sensation was evaluated by means of statistical graphs Boxplot (Figure 8) which displays the PET data grouped according to the ASV, considering the total sample and the different range age (children, young people and adults/elderly). According to this graph, 50% of the central values for range of PET to the thermal neutrality were distributed between 23.5 to 29.1°C, with a median value of 25°C. This range shows values above the ones previously found by Fontes et. al (2012) for the city of Bauru (16-27 °C). However, the superposition with other intervals that indicate discomfort, either by heat or cold, makes it difficult to define precisely the limits of thermal comfort and thermal discomfort.

When analyzing the different age groups, the adults/elderly demonstrate greater tolerance to heat, with values of neutrality for PET between 25.1 to 30°C and a median value of 26.5°C. The values for the comfort range of other users are similar, i.e., they show values of PET from 23.2 to 26.5°C for children and from 22.1 to 26.7°C for young people and a median values of 24.3 and 24.1°C respectively.

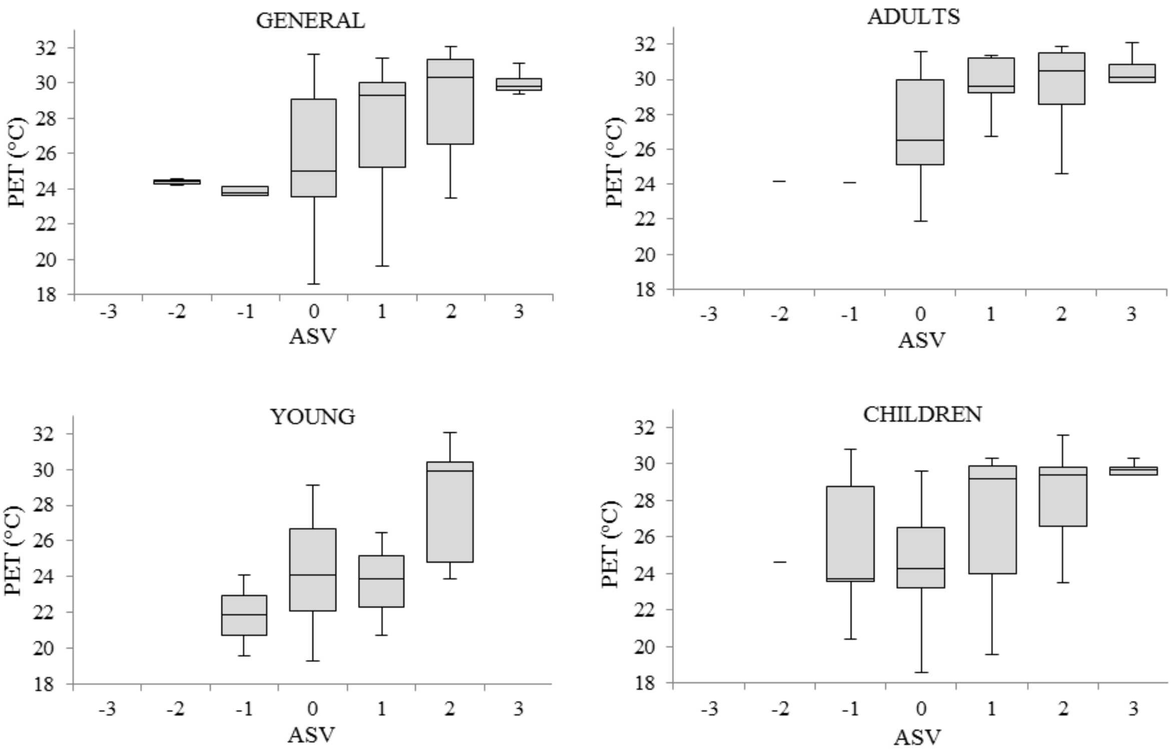

Figure 8 *Range of PET related to ASV range of the users, and separated by age group: children, teens and adults/elderlys. In the general graph, the percentage of respondents to ASV value to "Neither cool nor warm" is 26%.*

CONCLUSION

The evaluation of the thermal environment of open spaces is important to create design guidelines que can help to improve the comfort and consequently the quality of life of users. In this study, developed in warm wheather conditions, it was found que users of the park have little tolerance for direct solar incidence. Thus, for these weather conditions, future interventions shouldnt prioritize site shading, either through afforestation and / or built covers, not only in places of greater permanence, but Also in the circulation spaces.

The assessment of the Actual Sensation Votes (ASV) pointed a variation between the thermal sensation" neither cool nor warm", "little warm", "hot" and "very hot". Regarding thermal preference, most users preferred colder temperatures, specifically in the afternoon, when the air temperatures were very high (above 28 °C) and relative humidities were lower (around of 55%). The percentage of users who preferred the same local temperature was also significant.

In the microclimatic conditions evaluated, the range of thermal comfort found to PET index was 23.5 to 29.1°C for the total sample. This range shows minimum and maximum limits above those previously found by Fontes et. al (2012) for the city of Bauru (16-27 °C). In Both studies were there superposition que indicate ranges of comfort/discomfort, difficulty in proving the establishing clear limits of thermal comfort in open spaces, those already established in the literature. Regarding the analysis of the limits of thermal comfort by age groups, the differences between children and young people ranges were not significant (23.2-26.5 °C, 22.1-26.7 °C to children and young people respectively). However the differences between those thermal comfort limits and of the adult/elderly group (25.1-30.0 °C) were higher. This result shows higher tolerant to heat for that age group.

For being a pilot study, the field survey carried out in just two days was sufficient to test the methodology for the larger project that aim analyse the user thermal comfort by age group. This reasearch is unusual in surveys conducted in open spaces and can be used in architectural design in order to prioritize the needs of the largest portion of users. Thus, in the case of Bauru Zoo, an environment comfortable for children´s recreation may prevail over the other, creating more pleasant spaces and encouraging the permanence of that public.

ACKNOWLEDGMENTS

The authors would like to thank the IPMET (local weather station) for providing meteorological data during the fieldwork and historic data.

ABSTRACT

A methodology for the integrated sustainability assessment of schools facilities is presented together with its application to a case study in Milan. The study uses quantitative indicators such as non-renewable primary energy to quantify the total amount of energy used by student related to building energy consumption for comfort conditions and to food embodied energy consumed in the school canteen (from agricultural production to the cooking stage).The result is a critical review of possible sustainability improvements of the school service. In particular heating and electricity uses and food consumption are shown in the form of non-renewable primary energy. The final part describes the main improving strategies and measures their effectiveness in terms of primary energy reduction, expressed in terms of MJ per student per year of non-renewable energy. The proposed strategies include improvement measures on building envelope and on diet changes towards low energy scenarios.

INTRODUCTION

The work presented in this paper is part of the "Bioregione" research, funded by Fondazione Cariplo (www.fondazionecariplo.it). It illustrates a summary of the current state of development of the methodology Elar (Ecodynamic Land Register) with data relating to the school service.

Elar is a methodology to support energy and food integrated plans aided by application tools. The aim is to guide the suggestion of local self-sufficiency scenarios in an area defined as local (Clementi, 2008).

Thus, in accordance with the bioregional paradigm, this methodology should be used as a tool to assess the achievement of the self-sufficiency in local areas of different entity, from the municipal scale to larger areas.

The Bioregion research aims to propose different scenarios to bring together the local demand of catering and the supply potential of the region of Lombardy considering the public facilities sector.

As the school service is one of the main actors who express the collective demand for food in the regional area, Elar has been implemented in such a way as to allow the evaluation of the environmental impacts of the school service.

These activities allow the achievement of two main aims:

1. the development of different scenarios to bring together the local demand of catering and the supply potential of the region of Lombardy considering the school sector (the main aim of the Bioregion research);

Author A is Professor in the Department of Architecture and Urban Studies, Politecnico di Milano, Italy. Author B and C are Postdoctoral-researcher in the same Department. Author B is Assistant Professor in the Department of Architecture, Built Environment and Construction Engineering, Politecnico di Milano, Italy.

2. the development of the database to support Elar, with useful data to integrate the school service in the development of integrated food and energy plans.

All the data collected in this phase of the investigation allow to compare the energy consumption of buildings (energy consumption for heating and electricity) with the energy consumption due to the food supply chains.

In this way it is possible to assess the whole school service and to evaluate its sustainability level. Using quantitative indicators (such as the primary energy amount) and an appropriate functional unit (such as the annual primary energy consumption per student) it is possible to verify the effectiveness of different improvement scenarios.

METHODOLOGY

The main stages of Elar are the evaluation of the local demand for energy and matter and the implementation of local self-sufficiency scenarios through the adoption of best practices (stored in a specific database). The first aim is to reduce the energy and matter demand in the school sector, the second one is to better understand how the energy and matter demand could be satisfied by the local and renewable supply.

The studies conducted in the school sector reported in this text are related to the first phase, and they aim at reducing the energy and matter levies.

The ways to reduce the consumption of energy and matter in the school sector are listed in a database that shows different studies and data taken from the literature about specific best practices potentially transferable to the case studies investigated.

The transferability of good practice are related to the awareness of similar conditions related to the case study under analysis.

Considering the energy consumption of school buildings, similarities must be verified by the following points:

1. Climatic conditions (the same/similar weather conditions)
2. Use condition (the same use of the building)
3. Technological features (similar thermo-physical properties of the envelope an systems features)
4. Geometric features (similar ratio between surface and volume and between transparent/opaque areas)

Considering food consumption, similarities must be verified by the following other points:

1. Climatic conditions (to associate information on best practices about food production in the local context)
2. The number of users
3. The type of users (age of groups, etc.)

The choice of several alternatives is entrusted to impact indicators such as the accounting for primary energy and equivalent productive land (basic condition for estimating the level of local self-sufficiency).

In this first phase, the primary energy amount is the impact indicator considered.

Up to date, the applications of Elar (Clementi, Scudo, 2013) have mainly been related to the residential sector and to the population food demand and mobility.

The research presented in this text deals with the evaluation of integrated services focusing on the school service.

Future insights will be related to other types of services, such as health services, sports and public administration in order to have a most comprehensive scenario of all the activities that have taken place in the area under analysis.

Following the general steps of Elar, the next part of the text is organized as below:

1. Information about the energy consumption of the school sector in Italy is presented;
2. The case study and its energy/matter demand during a year is shown (considering all its

energy consumption);

3. information on best practices for upgrading school buildings is shown, highlighting the possibility of reducing the energy consumption and the ability to use renewable energy (such information is stored in the Elar database of good practices)
4. some of the possibilities to reduce the demand for energy and matter relating to the food supply system are suggested;
5. in the final part of the text, an integrated assessment of the effectiveness of the strategies is shown, identifying the relative weight of the different strategies on the total non-renewable primary energy consumed per student each year.

THE ENERGY CONSUMPTION OF SCHOOL BUILDINGS IN ITALY

The overall energy consumption of all the Italian public schools (representing approximately the 85% of the total energy consumption in the schools sector) and private schools, was estimated at 990,000 Tep/year, of which 762,000 of fuel for heating and 228,000 of electricity.

Italians schools consist on 62,217 buildings and they comprise up to 8,845,213 students.

In the Italian case, considering that a Tep is equal to 11,630kWh, the fuel consumption would amount to 886,060 MWh and the primary energy consumption for electricity would be equal to 2.65164 million of MWh.

The contribution per student in Italy would amount to 1,002 kWh / student = 3,606 MJ / student and electricity consumption is equal to 299 kWh / student/year = 1,079MJ

Dividing this last value by the efficiency of the national electricity system (45,9%), it appears that the annual electricity consumption per student amounts to 137kWh/year. The total energy consumption for the school service in Italy amount to 4,685MJ/student.

THE CASE STUDY: A SCHOOL BUILDING IN MILAN

The case study is a primary school building in a district in the east side of Milan. It houses 300 students and it is occupied in the morning and in the afternoon from Monday to Friday (from 8am to 5pm)

Figure 1, 2. Aerial view of the school in Milan taken as case study (source: Google Maps) and view of the south façade.

Climatic factors

Degree days 2,404 (comfort temperature: 20°C)

Annual solar radiation incident on a horizontal surface: 1,450 kWh/ m^2

Geometrical features

Floors above ground: 3

Eaves height: 15 m

Net area: 4,362 m^2 (the total area amounts to 14.6 square meters per student)

Value of S/V of the building: 0.38

Technological features

The opaque vertical envelope is composed of two types of both full plastered brick, the first one covers 4,290m^2, the thickness is 17cm, the thermal transmittance is 1.34 W/m^{2}K; the second one constitutes the masonry spandrel and it covers 520 square meters, the thickness is 43cm, the thermal transmittance is 2.46 W/m^{2}K .

The vertical windows are composed of wooden frame with single glazing and they cover 1,341m^2, the thermal transmittance is 5.7 W m^{2}K.

The total vertical surface amounts to 6,151mq, so the transparent surface occupies the 22% of the total vertical surface. The part of the opaque envelope with higher value of transmittance amounts to 8, 5%. The thermal trasmittance of the covering amounts to 1 W/m^{2}K, of the ground slab 0.7 W/m^{2}K

Energy Consumption for heating in winter

The building annually consumes 146 kWh/m^2 of natural gas. Since the square meters per student amount to 14.6 m^2, the per capita consumption of non renewable primary energy is 2,132kWh/student, equal to 7,673MJ/student.

Electrical consumption

Breaking down the energy consumption of the building the following items emerge:

- power consumption of the heating plant: 12,500kWh (29%)
- personal computer: 7,500 kWh / year (18%)
- Copiers: 1,000kWh/year (2%)
- washing machine: 400kwh/year (1%)
- Lighting system: 21,000 kWh (50%) ..

Adding together all the components, the total energy consumption for the building is equal to 42,400kWh of electricity, equal to an amount of non renewable primary energy of 1,107MJ per student.

ENERGY UPGRADING STRATEGIES ON THE BUILDING

The assumptions relating to the possible ameliorative actions to reduce energy consumption of the building were chosen among similar cases in the database of Elar. The Pirandello primary school in Moncalieri (province of Turin) was adopted as case study, cause of similar climatic conditions and similare geometrical and technological features.

Climatic factors

Degree days 2,553 (comfort temperature 20°).

Annual solar radiation incident on a horizontal surface 1,470 kWh/m^2

Geometric factors

Floors above ground: 3

Gross surface area of 5,049 m^2

Value of S/V of the building: 0.35

Vertical dispersant surface 3,363 m^2,% of total glazed area of the vertical surface 30%.

Technological factors

Opaque vertical envelope transmittance of walls 1.45 W/m^{2}K, transparent surfaces 6.1 W/m^{2}K, covering 0.31 W/m^{2}K, ground slab 1.44 W/m^{2}K.

Energy consumption before the intervention

The real energy consumption for heating in the case of Pirandello school is 759,069 kWh, the gross volume amounts to 19,441 cubic meters, so the real consumption per cubic meter would be 39 kWh, similar to the value of the school of Milan. In this latter case the actual consumption amounts to 146kWh/mq considering the net height of each floor of 4 m, the consumption for each cubic meter would amount to 36.5kWh/m^3.

Energy upgrading strategies on the building

The actions proposed in the case of Pirandello school in Moncalieri, are extracted from the data published by Silvia Tedesco (Tedesco, 2010) and consist solely of measures to improve the performance of the building envelope. They provide insulation of the ground floor, the insulation of opaque vertical external envelop, roof insulation and replace the tansparent parts with double-glazed windows with low-emittance layer, thermal transmittance 2W/m^2K.

In the case of the vertical opaque the upgrading intervention was hypothesized to isolate the masonry from the inside with polystyrene pre-coupled panels and plasterboard, not to lose the aesthetic connotation given by the presence of the elements in the facade. The implementation of this intervention guarantees a reduction of the heat dispersions for transmission greater than 60%. The thickness of the insulation measures 5 cm and 1 cm plasterboard.

The estimated reduction in primary energy consumption result of the proposed actions would amount to 65% of total consumption, going from 53.52 kWh/m^3*year to 18.61 kWh/m^3*year (theoretical continuous operation).

In the case in Milan adopting the same types of intervention consumption for heating could be reduced by the same percentage, then passing from 146 kWh /m^2 to 51kWh/ m^2, the contribution per student would therefore decrease from the current 7,673MJ/year to 2,686MJ/year.

STRATEGIES TO REDUCE ELECTRICITY CONSUMPTION

An additional intervention to reduce energy consumption could be provided replacing the lighting systems with LED lamps instead of fluorescent lamps. By adopting this solution, the actual consumption of 21,000 kWh would be reduced to 16,800. Such a calculation was performed by estimating an efficiency of 85 lumens/watt, compared to 65 lumens/watt related to fluorescent lamps. The reduction in consumption would amount to 20%, it would affect 10% of total electricity consumption (electricity s1 in Figure 4).

Considering the orientation of the building the installation of a photovoltaic system on the roof can be an effective solution. The system could perform energy exchange with the local power grid. One square meter of PV system tilted at 15 ° and facing south, allows the production of about 150 kWh of electricity (solar values extracted from the "pvgis" solar atlas with a safety margin of 5%, www.re.jrc.ec.europa.eu/pvgis/), the production of 141 kWh of electrical energy per student would require the installation of 0, 94 square meters per student of PV polycristalline collectors with the same orientation and tilt. 282 square meters of photovoltaic panels are therefore needed on the roof. The surface of the roof slopes facing south is sufficient to accommodate such an amount of solar panels, consequently, the balance between the consumption and the production of electricity in a year will be equal to 0 (electricity s2 in Figure 3).

ENERGY FOR FOOD SUPPLY AND CONSUMPTION

After noting that the number of students in the school is 300, estimation of food demand relative to meals eaten at school was carried out as follows:

The type of food in terms of the proportion of each type compared to the total mass was derived by taking the same proportions determined from the total food purchased in the urban area of Milan by the public school canteens (Spigarolo, 2014). The main foods between those consumed each year were taken into account , particularly those whose weight consumed per year per student exceed 1 kg (Table 1).

Table 1. Amount of food consumed annually by each student in the school canteen (only quantities exceeding a kg were considered) and primary energy.

Data sources related to the primary energy content associated to each food are reported in the references in the following order (a: Mila I Canals et al., 2008; b: Assomela, 2012; c: www.lcafood.dk; d: De Cecco, 2010; e: Karakaya, 2011; f: Gonzales et al, 2011)

Foods	kg/year*stud.	Primary energy, only food production MJ/year	Primary energy for cooking MJ/year	Data sources
Frozen vegetables	6,05	121,09	33,30	a
Apples	8,00	26,80	0,00	b
Bread	10,59	105,90	0,00	c
Bananas	6,89	37,20	0,00	c
Potatoes	10,16	9,85	55,87	c
Yogurt	4,13	15,52	0,00	c
Oranges	2,62	8,77	0,00	c
Carrots	6,54	11,05	35,95	c
Pears	3,06	10,25	0,00	c
Lettuce	1,96	3,32	0,00	c
Lettuce out of season	1,96	98,21	0,00	f
Pasta	8,13	127,65	44,72	d
Zucchini	3,88	6,55	21,32	c
Eggs	2,06	18,88	11,33	c
Rice	3,24	22,03	17,82	c
Tangerines	2,82	9,44	0,00	c
Poultry meat	5,20	91,53	28,60	c
Tomato sauce	1,86	18,91	10,20	e
Beef	2,45	191,31	13,50	c
Olive oil	2,57	61,59	0,00	c
Fresh cheese	3,51	155,63	0,00	c
Tomato	1,22	3,66	0,00	f
Tomato out of season	1,22	61,07	0,00	f
Milk	3,40	12,78	0,00	c
Fennel	2,66	4,50	14,63	c

The estimate concerning the non-renewable primary energy demand for food has been carried out using data from the scientific literature covering the main part of the food chain from production in the field up to the cooking. The stage of waste management are excluded from the counting. The table in figure 3 relates the annual food consumption to the amount of non-renewable primary energy used for the food production and cooking. To estimate the contribution of energy for cooking, the same value for all food cooked was adopted (equal to 5.5 MJ / kg), as an average value between the available data on cooking of vegetables, pasta, rice and meat (Carlsson Kanyama et al, 2001).

The total non-renewable primary energy consumed annually by each student for food consumption amounts to 2,127 MJ/year.

SCENARIOS TO REDUCE THE ENERGY CONSUMPTION IN FOOD DEMAND

The diet proposed to reduce energy consumption related to food demand consists of the following strategies:

1. Replacement of frozen vegetables with seasonal vegetables.
2. Replacement of vegetables produced in greenhouses with seasonal vegetables.
3. Replacing beef with chicken meat.
4. 50% reduction in protein intake from animal foods and replace them with foods of vegetal origin characterized by the same amount of protein.

To assess the relative weight of each action on the total, various scenarios are formulated. They allow to verify the contribution of different strategies to weigh the relative reduction compared to the total.

The first concerns the elimination of frozen vegetables, replaced with seasonal vegetables. The percentage reduction compared to the total primary energy used for feeding amounts to 7.3%.

The second adds to the strategies of the previous scenario the elimination of the vegetables grown in greenhouse, replacing them with seasonal vegetables. The percentage reduction compared to the total primary energy used for feeding increases to 17.4%.

The third suggests to replace beef with chicken meat: the percentage reduction compared to the total primary energy used for feeding increases to 26.9%.

The fourth is a further improving effect of the scenario 3 and foresees the replacement of 50% of the proteins derived from animals, (poultry meat and dairy products) with proteins of vegetal origin (in this exemplary case legumes). The percentage reduction compared to the total primary energy used for feeding increases to 30.6%.

CONCLUSIONS

Performing an assessment of the aggregate possible strategies, it appears that the use of non-renewable primary energy per student may be reduced by a percentage equal to 63.7%.

In summary it is the result of a 65% reduction in fuel consumption for heating due to energy efficient refurbishment of the building, a neutral electricity budget achieved through the installation of a photovoltaic system on the roof, and a reduction of the energy used to produce the foodstuffs consumed in the school canteen at 30.6%.

As mentioned in the introduction the experimental approach adopted in this study is aimed at the creation of tools to support the achievement of self-sufficiency at the local scale, through the development of integrated food and energy plans.

The spread and development of this approach are closely related to the intention by public institutions and local communities to build more resilient regional systems, based on the use of locally available resources and less dependent on fossil fuels.

The calculation of non renewable primary energy applied to all consumption categories that characterize the service provided is therefore a first essential step in this direction. The next step has not been treated in this text and has been presented in other publications (Scudo et al., 2013), it concerns the attachment to the primary energy accounting of the extension of local land needed to produce the food and renewable energy sources, intended as potential energy supply.

ACKNOWLEDGEMENTS

We wish to thank Professor Maria Fianchini for providing data concerning the characteristics and actual consumption of the school building under analysis (Ferrazza, Galimberti, Tondini, 2007), and Roberto Spigarolo for providing data on food consumption of the scholastic sector in the urban area of Milan (Spigarolo, 2014).

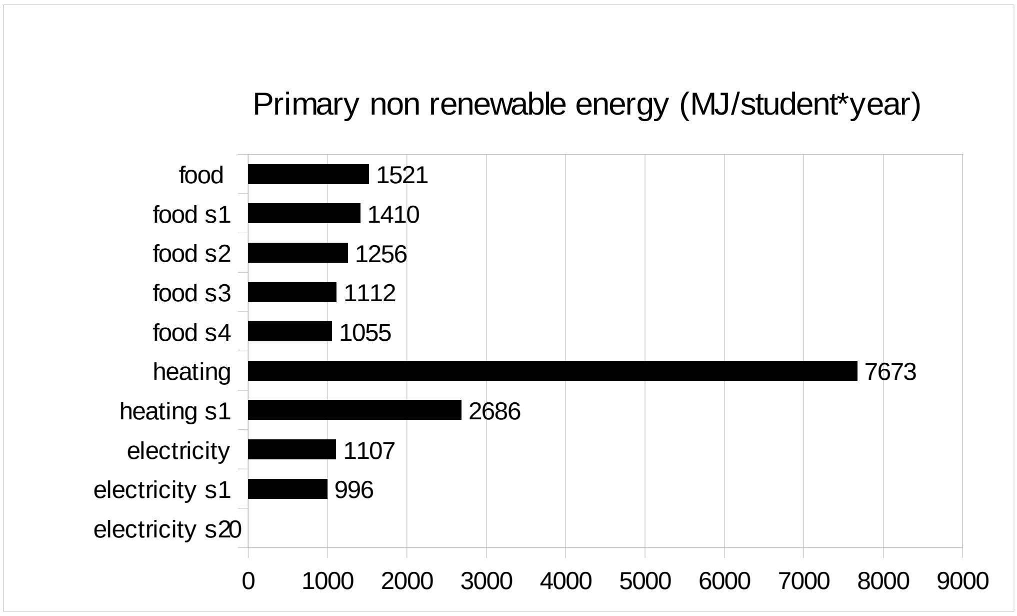

Figure 3. Comparison among items that constitute the total non-renewable primary energy per student per year. Items followed by the letter "s" refer to the improved solutions proposed in the scenarios presented in the text.

ABSTRACT

The need for affordable housing is a growing issue requiring sincere and urgent attention globally. With increasing focus on climate change and other environmental issues our housing must be environmentally sustainable too. We also need housing in remote areas where conventional construction is both cost and resource inefficient. Prefabrication offers great opportunities for both sustainability and affordability and hence is emerging as an attractive alternative to conventional on-site construction.

In this context, the CRC for Low Carbon Living in Australia has been engaged to develop designs for sustainable and affordable modular homes. The early optimisation was undertaken using AccuRate Sustainability – Australia's national benchmark software tool for rating the thermal performance of residential designs. An iterative process was employed where the rating software was used as a design and analytical tool to generate optimised designs for various orientations and climate zones throughout Australia. This paper explores the process of improving the performance of an existing design and developing a thermally optimised new design, and presents some of the early results of this optimisation.

The results show significant improvements in the thermal performance when compared to the existing design, but more importantly, the combined engineering and design research efforts developed general design principles that seemed to work well for most of the climates and orientations studied. This research contributes to the debate on integrative design process and its significance for sustainable built environment in general; it also ascertains the path forward for a more comprehensive approach to net zero energy and self-reliant modular housing – the eventual aim of the project.

INTRODUCTION

The need for adequate affordable housing is now considered a major issue in both industrialised and emerging countries (St Andrews Centre for Housing Research et al., 2014). With increasing focus on climate change mitigation and adaptation along with other environmental concerns these housing solutions need to be environmentally sustainable too. Both in Australia and overseas prefabricated housing solutions have been identified and are being proposed as an important path that can deliver both sustainable and affordable housing (Quale, 2012; The Greens, 2013). There is also a significant need for adequate solutions for remote area housing (regional communities, mining towns, emergency shelters, etc.) where conventional on-site construction is both costly and resource inefficient. Off-site construction or prefabrication in such situations becomes an especially attractive alternative.

In this context a multidisciplinary research team at the Cooperative Research Centre for Low Carbon Living (CRCLCL) has been engaged by Nova Deko, a modular housing manufacturer, to develop design solutions for 'Sustainable and Affordable Living through Modular, Net Zero Energy, Transportable, and Self-Reliant Homes and Communities'(Low Carbon Living CRC, 2014). The project is currently in its second year and this paper explores the recently completed first stage of this project – improving the operational performance of an existing design – and discusses the process of developing a thermally optimised new design for sustainable modular housing as per Nova Deko's requirements.

This paper presents the findings from the early thermal performance optimization process – a combined engineering and architectural design research effort – that started with the original design called 'Samara Pod' and finished with the creation and optimization of the final improved design called 'conceptPod'. An important part of this process was the well-designed integration of various services including domestic hot water, photovoltaic (PV) system, electrical services, equipment, white goods, and rainwater harvesting. The reason for this was twofold. First, to achieve a standardised and integrated product, so the installation of the complete Pod is easier, quicker, and therefore more cost effective. Second, to apply whole systems thinking during thermal performance optimization so the final design was efficient not only operationally but also throughout its lifecycle. In order to maintain the focus on the subject matter and in response to the space limitations here, however, the research on PV and other services integration is considered out of scope for this paper. The research presented here is a work in progress and achieving a net zero energy or self-reliant status, the eventual aim of the project, will be subject to further optimisation and renewable energy, water and waste system integration.

METHODOLOGY

The research for the project began with a study of literature on theory and practice of prefabrication and then employed an ongoing collaborative and integrative design process. The optimisation was performed as an iterative process using AccuRate Sustainability, a Nationwide House Energy Rating Scheme (NatHERS) accredited software, which measures thermal performance based energy efficiency of residential designs in Australia (CSIRO, 2014). The software, from here on referred to simply as AccuRate, was tested and validated using the Internation Energy Agency BESTEST protocol and was found to be very satisfactory (Delsante, 2005). During simulation AccuRate automatically switches between mechanical air conditioning and natural ventilation modes to maintain indoor thermal comfort within parameters specified by regulatory requirements. In doing so it calculates heating and cooling demands to maintain comfort conditions over a whole year. The total annual energy load (MJ/m2) expresses the overall thermal performance in a star rating for the specified climate zone. The rating ranges between 0 and 10 starts where a 0-star indicates the building envelop practically having no effect in reducing thermal discomfort while at 10-star performance the occupants are likely to need little or no mechanical cooling or heating to maintain comfort (Ren et al., 2013).

The National Construction Code's Building Code of Australia (BCA), in the absence of any specific state level regulations, requires all new houses to meet the minimum thermal performance of 6-stars for their regulatory approvals. Considering that the subject design will anyway need to be rated for regulatory compliance and that AccuRate has robust modeling capabilities to use it as a design decision making tool the research team decided that AccuRate was a very suitable tool for this particular research. The objective was to achieve as high a start rating as possible thereby minimising the size of a PV system to offset the remaining energy requirement.

The scope for this study included five key climate zones from Australia and eight orientations for each zone. The iterative process was designed so that the pod design and its thermal performance was improved to a satisfactory level for one climate and then that optimized design was used as the base model for improvement in the following climate, and so on. The idea behind this was to test if the "good design principles" applied in one climate could serve as a good starting point for a similar climate. To apply this approach the researchers used the following climate sequence: Brisbane, Sydney, Melbourne, and Hobart, i.e., from North to South, or warm to colder climates. Finally, the climate of Darwin, which is located further north, was also tested taking Brisbane results as the base model.

The process was essentially a parametric study where three key strategies – shading, insulation and glazing – were tested and parameters, such as type, position and amount of glazing, shading and insulation, were changed individually in order to reach local and global optimums. Although this required several iterations, due to space limitations only the first and the last simulation results are presented here. Three main types of shading devices tested were fixed horizontal, fixed vertical (wing walls), and "operable shading" such as operable louvers or sails. The performance of several types of glazing options were analysed mainly based on their U-value (W/m^{2}K) and solar heat gain coefficient (SHGC) value. Different types and levels of insulation based on their R-values (m^{2}K/W) were also tested for each location. As a general principle, the level of insulation was maximized and glazing was reduced, while trying to maintain good cross ventilation and connection with the outdoors. The optimization was finalised when no further meaningful improvements in the thermal performance (measured by star rating from the AccuRate simulation) could be achieved by modifying Shading, Glazing, and Insulation.

Changes in other parameters of the design were scheduled for the next stages of the project and hence were considered external to the scope for this particular exercise. Nevertheless, design quality and aesthetics of the interior spaces and the exterior, services and technology integration, weight of the completed Pod, and non-thermal environmental concerns were always part of the consideration even if they are not elaborated on in this paper due to space limitations. In every climate the simulation was started with the orientation of the front façade with bi-fold doors at the North before testing other orientations. The exposure was kept Suburban and ground reflectance as 0.2 in all AccuRate simulations.

EXISTING DESIGN AND ITS PERFORMANCE

The study started by taking the existing design of Samara Pod as the base model for Brisbane. The house with a simple rectangular floor plan (Figure 1) is manufactured with lightweight steel framing in a wide 40 foot shipping container size. The design has been developed so that a nearly complete house would be shipped to any site. With minimum onsite assembly requirements, except when other external features such as outdoor deck and additional shading were required, the house would be ready to occupy in a matter of days after arriving on site (Figure 2). The first AccuRate simulation was based on material specifications listed in Table 1 and produced a rating of 5.1 stars with detailed results tabled in Table 2.

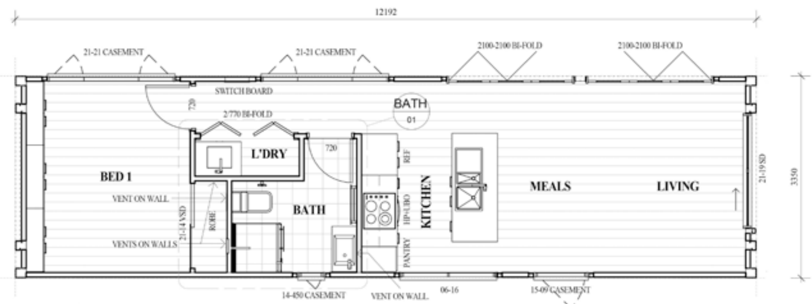

Figure 1 Floor plan of Samara Pod Base Model (Source: Nova Deko)

Figure 2 Samara Pod viewed from the North (Source: Nova Deko)

Table 1. Specification of Samara Pod Base Model

Element	Construction	R value (Up/Dn)
External wall	FC board/Reflective Barrier/Insulation/Plaster Board	3.38 / 3.38
Internal Wall	Plaster Board/Air Gap/ Plaster Board or FC board	0.44 / 0.44
Roof/ceiling	Steel/Ref. Barrier/Insulation/Plasterboard	4.12 / 4.35
Floor	Timber/FC board/Insulation	3.05 / 3.05
Windows	Glass/Air Gap/Glass; SHGC = 0.48; U = 3.92	0.25
Shading	As per Samara Pod (900mm North, 320mm rest)	NA
Underfloor	Enclosed 500mm height subfloor	NA

PERFORMANCE OPTIMISATION ACROSS DIFFERENT CLIMATES

Brisbane is located in a subtropical (no dry season) climate as per a modified Koppen classification (Bureau of Meteorology, 2012). The performance of the base model in Brisbane indicated disproportionate energy use in cooling. To address this issue main priority was given to reducing the amount and altering the type of glazing to reduce heat-gain. Through intense integrative design exercises a series of changes were identified and simulated. This included minor modifications to the internal layout mainly to redesign the bathroom and laundry to achieve better integration of various services. Key changes were in the building envelope for strategic placement of a mix of different types of high performance glazing (U=1.5 and SHGC=0.5 or less) especially on the East and West, and various types of shading devices especially on the North. With the help of these changes the optimised design – the conceptPod – was finally able to achieve 7.6 stars with total energy demand reduced to about 55% of the Base Model when the glazing area to floor area ratio was reduced to about 52% from the original 64%.

Table 2. Thermal Performance Improvement of conceptPod Base Model in Brisbane

Description	Heating (MJ/m^2)	Total Cooling (MJ/m^2)	Total Energy (MJ/m^2)	Rating (Stars)
Base Model conceptPod	12.3	41.0	53.3	5.1
Optimised conceptPod	10.3	19.2	29.5	7.6

As discussed earlier the conceptPod for Brisbane was taken as the Base Model for Sydney, which is located in a temperate (no dry season – warm summer) climate as per a modified Koppen classification (Bureau of Meteorology, 2012). The simulation for Sydney rated the design at 7.0 stars. Several modifications were made to the design, mainly shading and wing walls size and positions, but the best results were obtained with operable shading to the North allowing winter sun in the living areas and the bedroom, and deep shading in the form of a carport to the East. This gave a rating of 7.9 stars (Table 3).

Table 3. Thermal Performance Improvement of conceptPod Base Model in Sydney

Description	Heating (MJ/m^2)	Total Cooling (MJ/m^2)	Total Energy (MJ/m^2)	Rating (Stars)
Base Model conceptPod	12.7	17.1	29.9	7.0
Optimised conceptPod	7.8	15.2	23.0	7.9

Melbourne has a temperate (no dry season – warm summer) climate as per a modified Koppen classification (Bureau of Meteorology, 2012). When the optimized design for Sydney was tested for Melbourne, it rated at 6.9 stars, a decrease of 1 star compared with Sydney. A large number of changes in shading, glazing size and insulation were made without any significant improvement to the overall performance. It was only after converting most of the glazing into high performance glazing equivalent to top of the range double glazed windows that the rating of the Pod increased to 7.7 stars (Table 4).

Table 4. Thermal Performance Improvement of conceptPod Base Model in Melbourne

Description	Heating (MJ/m^2)	Total Cooling (MJ/m^2)	Total Energy (MJ/m^2)	Rating (Stars)
Base Model conceptPod	59.0	27.3	86.3	6.9
Optimised conceptPod	36.6	27.0	63.6	7.7

Hobart has a temperate (no dry season – mild summer) climate as per a modified Koppen classification (Bureau of Meteorology, 2012) and has a large proportion of energy use in heating spaces. Surprisingly, when the Melbourne design was simulated in the Hobart climate the obtained rating was, already higher than Melbourne, at 8.1 stars. A similar result was obtained with the base Samara Pod, which achieved a 6.0 star rating, highest so far of all tested climates. Because the obtained rating with the conceptPod was already above 8 stars, the optimization for this climate was based on obtaining the best rating possible while limiting the standard double glazing in the main windows for the living area and the bedrooms. Finally, with strategically placed high performance glazing and carefully sized and positioned operable horizontal and vertical shades the final design resulted in a rating of 7.6 stars.

Table 5. Thermal Performance Improvement of conceptPod Base Model in Hobart

Description	Heating (MJ/m^2)	Total Cooling (MJ/m^2)	Total Energy (MJ/m^2)	Rating (Stars)
Base Model conceptPod	64.0	4.6	68.6	8.1
Optimised conceptPod	82.1	7.1	89.3	7.6

Darwin is on the other end of the climate spectrum when compared to Hobart. It is located in the tropical (Savana) climate as per a modified Koppen classification (Bureau of Meteorology, 2012). Because of its proximity with the equator, the sun here can be in the South (summer) as well as in the North (winter). This meant that shading on both of these façades had to be considered very carefully. For this climate the optimized Brisbane Pod was taken as the based model. The first simulation showed a rating of 5.9 stars, the lowest rating obtained so far for any first iteration. After several changes, without much improvement, the highest rating of 7.2 stars was obtained when all Northern windows were made high performance glazing equivalent to triple glazing, insulation was maximized everywhere and 450mm fixed horizontal shading, similar to an eave, was added to all facades. However, the aesthetics of this solution remained unresolved with an intention to revisit the design and thermal performance improvement strategies employed in this climate. The maximum rating of 7.2 stars is the lowest achieved for all climates after the optimization and may be indicative of the limits of the current Pod design, its size or the small number of improvement strategies tested so far.

Table 6. Thermal Performance Improvement of conceptPod Base Model in Darwin

Description	Heating (MJ/m^2)	Total Cooling (MJ/m^2)	Total Energy (MJ/m^2)	Rating (Stars)
Base Model conceptPod	0.0	356.8	356.8	5.9
Optimised conceptPod	0.0	275.3	275.3	7.2

ORIENTATION SENSITIVITY ANALYSIS

The designs of Samara Pod and climate optimised conceptPods when simulated for all five climate zones across eight orientations they produced results as illustrated in Figure 3. The Brisbane results show that the conceptPod performs relatively well (above or close to 6 stars) for five of the eight orientations, mainly between North and East. The performance decreased markedly when the Pod was oriented to the South and West, with the West having the lowest thermal rating (4.7 stars) due, not surprisingly, to the increase in required cooling. The overall performance of the conceptPod showed improvements between 1.5 to 3.0 stars when compared to the Samara Pod. It is important to notice that the conceptPod design not only achieves a better rating, but is also more resilient to orientation changes.

Similar to Brisbane, in Sydney the conceptPod performs consistently 2 to 3 stars better than the base Samara Pod. In this case however, the performance penalty in the west and south orientation are less pronounced, with a minimum rating of 5.8 stars when facing west. This is an encouraging result as it shows a greater flexibility and resilience of the design to orientation changes. The conceptPod achieves near or above 6 stars rating across all orientations.

The results of the simulations show that orientation has lesser effect in Melbourne than in Sydney or Brisbane. This supports the hypothesis that in Melbourne the thermal performance is dominated by the R value of the envelope and quality of windows, instead of the solar gain. The Pod performs very well in all the orientations, with a minimum rating of 7.0 stars for the West orientation. This is also true for the base Samara design which obtains a more consistent performance for all orientations. The conceptPod performs consistently around 2.5 stars better than the base Samara Pod.

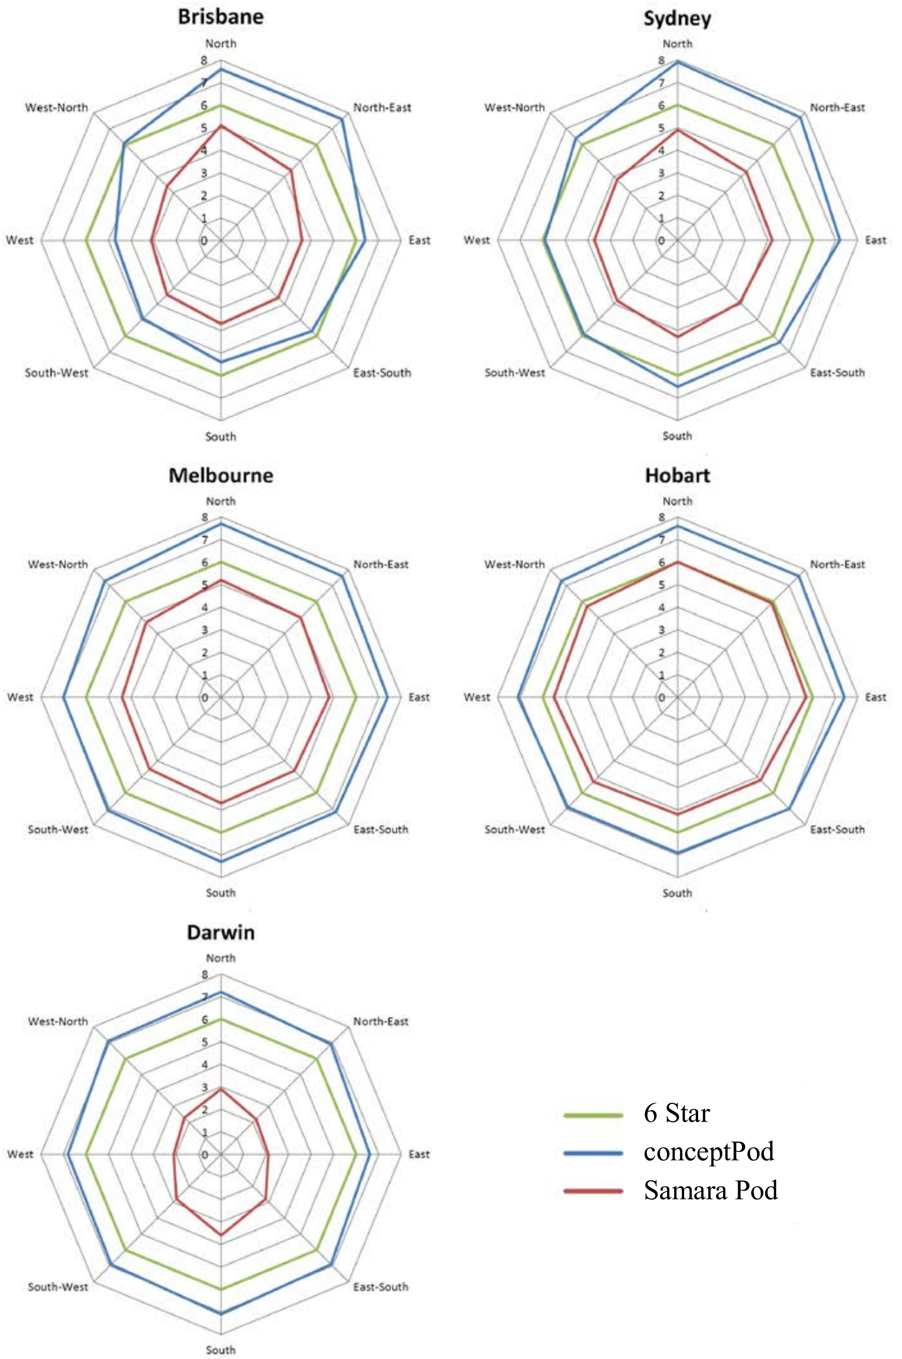

Figure 3 Orientation sensitivity analysis of Samara Pod and conceptPod

As evident in Figure-3 both the Samara Pod and the conceptPod perform very well in Hobart, although the conceptPod obtains minimum 1.5 stars more than Samara Pod across all orientations. It is worthwhile to note that, similar to Melbourne, the orientation of the Pods has less effect on the thermal performance, with only 0.8 stars and 0.7 stars of difference between the minimum and maximum rating for the Samara Pod and the conceptPod respectively. This may be due to the lesser effect of solar gain, optimised adaptive shading and highly insulated building fabric minimizing heat-loss from the Pods.

In Darwin the conceptPod performed reasonably well with performance varying between 6.6 stars as minimum on East and 7.2 stars as maximum on North (a difference of 0.6 stars). On the other hand, the base Samara Pod performed poorly, with a maximum rating of 3.6 stars when facing South, and a minimum rating of 2.1 stars for East and West orientations. This is a strong result showing the resilience and adaptability of the conceptPod design.

IMPROVED DESIGN AND ITS PERFORMANCE

All the lessons learnt from the optimization in each climate were applied to create a final design. The objective was to create a conceptPod that would work as best as possible in each climate. Even if the performance in some locations might be less than optimized, it could still have a good performance. This approach of standardisation, although counterintuitive and contrary to the notion of mass-customisation, was found to offer good manufacturing efficiencies for this particular manufacturer as it would require minimal changes in the Pod depending on the final location of the installation. In order to achieve this, further reviews of the effects of insulation levels and glazing types were carried out. It was found that two main insulation configuration (external wall/roof/floor) could be used in the Pod design depending on the location, for example, R = 4/4/2 for warm/hot climate such as Brisbane and Darwin, and R = 6/6/2 for mixed/colder climate such as Melbourne. Similar testing of glazing alternatives found that it was more effective to upgrade the main windows from double to triple glazing than to improve the insulation in the walls and roof from R4 to R6. It was also encouraging to find that the combination of triple glazing and insulation of R=6/6/2, resulted in ratings above 8 stars for Brisbane and Melbourne.

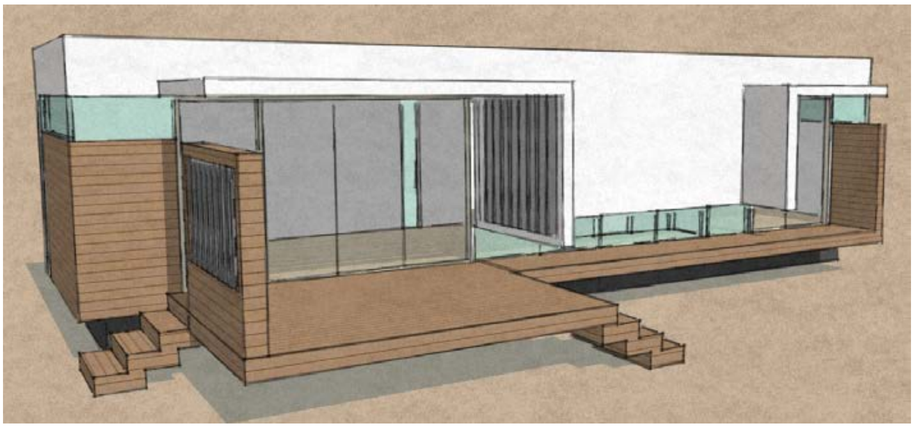

Figure 4 New integrated design of the conceptPod viewed from the North

The final conceptPod included carefully sized and located fenestrations with a mix of different types of high performance glazing. In combination with a mix of fixed and operable horizontal and vertical shading devices they simultaneously satisfied critical requirements of a good design – views, connection with the landscape, sense of spaciousness, privacy, aesthetics, and so on – and the essential aspects of a high thermal performance building – precise solar protection, passive solar heating, effective crossflow ventilation, and so on – to result in a truely integrated design.

A final set of simulations was carried out in order to assess the performance of the final conceptPod having insulation levels of R=4/4/2 and triple glazing in the main window as it was considered best option for balance between performance and cost. The simulations results are shown in Table-7. The only change in the Pod design between each location was the SHGC value of the glazing. The operable shades were designed to be easily adaptable to each climate without changing the overall design. The final results showed consistency with the earlier optimization exercise. The final conceptPod design performed well above regulatory requirements in all climates and achieved star rating up to 8.6 stars.

Table 7. Thermal Performance of Final conceptPod Design

Location	North (Stars)	East (Stars)	South (Stars)	West (Stars)	Comments
Brisbane	8.6	7.8	6.9	6.3	Glazing with SHGC = 0.3
Sydney	8.3	8.2	7.4	7.3	Glazing with SHGC = 0.3
Melbourne	7.7	7.5	7.4	7.1	Glazing with SHGC = 0.5
Hobart	8.2	8.1	7.7	7.9	Glazing with SHGC = 0.5
Darwin	6.7	6.2	6.7	6.3	Glazing with SHGC = 0.3

CONCLUSION

This study was designed to test several ideas and principles regarding the performance of the current Pod design and the limits of various strategies. The results of the final outcome show significant improvement in the thermal performance when compared to the existing design. More importantly, the combined engineering and architectural design research efforts produced an overall design that is easily adaptable for most of the climates and orientations studied. It is well-established that an optimized design for an individual climate and orientation would provide better result than a single “one size fits all” design. However, this particular optimisation process revealed that integrated design approach, with strategically embedded flexibility and economically rationalized redundancy in the type, amount and location of shading, glazing, and insulation, could result in a robust overall design outcome. This outcome – the conceptPod – showed remarkable resilience, for which the performance penalty from different locations and orientations was minimized significantly.

This research contributes to the debate on integrative design process and its significance for sustainable built environment in general; it also ascertains the path forward for a more comprehensive approach to net zero energy and self-reliant modular housing. The next phase of this research focuses on further integration of services and low carbon technologies to achieve this outcome. The lessons learned so far are being used to develope a next generation of ‘greenPod’, a prototype of which will be tested for a year to measure its actual performance and to compare with its predicted performance.

ABSTRACT

The aim of sustainable development is a big challenge in the building sector. On one hand new technologies and materials are available, on the other hand life cycle assessment, including the energy performance and indoor air quality should be in line with green building standards. In many cases key players do not share common objectives for the project, may not understand how their work affects others.

Integrated design is thinking about how the parts fit together. But no matter what the scope of the project, structural design, heating, ventilation, air conditioning, lighting and wiring, and other key parts of the project are viewed as interrelated parts of the whole project. "Nearly Zero Energy Building" will be the standard for new buildings in Europe from beginning of 2020, due to the European Building Directive. Austria was one of the forerunners in eco building in the last twenty years. The measures and the experience how eco building, low energy and passive house standard disseminated in Austria are well documented and available.

The toolbox for integrated design contains experience with the most relevant elements: Starting with the establishment of clear project goals and quality management and ending with final inspection protocols, user information and maintenance. Certification systems for buildings aim to make sustainability transparent and provide a means of comparison. The paper proposes a similar concept for India, making the most of European experiences in building process and energy demand optimization and taking into consideration existing subsidies by the Government of India and evaluation procedures within the Green Buildings Rating System India.

Even though the climate is different, principles and products are basically same all over the world. After the discussion useful elements of the toolbox can be adapted to promote sustainable engineering and buildings.
